To the countless pioneers, inventors and scholars
whose seminal contributions have developed
radiation detection into a mature discipline

About the Cover Picture

A 1960 image from CERN's first liquid hydrogen bubble chamber, which was 32 cm in diameter. Here 16-GeV negative pions enter from the left and are seen as the horizontal bubble trails. One pion interacts with a proton in the liquid hydrogen producing a spray of new particles including a neutral Λ^0 that quickly decays into a proton and negative pion to produce the sideway "V" (slightly left of center). Lower energy charged particles produced in the original and subsequent interactions create spiral tracks in the magnetic field of the chamber. Photograph courtesy of CERN.

Contents

Preface xxi

About the Authors xxv

1 Origins 1
- 1.1 A Brief History of Radiation Discovery 1
- 1.2 A Brief History of Radiation Detectors 10

2 Introduction to Nuclear Instrumentation 19
- 2.1 Introduction 19
- 2.2 The Detector 20
- 2.3 Nuclear Instrumentation 21
- 2.4 History of NIM Development 21
- 2.5 NIM Components 23
  - 2.5.1 The NIM Bin 23
  - 2.5.2 Detector Power Supplies 24
  - 2.5.3 Preamplifier 26
  - 2.5.4 Amplifier 27
  - 2.5.5 Oscilloscope 27
  - 2.5.6 Pulse Discriminators 27
  - 2.5.7 Counter/Timer 28
  - 2.5.8 Pulse Generator 28
  - 2.5.9 Coincidence Modules 28
  - 2.5.10 Time-to-Amplitude Converters 29
  - 2.5.11 Analog-to-Digital Converters 29
  - 2.5.12 Photomultiplier Tube Base 29
  - 2.5.13 Multichannel Analyzer 29
  - 2.5.14 Other NIM Components 30
- 2.6 CAMAC 31
- 2.7 Nuclear Instruments other than NIM or CAMAC 31

2.8 Cables and Connectors 31
2.8.1 Cables 32
2.8.2 Delay Lines 33
2.8.3 Connectors 33

3 Basic Atomic and Nuclear Physics 37
3.1 Modern Physics Concepts 37
3.1.1 The Special Theory of Relativity 37
3.1.2 Principle of Relativity 38
3.1.3 Results of the Special Theory of Relativity 39
3.2 Highlights in the Evolution of Atomic Theory 41
3.2.1 Radiation as Waves and Particles 42
3.2.2 Early Observations 42
3.2.3 The Photoelectric Effect 42
3.2.4 Compton Scattering 44
3.2.5 Electromagnetic Radiation: Wave-Particle Duality 45
3.2.6 Electron Scattering 46
3.3 Development of the Modern Atom Model 47
3.3.1 Discovery of Radioactivity 47
3.3.2 Thomson's Atomic Model: The Plum Pudding Model 48
3.3.3 The Rutherford Atomic Model 49
3.3.4 The Bohr Atomic Model 49
3.3.5 Extension of the Bohr Theory: Elliptic Orbits 52
3.3.6 The Quantum Mechanical Model of the Atom 53
3.3.7 Wave-Particle Duality 54
3.4 Quantum Mechanics 54
3.4.1 Schrödinger's Wave Equation 54
3.4.2 The Wave Function 55
3.4.3 The Uncertainty Principle 56
3.4.4 Particle in a Potential Well 56
3.4.5 The Hydrogen Atom 60
3.4.6 Energy Levels for Multielectron Atoms 62
3.4.7 Success of Quantum Mechanics 64
3.5 The Fundamental Constituents of Ordinary Matter 64
3.5.1 Dark Matter and Energy 66
3.5.2 Atomic and Nuclear Nomenclature 67
3.5.3 Relative Atomic Masses 68
3.5.4 The Atomic Mass Unit 68
3.5.5 Avogadro's Number 69
3.5.6 Mass of an Atom 69
3.5.7 Number Density of Atoms and Isotopes 69
3.5.8 Size of an Atom 70
3.5.9 Nuclear Dimensions 70
3.6 Nuclear Reactions 71
3.6.1 Q-Value for a Reaction 71
3.6.2 Conservation of Charge and the Calculation of Q-Values 72
3.6.3 Special Case for Changes in the Proton Number 73

3.7 Radioactivity 73
3.7.1 Types of Radioactive Decay 74
3.7.2 Radioactive Decay Diagrams 74
3.7.3 Energetics of Radioactive Decay 76
3.7.4 Exponential Decay 84
3.7.5 The Half-Life 85
3.7.6 Decay Probability for a Finite Time Interval 85
3.7.7 Mean Lifetime 86
3.7.8 Activity 86
3.7.9 Decay by Competing Processes 87
3.7.10 Decay Dynamics 87

4 Radiation Interactions 93
4.1 Introduction 93
4.2 Indirectly Ionizing Radiation 93
4.2.1 Attenuation of Neutral Particle Beams 93
4.2.2 The Linear Interaction Coefficient 94
4.2.3 Attenuation of Uncollided Radiation 95
4.2.4 Average Travel Distance Before an Interaction 96
4.2.5 Half-Thickness 96
4.2.6 Microscopic Cross Sections 96
4.2.7 Calculation of Radiation Interaction Rates 97
4.3 Scattering Interactions 99
4.3.1 Differential Scattering Coefficients 99
4.3.2 Conservation Laws for Scattering Reactions 100
4.3.3 Scattering of Photons by Free Electrons 101
4.3.4 Scattering of Neutrons by Atomic Nuclei 102
4.3.5 Threshold Energies for Neutron Inelastic Scattering 103
4.3.6 Neutron Scattering in the Center-of-Mass System 104
4.3.7 Limiting Cases in Classical Mechanics of Elastic Scattering 105
4.3.8 Relativistic Elastic Scattering of Electrons and Heavy Charged Particles 106
4.4 Photon Cross Sections 106
4.4.1 Thomson Cross Section for Incoherent Scattering 107
4.4.2 Klein-Nishina Cross Section for Incoherent Scattering 107
4.4.3 Incoherent Scattering Cross Sections for Bound Electrons 112
4.4.4 Coherent (Rayleigh) Scattering 112
4.4.5 Photoelectric Effect 112
4.4.6 Pair Production 114
4.4.7 Photon Interactions—Minor Effects 115
4.4.8 Photon Attenuation Coefficients 116
4.5 Neutron Interactions 116
4.5.1 Classification of Types of Interactions 117
4.5.2 Thermal Neutron Interactions 121
4.5.3 Neutron Differential Scattering Cross Sections 123
4.5.4 Average Energy Transfer in Neutron Scattering 124
4.5.5 Radiative Capture of Neutrons 125
4.5.6 Neutron-Induced Fission 126

4.6 Charged-Particle Interactions 126
4.6.1 Collisional Energy Loss 127
4.6.2 Radiative Energy Loss 130
4.6.3 Estimating Charged-Particle Ranges 131
4.6.4 Electron Energy Loss and Range 132
4.6.5 Spatial Distribution of the Electron Energy Absorption 136
4.6.6 Heavy Charged-Particle Energy Loss 139
4.6.7 Heavy Charged-Particle Range 140
4.6.8 The Bragg Curve 143
4.6.9 Approximate Range Formula for Charged Particles 144
4.6.10 Range of Fission Fragments 147

5 Sources of Radiation 153
5.1 Introduction 153
5.1.1 Origins of Ionizing Radiation 153
5.1.2 Physical Characterization of Radiation Sources 154
5.2 Sources of Gamma Rays 154
5.2.1 Naturally Occurring Radionuclides 155
5.2.2 Prompt Fission Gamma Photons 157
5.2.3 Fission-Product Gamma Photons 157
5.2.4 Capture Gamma Photons 158
5.2.5 Inelastic Scattering Gamma Photons 159
5.2.6 Activation Gamma Photons 159
5.2.7 Positron Annihilation Photons 159
5.3 Sources of X Rays 159
5.3.1 Characteristic X Rays 161
5.3.2 Bremsstrahlung 163
5.3.3 X-Ray Machines 166
5.3.4 Synchrotron X Rays 168
5.4 Sources of Neutrons 168
5.4.1 Fission Neutrons 168
5.4.2 Fusion Neutrons 169
5.4.3 Photoneutrons 170
5.4.4 Alpha-Neutron Sources 172
5.4.5 Activation Neutrons 173
5.4.6 Spallation Neutron Sources 173
5.5 Sources of Charged Particles 174
5.5.1 Beta Decay 174
5.5.2 Alpha Decay 176
5.5.3 Photon Interactions 177
5.5.4 Neutron Interactions 178
5.5.5 Accelerators 179
5.6 Cosmic Rays 179
5.6.1 High Energy Gamma Rays 180

6 Probability and Statistics for Radiation Counting 183
6.1 Introduction 183
6.1.1 Types of Measurement Uncertainties 184
6.1.2 Probability and Statistics 184
6.2 Probability and Cumulative Distribution Functions 185
6.2.1 Continuous Random Variable 185
6.2.2 Discrete Random Variable 185
6.3 Mode, Mean and Median 185
6.3.1 Mode 186
6.3.2 Mean 186
6.3.3 Median 187
6.4 Variance and Standard Deviation of a PDF 187
6.5 Probability Data Distribution 188
6.5.1 Sample Mean 189
6.5.2 Sample Median 191
6.5.3 Trimmed Sample Mean 193
6.5.4 Sample Variance 194
6.6 Binomial Distribution 196
6.6.1 Radioactive Decay and the Binomial Distribution 199
6.7 Poisson Distribution 200
6.8 Gaussian or Normal Distribution 204
6.8.1 Standard Normal Distribution 207
6.8.2 Cumulative Normal Distribution and the Error Function 209
6.8.3 Discrete Gaussian Distribution 211
6.8.4 The Normal Distribution in Radiation Measurements 212
6.9 Error Propagation 214
6.9.1 A Measurement is Scaled by a Constant 217
6.9.2 Random Variables are Added or Subtracted 218
6.9.3 Random Variables are Multiplied or Divided 219
6.9.4 Random Variables in Exponents or Logarithms 221
6.9.5 A Series of Radiation Measurements 222
6.9.6 Measurements Over Different Time Intervals 224
6.9.7 Caution about Error Propagation 227
6.10 Data Interpretation 227
6.10.1 Radiation Detection Limits 229
6.10.2 Chi-Square Test for "Goodness" of Data 233
6.10.3 Presentation of Data 236
6.10.4 Concluding Remarks 238

7 Source and Detector Effects 243
7.1 Detector Efficiency 243
7.2 Source Effects 245
7.2.1 Alpha Particles 246
7.2.2 Beta Particles 250
7.2.3 Penetrating Radiations (γ rays, x rays, neutrons) 253
7.2.4 Source Decay During Measurement 253
7.2.5 Contamination 254

7.3 Detector Effects 254
7.3.1 Scattering and Absorption by the Detector Window 254
7.3.2 Time Interval Distribution between Radioactive Decays 255
7.3.3 Dead Time 255
7.3.4 Models for Dead Time 257
7.3.5 Counting Error Associated with Dead Time 260
7.3.6 Methods for Measuring Dead Time 261
7.4 Geometric Effects: View Factors 267
7.4.1 Point Isotropic Sources 268
7.4.2 Isotropic Area Sources 272
7.4.3 Monte Carlo Approach to View Factor Angle Calculations 274
7.5 Geometric Corrections: Detector Parallax Effects 274
7.5.1 Attenuation and Scattering Effects Outside the Detector 276

8 Essential Electrostatics 281
8.1 Electric Field 281
8.1.1 Alternate Derivation of Gauss' Law 284
8.2 Electrical Potential Energy 284
8.3 Capacitance 286
8.4 Current and Stored Energy 287
8.5 Basics of Charge Induction 288
8.5.1 Green's Reciprocation Theorem 290
8.6 Charge Induction for a Planar Detector 290
8.6.1 Planar Detector with Stationary Space Charge 294
8.6.2 A Planar Detector Composed of Two Materials 298
8.7 Charge Induction for a Cylindrical Detector 300
8.8 Charge Induction for Spherical and Hemispherical Detectors 301
8.9 Concluding Remarks 303

9 Gas-Filled Detectors: Ion Chambers 305
9.1 General Operation 305
9.2 Electrons and Ions in Gas 307
9.2.1 Ionization 307
9.2.2 Diffusion Effects 309
9.2.3 Electron and Ion Transport 312
9.2.4 Charge Transfer 317
9.2.5 Electron Attachment 318
9.3 Recombination 321
9.3.1 Columnar Recombination 321
9.3.2 Volumetric Recombination 323
9.3.3 Preferential Recombination 329
9.4 Ion Chamber Operation 330
9.4.1 Planar Ion Chambers 331
9.4.2 Coaxial Ion Chambers 337
9.5 Ion Chamber Designs 340
9.5.1 Basic Designs and Characteristics 341
9.5.2 Gamma-Ray Ion Chamber Designs 343
9.5.3 Neutron-Sensitive Ion Chambers 344

9.5.4 Compensated Ion Chambers 344
9.5.5 Frisch Grid Ion Chambers 345
9.5.6 Free Air Ion Chambers 346
9.5.7 Pocket Ion Chambers 347
9.5.8 Cloud Chambers 348
9.5.9 Smoke Detector Ionization Chambers 351
9.6 Summary 351

10 Gas-Filled Detectors: Proportional Counters 355
10.1 Introduction 355
10.2 General Operation 356
10.3 Townsend Avalanche Multiplication 357
10.3.1 The Rose-Korff Formula for M 358
10.3.2 The Diethorn Formula for M 362
10.3.3 The Zastawny Formula for M 363
10.3.4 The Kowalski Formula for M 364
10.4 Gas Dependence 364
10.4.1 Quenching Gas 365
10.4.2 Penning Mixtures 367
10.5 Proportional Counter Operation 368
10.5.1 Pulse Shape 369
10.5.2 Space Charge Effects 373
10.5.3 Counting Curve 373
10.5.4 Fluctuations of the Gas Multiplication Process 377
10.6 Selected Proportional Counter Variations 386
10.6.1 Gas-Flow Proportional Counters 386
10.6.2 Sealed Proportional Counters 389
10.6.3 Proportional Counters for Low Energy Gamma-Rays 390
10.6.4 Position Sensitive Proportional Counters 391
10.6.5 Multiwire Proportional Counters 392
10.6.6 Microstrip Gas Chambers 394
10.6.7 Straw Tubes 396
10.6.8 Gas Electron Multiplier 397
10.6.9 Neutron-Sensitive Proportional Counters 397
10.6.10 Selected Planar Proportional Counters 398

11 Gas-Filled Detectors: Geiger-Müller Counters 403
11.1 Geiger Discharge 403
11.2 Basic Design 404
11.3 Fill Gases 406
11.3.1 Quenching 407
11.4 Pulse Shape 410
11.4.1 Dead, Resolving, and Recovery Times 411
11.5 Radiation Measurements 412
11.5.1 Counting Plateau 412
11.5.2 Alpha and Beta Particle Counting 414
11.5.3 Gamma-Ray Detection 415

11.6 Special G-M Counter Designs 416
11.7 Commercial G-M Counters 417

12 Review of Solid State Physics 423
12.1 Introduction 423
12.2 Solid State Physics 423
12.2.1 Crystals and Periodic Lattices 423
12.2.2 Bravais Lattice 424
12.2.3 Miller Indices 426
12.2.4 Reciprocal Lattice 429
12.2.5 Energy Band Gap 430
12.3 Quantum Mechanics 432
12.3.1 Potential Barriers 432
12.3.2 Kronig-Penney Model 436
12.4 Semiconductor Physics 438
12.4.1 Brillouin Zones 438
12.4.2 Effective Mass 439
12.5 Charge Transport 449
12.5.1 Charge Carrier Mobility 456
12.5.2 Material Resistivity and Capacity 457
12.5.3 Intrinsic Semiconductors 458
12.5.4 Impurities and Extrinsic Semiconductors 465
12.6 Summary 478

13 Scintillation Detectors and Materials 481
13.1 Scintillation Detectors 481
13.2 Inorganic Scintillators 482
13.2.1 Theory of Scintillation for Inorganic Scintillators 485
13.2.2 General Properties of Inorganic Scintillators 489
13.2.3 Properties of Several Common Inorganic Scintillators 502
13.3 Organic Scintillators 522
13.3.1 Theory of Scintillation for Organic Scintillators 523
13.3.2 Organic Crystalline Scintillators 532
13.3.3 Liquid Scintillators 537
13.3.4 Plastic Scintillators 546
13.4 Gaseous Scintillators 548
13.4.1 Development of Gas Scintillator Counters 549
13.4.2 Theory of Gas Scintillation Counters 550
13.4.3 Factors Affecting Performance 551
13.4.4 Mixtures of Noble Gases 552
13.4.5 Liquid and Solid Noble Elements 553
13.4.6 Gas Proportional Scintillation Counters 554

14 Light Collection Devices 565
14.1 Photomultiplier Tubes 565
14.1.1 Basic Design 567
14.1.2 Light Collection and Coupling 568

14.1.3 Photocathode Materials and Design 575
14.1.4 Dynode Materials 586
14.1.5 PMT Dynode Designs and Configurations 593
14.1.6 Gain 599
14.1.7 Factors Affecting the Performance of a PMT 600
14.1.8 Ancillary Equipment 607
14.1.9 Environmental Effects 611
14.2 Semiconductor Photodetectors 611
14.2.1 Photodiodes 612
14.2.2 Drift Diodes 616
14.2.3 Avalanche Diodes 617
14.2.4 Semiconductor Photomultipliers 621

15 Basics of Semiconductor Detector Devices 627
15.1 Introduction 627
15.2 Charge Carrier Collection 627
15.2.1 Charge Carrier Generation, Recombination and Injection 628
15.2.2 Radiative Recombination 628
15.2.3 Shockley-Read-Hall Recombination 629
15.2.4 Equations of Continuity 631
15.3 Basic Semiconductor Detector Configurations 634
15.3.1 The *pn* Junction 635
15.3.2 ***pin*** Junction Devices 645
15.3.3 Metal-Semiconductor Contacts 646
15.3.4 The MOS Structure 658
15.3.5 Ohmic Contacts 663
15.3.6 Series Resistance and Space Charge Effects 665
15.3.7 Resistive and Photoconductive Devices 668
15.3.8 Photon Drag Detectors 670
15.4 Measurements of Semiconductor Detector Properties 671
15.4.1 ***IV*** Measurements 671
15.4.2 ***CV*** Measurements 673
15.4.3 Measurement of Contact Resistance 675
15.4.4 Measurement of Resistivity 677
15.4.5 Measurement of Charge Carrier Mobility 679
15.4.6 Measurement of the $\boldsymbol{\mu\tau}$ Product 682
15.5 Charge Induction 684
15.5.1 Charge Induction With Trapping 684
15.5.2 Energy Resolution Improvement Methods and Designs 690

16 Semiconductor Detectors 705
16.1 Introduction 705
16.2 General Semiconductor Properties 707
16.2.1 Atomic Numbers and Mass Density 708
16.2.2 Band Gap 709
16.2.3 Ionization Energy 710
16.2.4 Mobility 713

16.2.5 Resistivity 716
16.2.6 Mean Free Drift Time 717
16.2.7 Linearity 717
16.3 Semiconductor Detector Applications 719
16.3.1 Charged Particle Detectors 719
16.3.2 Gamma-Ray and X-Ray Detectors 719
16.3.3 Neutron Detectors 721
16.4 Detectors Based on Group IV Materials 722
16.4.1 Detectors Based on Silicon 722
16.4.2 Detectors Based on Ge 747
16.4.3 Diamond Detectors 765
16.5 Compound Semiconductor Detectors 767
16.5.1 SiC Detectors 769
16.5.2 Detectors Based on Group III-V Materials 771
16.5.3 Detectors Based on Group II-VI Materials 777
16.5.4 Detectors Based on Halide Compounds 787
16.6 Additional Semiconductors of Interest 793
16.7 Summary 797

17 Slow Neutron Detectors 813
17.1 Cross Sections in the $\mathbf{1/v}$ Region 813
17.2 Slow Neutron Reactions Used for Neutron Detection 815
17.2.1 The ^{3}He Reaction 816
17.2.2 The ^{10}B Neutron Reaction 817
17.2.3 The ^{6}Li Neutron Reaction 818
17.2.4 The ^{155}Gd and ^{157}Gd Neutron Reactions 819
17.2.5 The ^{113}Cd Neutron Reaction 820
17.2.6 The ^{199}Hg Neutron Reaction 820
17.2.7 Fission Reactions 821
17.3 Gas-Filled Slow Neutron Detectors 822
17.3.1 Detectors with Neutron Absorbing Fill Gases 822
17.3.2 Detectors with Neutron Reactive Coatings and Layers 829
17.4 Scintillator Slow Neutron Detectors 848
17.4.1 Neutron Reactive Scintillators 848
17.4.2 Scintillators Loaded with Neutron Reactive Materials 851
17.5 Semiconductor Slow Neutron Detectors 855
17.5.1 Bulk Semiconductor Neutron Detectors 859
17.6 Neutron Diffraction 861
17.6.1 The Structure Factor for Crystals $\boldsymbol{F}_{hkl}$ 863
17.6.2 Angular Response to a Maxwellian Neutron Distribution 864
17.6.3 Measurements with Diffracted Neutron Beams 865
17.7 Calibration of Slow Neutron Detectors 866
17.7.1 Method of the NIST 866
17.7.2 Method of Reuter Stokes 867
17.7.3 Method of ORNL 867
17.7.4 Method of Sampson and Vincent 867
17.7.5 Method of McGregor and Shultis 868

17.8 Neutron Detection by Foil Activation 870
17.8.1 Cadmium Ratio 874
17.8.2 Measuring Activation Rates 875
17.8.3 Flux Correction Factors 876
17.8.4 Correction for Non-$1/v$ Absorption 877
17.8.5 Correction for Cadmium Filter Effects 877
17.8.6 Correction for Flux Perturbation and Self-Shielding 878
17.9 Self-Powered Neutron Detectors 881
17.10 Time-of-Flight Methods 887

18 Fast Neutron Detectors 897
18.1 Detection Mechanisms 897
18.1.1 Neutron Moderation and Scattering 897
18.1.2 Multiscattered Neutrons 898
18.1.3 Absorption 899
18.2 Detectors Based on Moderation 899
18.2.1 Bonner Spheres 899
18.2.2 REM Counters 904
18.2.3 Long Counter 907
18.2.4 Directional Neutron Spectrometer 909
18.2.5 Other Moderated Detectors 910
18.3 Detectors Based on Recoil Scattering 910
18.3.1 Gas Detectors Based on Recoil Scattering 913
18.3.2 Unfolding the Recoil Energy Spectrum 918
18.3.3 Scintillators Used in Recoil Neutron Scattering 919

Preface

Ever since the discovery of x rays by Röntgen almost 125 years ago, who used fluorescing barium-platinocyanide coated plates and later photographic film as the first radiation detectors, there has been increasing activity in the design and development of detectors to measure ionizing radiation. Early radiation detector development was driven by both the discovery of new types of ionizing radiation and a better understanding of how radiation interacts with matter. In the last half of the twentieth century detector technology saw major advances with the introduction of supporting electronics, notably the photomultiplier tube, and the introduction of new detector materials such as semiconductors and new scintillator materials. In this era, the fundamental principles of radiation detection and measurement were firmly established. Then in the last two decades, a vast number of researchers introduced an ever increasing number of new detector designs, almost all based on twentieth century technology. In the past decade the introduction of new variations in basic detector technology has become a growth industry, fueled largely by national security concerns and government sponsorship.

At the same time that radiation detector technology was advancing, many books on the subject were introduced. Many were limited to a single aspect or type of detector technology and were intended for a specialist in radiation detection and, consequently, were not suitable as texts in courses on radiation technology. Other books designed primarily as text books attempted to present a broad coverage of the many facets of radiation detections but were somewhat superficial because of their reliance on old analyses, rules of thumb, simple derivations, and a limited number of detector designs. Yet other more ambitious text books became encyclopedic by trying to cover the many different types of detectors while necessarily scrimping on analytic details or simply quoting analytical results. Also lacking in most of these treatises was a review of the history of radiation detector development and a presentation of the important milestones achieved by the vast research on radiation detection.

When we embarked on this book project over ten years ago, we envisioned a book that could serve both as a text for different courses in radiation detection and as a reference work for practitioners in radiation detection. Four goals guided us: (1) to include information about the historical development and the major achievements in detector technology, (2) to provide fundamental information about radiation interactions, nuclear physics, and electrostatics, (3) to present a broad and detailed coverage of the many types of radiation detectors that have been introduced, and (4) to present important mathematical models and analyses used in detector designs and applications. With these goals in mind, we have attempted to develop the fundamentals of radiation detection and detector technology so that a researcher or user of these devices can understand radiation interactions in materials, physics of the radiation detectors, commercially available and conceptual detectors, detector designs, characterization techniques, and special electronics used for various detector configurations and applications. Many of the topics covered are interrelated and, hence, the presentation of

these topics could be arranged in a number of different ways. The sequence chosen by us was done so as to reduce redundancy while, at the same time, to develop a logical and clear path of presentation.

Overall, this book is designed to give the reader more than a glimpse at radiation detection devices and a few packaged equations. Rather it seeks to provide an understanding that allows the reader to choose the appropriate detection technology for a particular application, to design detectors, and to competently perform radiation measurements. For this reason, there are many equations derived from first principles, derivations which may seem tedious to some readers. Yet, we believe that a firm understanding of the assumptions used to derive many frequently encountered equations used in the discipline helps a radiation detector user to decide when, and also when not, to apply them, and how to arrive at an appropriate alternative, if needed. Many of the later chapters on specific aspects of radiation detectors attempt to provide a comprehensive review of the historical development and current state of the topic. Such a review necessarily entails citations to many of the important discoveries and the many references provided allow a reader to quickly find additional and more detailed information.

This book has five main themes: General Concepts for Radiation Detection, Common Radiation Detector Properties, Types of Radiation Detectors, Radiation Measurements, and finally a single chapter on Introductory Electronics. Although these themes are represented by various chapters, there is some redundancy between chapters both because the themes are closely related and because some overlap assists with clarity. For instance, semiconductor photodiodes are used as light collecting devices for some scintillators, hence there is a discussion on photodiodes in the chapter on light collecting devices. Yet, the physics of semiconductor diode detectors is detailed in those chapters covering semiconductor detectors, which comes after the chapter on light collecting devices. This order may seem out of sequence, yet is unavoidable because the chapters on scintillator detectors precede the chapters on semiconductor detectors, and the authors deem it best to include the chapter on light gathering devices next to the chapters on the scintillation detectors because they are used together as a single unit. Neutron detectors are configured as gas-filled, scintillator, and semiconductor devices, as well as a few special detector designs. As a result, there are chapters dedicated specifically to neutron detectors. Yet many of the principles of these neutron detectors borrow heavily from those concepts outlined in the chapters dedicated to gas-filled, scintillator, and semiconductor detectors.

Acknowledgments

Although we have included a few original contributions, the vast amount of material presented is the result of the work by thousands of researchers in radiation detection and its related fields. For their efforts and for what they have taught us we are extremely grateful. Although it is impossible to give credit to all of these specialists, we have attempted to cite many of the key papers, reports and books that have guided the development of radiation technology. Because of the breadth of the goals for this book, the time required to write it and its resulting size are unusually long. Special thanks go our publisher's forbearance and patience in this book project.

The authors acknowledge and give their appreciation for the support and assistance of numerous individuals who made this project possible through their contributions, guidance, and encouragement. Great appreciation is extended to those current and former students who took time to proofread this text and, in doing so, made valuable contributions and suggestions. These include Elsa Ariesanti, Steven Bellinger, Brian Cooper, Benjamin Damm, Nathaniel Edwards, Ryan Fronk, Priyarshini Ghosh, Nikolas Hinson, Alireza Kargar, Michael Meier, Benjamin Montag, Kyle Nelson, Taylor Ochs, and Michael Reichenberger. Many of these same students contributed to text material in the form of radiation detection data and instrument photographs. We thank the library staff at Kansas State University for acquiring the several hundreds of citations, many rare and difficult to locate, used in the references listed at the end of each chapter. Special gratitude is extended to Rick Brake (retired Los Alamos Nat. Lab.), Anthony Caruso (UMKC), Stephan Friedrich (LLNL), Kimberlee Kearfott (U. Michigan), Mike Kusner (Saint-Gobain), Michael Mayhugh (re-

tired Saint-Gobain), Tim Sobering (KSU), and Jack Thiesen (U. Michigan) for reviewing certain chapters of this book and providing valuable comments, corrections, and improvements.

The authors also extend appreciation to their colleagues and friends who contributed to the knowledge and material presented in the text. These include Anthony Caruso (UMKC), Elias Chavez (Ludlum), Paul Davison (ADIT), William Dunn (Kansas State U.), Peggy Groff (Photonis), Daniel Herr (Saint-Gobain Crystals), Kimberly Kearfott (U. Michigan), Ben Kennedy (Ortec Ametek-AMT), Mike Kusner (Saint-Gobain Crystals), Bill Lehnert (LND, Inc.), Michael Mayhugh (retired Saint-Gobain Crystals), Jeremy Roberts (Kansas State U.), Ronald Rojeski, and Ron Stubberfield (ET Enterprises).

A special acknowledgement is extended to Richard (Rick) Brake, whose encouragement and financial support allowed one author (McGregor) to build his first radiation detectors while a graduate student intern at Los Alamos National Laboratory. Along with Rick Brake were those who took time to teach the author fundamentals of semiconductor device fabrication and detector construction, including Victor Swenson and Bill Gibler of Texas A&M University, and Alan Gibbs and David Brown of Los Alamos National Laboratory. It is the initial encouragement from these mentors that eventually led to the compilation of this text. Also acknowledged is former advisor and instructor Mark Weichold of Texas A&M University, whose constructive and detailed explanations of solid state and semiconductor physics have served one author (McGregor) well.

Above all we have valued the support and encouragement of our wives, Vilelmina and Sue, whose forbearance of too many evenings of neglect because of this tome will forever be remembered and appreciated.

About the Authors

Douglas S. McGregor, born in Dallas, Texas in 1957, received BA (1985) and MS (1989) degrees, both in electrical engineering, at Texas A&M University. He then received MS (1992) and PhD (1993) degrees, both in nuclear engineering, from the University of Michigan. From 1994 to 1996 he held a post doctoral position at Sandia National Laboratory in Livermore, California before returning to the University of Michigan where he was an assistant research professor from 1997 to 2002. In 2002, he joined the Nuclear Engineering faculty at Kansas State University (KSU) where he now is a University Distinguished Professor and holds the Boyd D. Brainard Chair in Mechanical and Nuclear Engineering. Professor McGregor serves as director of the Semiconductor Materials and Radiological Technologies Laboratory at KSU, a 9500 sq ft laboratory dedicated to radiation detector research.

Professor McGregor teaches and conducts research on the design, development, and deployment of radiation detectors and detector systems. In particular, he develops systems for measuring various ionizing and non-ionizing radiations based on semiconductor, scintillator, and gas-filled detectors. He specializes in semiconductor device physics, semiconductor device designs, radiation detector physics, neutron detector designs, and radiation detection and measurement. He has published over 200 research articles and reports, is co-inventor on over 20 radiation detector patents, and his research group has received five R&D-100 Awards for radiation detector innovations. Prof. McGregor is also the recipient of various other honors, including the KSU College of Engineering (CoE) Frankenhoff Outstanding Research Award (2006) and the CoE Engineering Distinguished Researcher Award (2016).

J. Kenneth Shultis, born in Toronto Canada in 1941, graduated from the University of Toronto with a BASc degree in Engineering Physics. He gained his MS (1965) and PhD (1968) degrees in Nuclear Science and Engineering from the University of Michigan. After a postdoctoral year at the Mathematics Institute of the University of Groningen, the Netherlands, he joined the Nuclear Engineering faculty at Kansas State University in 1969 and where he presently holds the Black and Veatch Distinguished Professorship and is the Ike and Letty Conerstone teaching scholar.

Professor Shultis teaches and conducts research in neutron and radiation transport, radiation shielding, reactor physics, numerical analysis, particle combustion, remote sensing, and utility energy and economic analyses. He has had a rich collaboration in research and scholarship. Besides being coauthor of this book he has coauthored the books *Fundamentals of Nuclear Science and Engineering*, *Radiation Shielding*, *Radiological Assessment*, *Principles of Radiation Shielding*, and *Exploring Monte Carlo Methods*. In addition, he has produced over 150 research papers and reports and served as a consultant to many private and governmental organizations. He is a Fellow of the American Nuclear Society (ANS), and has received many awards for his teaching and research, including the infrequently awarded ANS Rockwell Lifetime Achievement Award for his contributions over 50 years to the practice of radiation shielding.

Chapter 1

Origins

Great discoveries are made accidentally less often than the populace likes to think.

Wilhelm Röntgen

1.1 A Brief History of Radiation Discovery

In 1895, within the town of Strasbourg (then located in Germany, but now in France), Wilhelm Conrad Röntgen (see Fig. 1.1) made the first observation of mysterious penetrating rays. For many years, these mysterious rays were called "Röntgen rays"; however, Röntgen actually named them "x rays," as we know them today, after the common algebraic symbol for an unknown. In the famous experiment, Röntgen was operating a type of Crookes tube (see Fig. 1.2) while performing experiments with "cathode rays." With the Crookes tube covered with black paper, he noticed that a plate coated with barium-platinocyanide ($BaPt(CN)_4$), located approximately six feet away in the darkened room, was glowing. By placing objects with varying densities and thicknesses between the Crookes tube and the plate, he deduced that the mysterious emanations originated from the Crookes tube and that they were attenuated according to mass density and thickness of the absorber. A short while later, it was discovered that x rays are actually a form of electromagnetic radiation emitted from accelerated charged particles (electrons in Röntgen's experiment). Röntgen also used photographic plates for his studies after he learned that film emulsions were exposed by the x rays. After experimenting with many x-ray image exposures of inanimate objects, perhaps the most famous x-ray photograph he developed is traditionally believed to be an image of his wife's hand, Bertha Röntgen (see Fig. 1.3). Indeed photographic film is a type of radiation detector, and the x-ray image of Bertha Röntgen's hand marks the beginning of medical imaging. For his discovery of x rays, Röntgen became the recipient in 1901 of the first Nobel Prize in Physics. These discoveries were made with two types of *radiation detectors*, namely the scintillating $BaPt(CN)_4$-coated plate and the photographic plates.

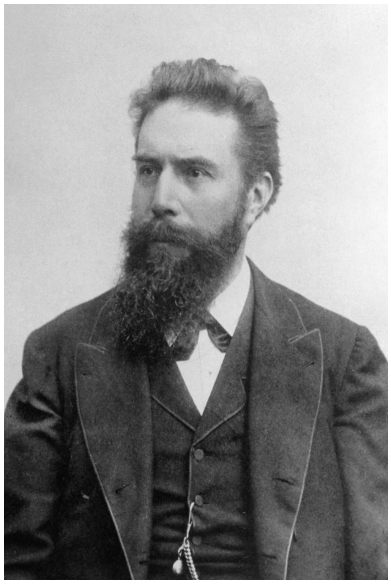

Figure 1.1. Wilhelm Conrad Röntgen (1845–1923).

In 1896, shortly after the announcement of the discovery of x rays, Henri Becquerel (Fig. 1.4), while conducting experiments with his father's geology samples, discovered natural radiation emissions. It was already known that many substances could be made to fluoresce by exposing them to visible light, and Becquerel was studying the fluorescence of sulphates of uranium and potassium by exposing his samples

Figure 1.2. A Crookes tube was used as the x-ray source in Röntgen's experiments. The Maltese cross in the vacuum tube is connected to a hinge that allows it to be flipped up or down.

Figure 1.3. (Left) Traditionally labeled as Bertha Röntgen's hand, and probably the case, it actually was not labeled as such at the time of publication. (Right) Often mistakenly labeled as Bertha Röntgen's hand, this image taken by Röntgen is actually that of Alfred von Kölliker's hand. The discovery that x rays can be used to produce images of bone structure marks the beginning of the modern medical imaging profession.

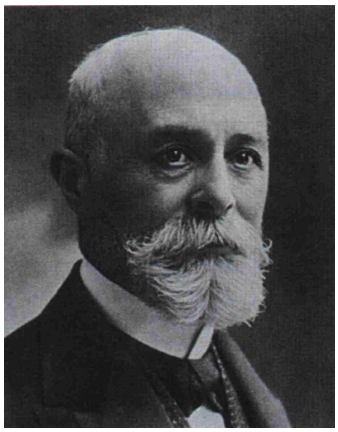

Figure 1.4. Antoine Henri Becquerel (1852–1908).

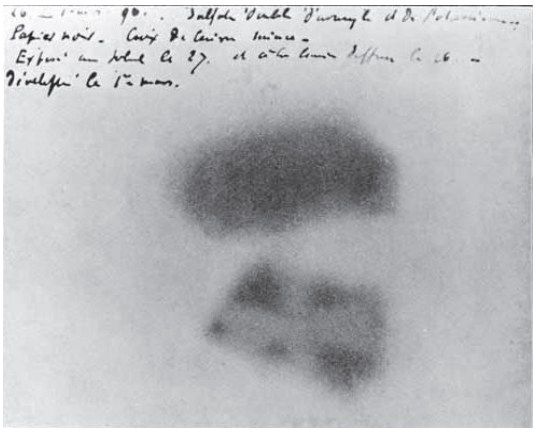

Figure 1.5. The original photographic plate images, taken by Henri Becquerel, of uranium ore samples.

to sunlight and measuring the light emissions with photographic plates. In one instance, he prepared a sample set of uranium salts for an exposure experiment, but decided to delay the experiment that day due to cloudy weather. Instead, he placed the uranium salt samples in a dresser drawer, fortuitously atop a stack of photographic plates. A few days later, he decided to check the quality of his photographic plates before trying the fluorescence experiment again, and developed the top photographic plate on which the samples lay, only to find that an image had formed (see Fig. 1.5). At first, Becquerel actually thought that the uranium salt samples were exposed to enough light to cause fluorescence, which he believed then exposed the film. He continued to conduct the experiments, but instead covered the photographic plates with black paper, upon which he placed the samples. He later discovered uranium salts not yet exposed to sunlight had the same effect on the photographic plates. Finally, several months after the initial discovery, he found that non-fluorescent uranium ore could also expose the plates, and he deduced that unknown emanations from the rock samples themselves caused the exposure. Initially referred to as "Becquerel rays," we now know the emanations he observed were a combination of alpha particles, beta particles, and gamma rays. For the discovery of radioactivity, Becquerel shared in the third Nobel Prize in Physics in 1903[1] along with Pierre and Marie Curie for their work and discovery of polonium and radium. Again, the discovery was made possible with a type of radiation detector (photographic plates). It is interesting to note that in February 1896 an English physicist and mathematician by the name of Silvanus Thompson independently conducted the same experiment as Becquerel, in which he exposed uranium samples to sunlight as they were placed upon a paper-covered photographic plate. He also discovered the mysterious emanations, but when he sent his results in for publication (to the Royal Society in London), he was informed that Becquerel had already reported the same findings only two weeks earlier to the French Academy of Sciences.

During the 1890s, many other significant experiments were being conducted with cathode ray tubes. Cathode ray tubes were built in many configurations, but common features included a negatively charged electrode (cathode) and a positively charged electrode (anode) sealed in an elongated vacuum tube, where the far end of the tube opposite the cathode was coated with a phosphor.

[1] Interestingly enough, there is evidence that natural radiation had been observed from uranium salts much earlier by Claude Félix Abel Niepce de Saint-Victor, in which a uranyl nitrate sample had been brought into close proximity to a photo sensitive paper sheet [Saint-Victor 1858]. The Niepce de Saint-Victor experiments were reported to the French Academy of Sciences in 1858, and evidently Becquerel was aware of the work [Fournier and Fournier 1990]. Regardless, Becquerel was the first to explain and understand the significance of the discovery.

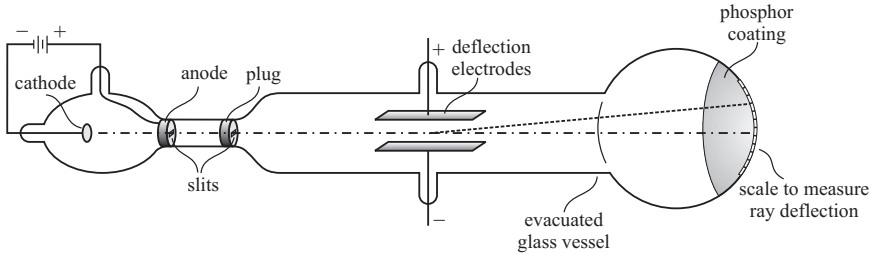

Figure 1.7. The cathode ray tube apparatus used by Thomson to measure the q/m ratio for cathode rays.

In 1895, through the use of a cathode ray tube, Jean Baptiste Perrin made the discovery that cathode rays were composed of negative electricity. Building on this knowledge, Joseph John Thomson (see Fig. 1.6) conducted experiments with different cathode ray tubes (CRTs) to investigate the nature of the cathode rays, where he paid special attention to evacuating the CRT. This simple precaution allowed experiments to be conducted without contaminant gases which could become ionized during the operation of the tube. A schematic of such a tube is shown in Fig. 1.7. With these tubes Thomson made three fundamental experimental observations. First, he noted that magnetic fields and electric fields could deflect the trajectory of the cathode rays.

Figure 1.6. Joseph John Thomson (1856–1940).

Further, given a known magnetic field strength, he noted that the deflection of these cathode rays was far greater than observed for positively charged hydrogen gas. Finally, by comparing the results of the cathode rays and the hydrogen gas, Thomson noted that the charge-to-mass ratio was approximately 1800 times greater for the cathode rays than for hydrogen ions.[2] Because he was confident no gas was inside the cathode ray tube, in 1897 Thomson correctly deduced that cathode rays were in fact negatively charged particles emitted from the cathode surface or, more correctly, emitted from the atoms composing the cathode. Although Thomson named these newly identified negative particles "corpuscles," the eventual name given to them was *electrons* as suggested by George Johnston Stoney, who had actually predicted the presence of these negative particles as early as 1874.

It should be noted that Thomson's discovery was the first recorded indication that atoms consisted of subatomic particles, thereby, earning him the 1906 Nobel Prize in Physics. Thomson's discovery was made possible, in part, with another type of radiation detector, namely the fluorescent screen of the CRT.

The observations and findings of Becquerel caught the interests of Pierre and Marie Curie, both chemists by education (see Fig. 1.8). Marie began studying under Becquerel, and began a systematic investigation of the known elements to determine if other materials emitted energetic rays similar to those from uranium. While studying pitchblende, an uranium ore containing various oxides, thorium, and other rare earth elements, she found that thorium and thorium compounds also emitted energetic rays. Marie is generally

[2]The same observation was made by Arthur Schuster in 1890, where he also measured the charge-to-mass ratio of cathode rays to be over 1000 times greater than positively charged hydrogen gas. However, he believed the measurements to be in error and his observations went largely unnoticed.

credited with recommending the name *radioactivity*[3] to describe these energetic emissions. Marie quickly reported these findings, only to learn that German physicist Gerhard Schmidt had published similar findings on thorium only two months earlier. However, of genuine interest in Curie's work was the observation that the pitchblende, after removing the uranium, was more radioactive than the uranium. The Curies thus deduced correctly that another radioactive element must be present.

Figure 1.8. Marie (1867–1934) and Pierre (1859–1906) Curie discovered polonium and radium.

In 1898, Pierre joined Marie's research effort, and together they worked to separate and identify the other radioactive substances in pitchblende. They used a quartz piezoelectric electrometer (named a Curie electrometer), invented by Pierre and his brother Jacques, to measure the ionization produced in air by the radiation emitted from the purified samples. They separated literally tons of pitchblende material to attain just a few milligrams of the purified radioactive substance, which they named polonium (after Marie's country of birth, Poland) and they reported the new material in July 1898. Five months later in December 1898, they reported a second new element, which they named radium. For their work on radioactive materials, both Pierre and Marie Curie shared the 1903 Nobel Prize in Physics with Henri Becquerel. Marie Curie also received the 1911 Nobel Prize in Chemistry for discovering two new elements[4] (Pierre had been accidentally killed by a horse and wagon in 1906, and did not share in the award).

In 1899 Ernest Rutherford (see Fig. 1.9), who was a former student of J.J. Thomson, took on the task of identifying the natural radiation discovered by Becquerel. Rutherford used a gold foil electroscope as the detector in his experiments. Understanding that the radiation produced free charges in air, he placed a uranium ore sample in the electroscope compartment, charged the electroscope, and then recorded the discharge rate of the gold foils. Rutherford then placed thin layers of aluminum foil (each 5-μm thick), one at a time, over the uranium ore sample. For each foil added, he observed the change in the discharge rate. He noted that a significant change in discharge rate occurred each time for the first three foils used, but the change in discharge rate was dramatically less afterwards. In fact, after the first three foils were in place the discharge rate had dropped to 8% of the initial rate with no attenuators. However, it took an extra 100 aluminum foil layers to reduce the discharge rate to 2% of the initial rate. Rutherford correctly deduced that two types of radiation were present. He named those radiations stopped with only three foils *alpha rays* and those higher penetrating radiations were named *beta rays*. We now know these rays to be particles, with α particles being ^{4}He nuclei and β particles being electrons. For these discoveries, Ernest Rutherford was awarded the 1906 Nobel Prize in Chemistry. Using magnetic fields, Rutherford later showed that beta particles could be easily deflected, while

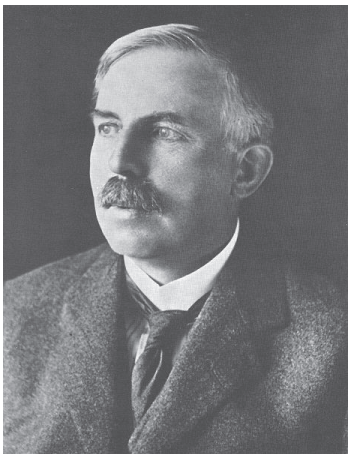

Figure 1.9. Sir Ernest Rutherford (1871–1937) discovered alpha and beta particles.

[3]The word radioactivity was chosen because of its Latin root word "radius," which means 'ray' or 'spoke of a wheel.'
[4]Marie Curie is the first (and presently only) person to receive Nobel prizes in two different scientific fields.

Figure 1.10. Paul Ulrich Villard (1860–1934) discovered what were later called gamma rays.

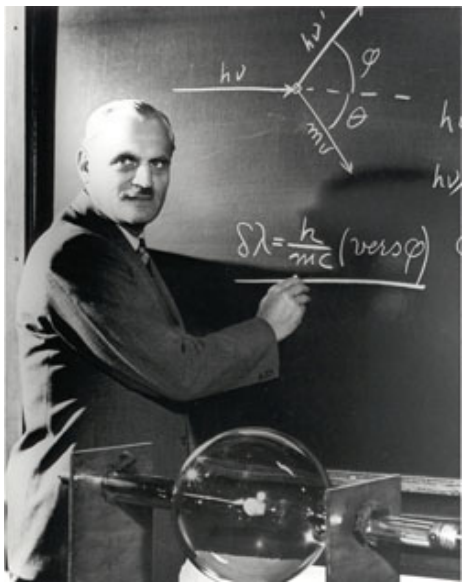

Figure 1.11. Arthur Holly Compton (1892–1962) discovered what is known as Compton scattering.

alpha particles were deflected very little, and in the opposite direction of beta particles, indicating different masses and different characteristic charges.

Shortly thereafter, in 1900, Paul Villard (see Fig. 1.10) conducted experiments with radium samples and photographic plates. He collimated the radiation from a radium sample towards a photographic plate that was shielded with a thin layer of lead. The lead stopped the α particles, but allowed the highly penetrating radiation to pass. Using a magnetic field, he noted that two types of penetrating radiation were present, one type that was deflected by a magnetic field, and another that was not. He concluded that the deflected radiation was composed of the β particles discovered by Rutherford, but the undeflected radiation must be a third and different kind. Initially, Rutherford thought these emanations to be nothing more than highly energetic β particles, but eventually came to believe that Villard was correct. Villard did not name the radiation he discovered, but instead, in 1903, it was Rutherford who named the third radiation *gamma rays*. In 1914 it was shown that these highly penetrating rays, which were not affected by magnetic fields, could also be diffracted off crystal surfaces. Hence, Villard was correct, and gamma radiation was something quite different. The nature of gamma rays was explored further in 1918 by Arthur Holly Compton (see Fig. 1.11), who developed the fundamental physics behind what is referred to as Compton scattering. He showed that gamma rays lose energy after scattering with electrons, demonstrating the particle nature of gamma rays, for which he earned the 1927 Nobel Prize in Physics.

Noted in Millikan's book *Electricity, Sound and Light* [1908], there were certain aspects of the atom not clearly understood. For instance, as Millikan deduced, because electrons possess negative electricity and atoms themselves are neutral, then there must be some form of positive charge within the atomic structure to cancel the negative charge of the electron. J.J. Thomson proposed an atomic model, later disproved, in which the atomic nucleus consisted of positive electricity (now known as protons) about which, or within which, the negative electrons were rotating. This model is often referred to as the "plum pudding model," with the pudding being the positive stuff and the electrons the plums. In 1909, Ernest Rutherford performed an important experiment that proved the plum pudding model wrong. In his experiment, Rutherford collimated

Figure 1.13. Robert Andrews Millikan (1868–1953).

alpha particles from a Po sample into an ultra-thin sheet of Au foil, using the alpha particles as a method to probe the atomic structure of Au. If Thomson was correct and the Au atoms resembled the plum pudding model, then the alpha particles should just pass through the Au foil with hardly any deflection. Although Rutherford found that many alpha particles did actually pass directly through the Au foil, he also found that a small fraction were strongly deflected, and some scattered in the backwards direction. He concluded that such strong interactions could only happen if the positively charged alpha particles came into the close vicinity of another small but heavy positive mass, unlike the small deflections expected from the large neutralized atomic core suggested by Thomson. From his findings, Rutherford postulated the following:

(1) Most of the atomic mass and positive charge are contained in a small core called the nucleus.[5]

(2) Most of the volume of the atom is empty space about which the negative electrons are dispersed.

(3) Within the atom, the number of negatively charged electrons and the number of positively charged particles (protons) are equal.

In 1911 Charles Wilson (see Fig. 1.12) devised what is now known as a cloud chamber[6] to visualize the paths of charged particles by trails of condensed droplets in supersaturated water vapor and air mixture. These vapor trails would drift downwards under the influence of gravity. Wilson realized that the ion trails could be forced downwards faster by applying an electric field such that the droplets fell under the influence of both gravity and the electrostatic field [Kaplan 1962]. Wilson managed to obtain an estimate of the charge of an electron by comparing the rates of fall with and without the electric field force applied. However, two significant errors prevented accuracy, namely (a) the droplets could reach terminal velocity in the air and water vapor mixture regardless of the applied field, hence a true measure of the electric field influence was not possible, and (b) a water droplet would begin to evaporate so that the droplet mass changed as the cloud

[5] Traditionally, because of his identification of a distinct positive core within the atom, Rutherford is credited with discovering the proton.

[6] Wilson received the 1919 Nobel Prize in Physics for this interesting detection device.

trail fell downwards. Further, Wilson measured only the upper part of the cloud trails because the lower droplets in the trails were more heavily charged and generally moved faster than the upper portion.

Robert Millikan (see Fig. 1.13) thought that Wilson's method could be improved by applying the electric field force in the opposite direction of gravity so that the tiny charged vapor droplets could be made to remain stationary (balancing electric field and gravitational forces). No assumptions need be made about terminal velocities and what portion of the cloud should be inspected. Specific droplets could be selected, using a microscope, and observed. However, the problem remained that water and alcohols quickly evaporated. As the story goes, Millikan thought of the idea of substituting clock oil for water vapor while on a train trip. When looking at his watch, he realized that clock oil was used as a long lasting lubrication because it did not evaporate. Using an atomizer to inject a fine mist of oil droplets into a chamber, Millikan irradiated the chamber with x rays to produce charges on the oil droplets (see Fig. 1.14). He held a single droplet stationary by balancing the electric field force with the gravitational force. Regardless of the droplet chosen, he observed that the measured electric field (coulombs per unit distance) required to hold an oil droplet stationary were multiples of 1.6×10^{-19} coulombs. A single oil droplet might have an excess or deficiency of one or more electrons, but could not gain or lose a fraction of an electron.[7] This measurement also led to the electron mass being estimated as 9.1×10^{-31} kg, again remarkably close to the presently accepted value of $9.109\,382\,91 \times 10^{-31}$ kg.

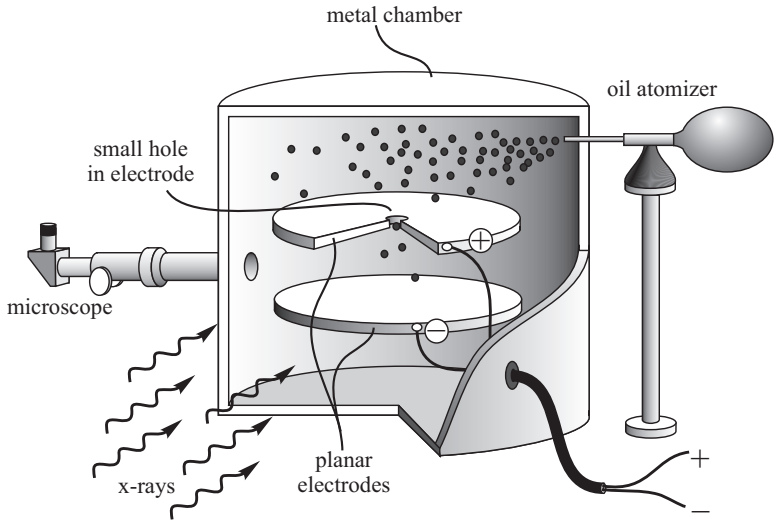

Figure 1.14. The basic components of Millikan's oil drop apparatus.

In 1920, Rutherford noted that there was some problem balancing the atomic masses of elements and their charge. For instance, the mass of hydrogen could be measured, as could other elements. It had also

[7] There is controversy over Millikan's selective use of data, in which over 60% of his recorded measurements were not included in his publications. Note also that a great controversy arose between Millikan and Felix Ehrenhaft, who also tried to measure the fundamental negative charge. Ehrenhaft's data suggests the existence of a smaller fundamental charge, sometimes recorded as low as 1/10 that of 1.6×10^{-19} coulombs. It has been suggested that Ehrenhaft may have observed the effect of elementary particles (such as quarks), although a more likely explanation is that the observed differences were a result of experimental error. Regardless, Millikan's conclusion, reported in 1913, has less than 0.5% error of the presently accepted value of $q_e = 1.602\,176\,565 \times 10^{-19}$ coulombs. Delayed by the "Millikan-Ehrenhaft controversy," Millikan did eventually receive the Nobel Prize in Physics (1923) for his work.

been determined that a proton had an intrinsic charge equal in magnitude to that of an electron, yet opposite in polarity. This all made sense, except that the masses did not scale linearly with the quantity of electrons or protons. Rutherford hypothesized, therefore, that some additional mass, neutral in nature, must be present. Many years later, in 1928, experiments were conducted by Walther Bothe[8] and Herbert Becker where alpha particles from Po were used to bombard Be. The result was the discovery of a new form of highly penetrating neutral radiation. Initially thought to be high energy gamma rays, this idea was quickly discarded as unlikely because of the constraints of conservation of energy and mass requirements in Compton scattering. Irene Curie (daughter of Marie and Pierre Curie) and her husband, Frédérick Joliot, studied the effects further by also bombarding Be with alpha particles emitted from Po, causing the unidentified neutral radiation to be emitted into a paraffin sample. The result was the emission from the paraffin of energetic protons. These protons were measured with a gas-filled counter (a detector developed by Hans Geiger and Ernest Rutherford) to have approximately 5.3 MeV of kinetic energy. From Compton's previous findings with gamma-ray scattering, the observed result was unlikely if the unknown neutral emissions really were gamma rays.

James Chadwick (see Fig. 1.15), who was Rutherford's student, used a similar arrangement as Curie and Joliot with a few changes. A Po alpha particle source was used to produce the neutral particles from a boron sample, and a gas-filled detector similar to early Geiger models was placed near the Be sample such that the neutral emissions could enter the detector [Chadwick 1932]. Separately using N_2 and then H_2 gas in the detector, along with conservation of mass and energy calculations, Chadwick measured and calculated the mass (or energy) of the neutral radiation to be 938 MeV/c^2, nearly the same, but slightly larger than that of protons. Thus, Chadwick found the missing particle that Rutherford had hypothesized, and because they have no intrinsic charge, he named them *neutrons*. Remarkably, Chadwick's calculations were within 0.17% error of the presently accepted value of 939.272 046 MeV/c^2. For the discovery of neutrons, Chadwick received the 1935 Nobel Prize in Physics.

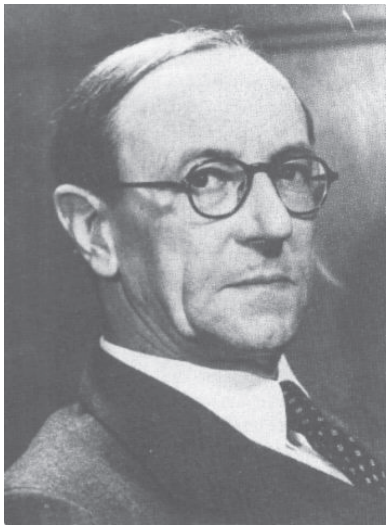

Figure 1.15. James Chadwick (1891–1974) discovered neutrons.

Following the discovery of these basic subatomic particles (electrons, protons, and neutrons), numerous other subatomic particles and elementary particles have been discovered. *Quarks* are elementary particles that combine to form *hadrons*, and all quarks follow Fermi-Dirac statistical models in which no quark can occupy the same quantum state as another. Hence, quarks belong to the group of particles classified as *fermions*. Independently postulated as existing by Murray Gell-Mann and George Zweig in 1964, the quark was discovered in 1968 at the Stanford Linear Accelerator Center (SLAC). Gell-Mann received the 1969 Nobel Prize in Physics for his contributions to the theory and his prediction of the quark.

There are six types of quarks, with the fanciful names of up, down, top, bottom, charm and strange, in what is now known as the standard model. Hadrons are subcategorized as *mesons* and *baryons*, where mesons are composed of two quarks and baryons are composed of three quarks. The two most well-known and stable baryons are protons and neutrons. Protons are composed of two up-quarks (each with charge of $+2/3\ q_e$) and one down-quark (charge of $-1/3\,q_e$), yielding a total

[8] Walther Bolthe used Geiger counters to invent a method of coincidence counting in 1924. He used this technique to discover and verify several physical principles about penetrating radiation and light quanta. For his invention of coincidence counting, and his many discoveries, he received the 1954 Nobel Prize in Physics.

charge of $+q_e$. Neutrons are composed of one up-quark and two down-quarks, yielding a total neutral charge. Neutrons not bound in an atomic nucleus are radioactively unstable with a half-life of 10.23 minutes. When a neutron is free from an atomic nucleus, one of the down-quarks decays into an up-quark, causing the neutron to decay into a proton, an electron, and an antineutrino.

The existence of mesons, a particle with binding force capable of holding the atomic nucleus together, was predicted by Hideki Yukawa in 1935. Convincing evidence of Yukawa's theory was found in 1945 with the discovery of the π-meson (pion) at the University of Bristol, a particle that was later proved to have a strong nuclear force that participates in binding of the nucleus. Yakawa received the 1948 Nobel Prize in Physics for his theory on the behavior and properties of mesons, in particular, the pion.

Another set of elementary particles are the *leptons*, also classified as fermions, which are categorized into six *flavors* subdivided as three *generations*. The electronic generation is composed of electrons and electron-neutrinos, the second generation is composed of muons and muon-neutrinos, and the third generation is composed of tauons and tauon-neutrinos. The existence of the various neutrino forms was discovered in 1962 by Leon M. Lederman, Melvin Schwartz, and Jack Steinberger who were awarded the 1988 Nobel Prize in Physics.

All fermions (hadrons and leptons) have corresponding anti-particles. For hadrons the anti-particle is composed of the corresponding anti-quarks producing anti-hadrons with identical mass but opposite charge as their real hadron counterparts. In fact anti-matter seems to interact with the strong and electromagnetic forces identically as does matter. Thus, it is possible to envision anti-atoms and macroscopic masses composed of anti-matter. However, matter and anti-matter cannot coexist. Just as positrons annihilate with electrons, anti-nucleons annihilate with nucleons.

Finally, a third branch of elementary particles contains the *bosons* consisting of photons, gluons, Z and $W^{\pm}$ particles. These particles are governed by Bose-Einstein statistics and, hence, they can occupy the same quantum state at the same time. Photons represent the force component of an electromagnetic field, gluons are the strong binding force among the quarks in the neutron and proton as well as the binding of the nucleons in an atomic nucleus, and the Z and $W^{\pm}$ particles are responsible for the so-called weak nuclear force. A fifth boson, the Higgs boson (H^0) is a theoretical particle predicted by the standard model, but for years it remained elusive. Finally in 2012, researchers at the European Organization for Nuclear Research (known as CERN) announced its discovery, completing the search for all the elementary particles required by the standard model. This last boson is important because it is the particle that gives mass to all the other elementary particles.

Today the search for a better understanding of the sub-atomic realm continues. The ingenious methods used by Thompson, Rutherford, Millikan and their contemporaries have been largely replaced with enormous particle accelerators and sophisticated detection systems. Rather than a single observer performing experiments in a one-room laboratory, teams of physicists and engineers work together at large facilities, such as CERN, to measure and observe the effects of these numerous elementary particles. Yet, even today, it is the innovative thought and creativity of *individuals* that continues to be the driving force behind discovery.

1.2 A Brief History of Radiation Detectors

There are three essential features in any radiation detector. First, the detector must have a material capable of interacting with the radiation of interest. Otherwise, the radiation would simply pass through it as if no detector were present. Second, upon interacting with the radiation, the material must exhibit an observable response. The response can be any of a multitude of possibilities such as temperature changes, color shifts, light emission, or ionization of the material. Third, the observable must be measurable. For instance, radiation interactions may occur in a common stone on the ground and ionization may occur in the stone as a result, but accurate measurement of the ionization is prevented because the stone can not conduct the

charges to allow their measurement. A person seeking either to use or to design radiation detectors must keep these three simple, yet important, concepts in mind.

All the important discoveries of subatomic particles and radiations were accomplished with the use of various types of radiation detectors, including photographic plates, electroscopes, scintillating materials, and gas-filled detectors. In the case of photographic film, the absorber is the photo-emulsion, the observable is the chemical change in the Ag halide crystals in the emulsion, and the measurable is the developable Ag left behind as an image. In scintillating film, the absorber is the scintillation material, the observable is the excitation of electrons in the material, which deexcite to give a measurable number of visible photons. In an electrometer, two Au leaves are held apart by positive charges. When radiation is absorbed in the air surrounding the Au leaves, it ionizes the air—the observable. Electrons are attracted to the Au leaves and neutralize some of the charge on the leaves, thereby, causing the Au leaves to move closer together—the measurable result.

An odd form of radiation detector, not recommended by the authors, is the warming or reddening of skin from radiation exposure. During the year 1900, Friedrich Walkoff and Friedrich Giesel both conducted self-exposure experiments with radium. Giesel [1900] reported that he strapped 270 mg of Ra salt to his inner forearm for hours, and he communicated his observations to Henri Becquerel and Pierre Curie. Walkoff [1900] reported a similar experiment, except he performed two exposures, each 20 minutes in duration. He wrote that a skin inflammation formed that had "already lasted over two weeks." Apparently these findings piqued the interest of Pierre Curie, who decided to perform a similar experiment of his own [Becquerel and Curie 1901]. He purposely exposed his arm to Ra for several hours, which "resulted into a lesion that resembled a burn that developed progressively and required several months to heal." The circumstances surrounding Becquerel are not as clear, but apparently he carried a glass vial of Ra salts in his vest pocket and developed a similar radiation burn which took 49 days to heal and left a permanent scar [Becquerel 1903]. In these experiments the skin tissue was the absorber, the observable was a radiation burn, and the measurable was the intensity of red as seen by the eye. Amazingly, technicians demonstrating x-ray machines to potential customers often held one hand near the x-ray tubes until the hand became warm, which indicated to them that the machine was operating. Since those times, much has been learned regarding the health risks involved with radiation exposure, and government regulations are in place to limit the radiation dose to civilians and radiation workers.

As the understanding of radiation interactions in materials increased, more convenient methods of detecting the presence of radiation were sought and developed. For several years after Röntgen's initial discovery of x rays, tedious methods were employed using photographic plates, fluorescing screens, or electroscopes. These early methods of radiation detection relied upon a large amount of radiation exposure and were not capable of recording individual radiation quanta. The first radiation detector capable of distinguishing individual radioactive particles was the *spinthariscope*, invented by Crookes in 1903. It consisted of a ZnS scintillation screen and a magnifying eyepiece as one unit. Within the device, a tiny Ra source was suspended by a wire between the eyepiece and the ZnS screen. In a darkened room, the spinthariscope could be used to visually see individual alpha particle interactions from the radiation source.[9] As a post-doctoral researcher studying under Rutherford, Hans Geiger used the same principle by counting, through a microscope, flashes of light caused by individual alpha particles as they interacted with a scintillating ZnS screen. The process was tedious and Geiger would quickly become fatigued.

With the understanding that radiation would ionize gas, in 1908 Ernest Rutherford and Hans Geiger fashioned a type of gas-filled radiation detector based on the principle of drifting the liberated charges with

[9] Believe it or not, spinthariscope rings (named *Lone Ranger Atomic Bomb Rings*), complete with alpha particle emitting material, were available from General Mills Cereals between 1947 and the early 1950s for the bargain price of 15 cents and a Kix cereal box top.

an electric field [Flakus 1981; Frame 2004; Geiger 1913]. This simple detector, at first, consisted of a thin wire strung coaxially through a metal cylinder. Gas was introduced into the cylinder, and a charged particle interacting in the gas would produce ionization. The opposite charges (electrons and ions) were drifted apart by an electric field applied across the wire and cylinder and the charge movement was measured as a current. The device was redesigned such that the central wire was replaced with a needle point inserted into a metal cavity, known as *Geiger point counters*. Later in 1928, returning to the original coaxial design, Walther Müller (Geiger's student) improved the device by running the central wire through a glass tube and attaching the device to electronic tube circuit for readout [Flakus 1981; Frame 2004]. This was an early version of present day *Geiger-Müller* counters. Various forms of gas-filled detectors were designed specific to experimental needs of the times.

Over the following decades, a variety of improvements in the design and operation of gas-filled detectors were implemented. For instance, it was learned that the proper application and selection of gas components permitted much better operation of Geiger-Müller counters. New electrode designs permitted large detectors to be built, some spanning over a meter in area with multiple anodes. Gas detectors have found uses as gamma-ray spectrometers and neutron detectors and, today, gas-filled detectors continue to be used routinely for radiation detection applications.

Better detectors were also sought that might be more efficient, less cumbersome and easier to use. It was understood that solids absorbed radiation more effectively than gases, and so there was effort to develop a solid-state conducting detector. Röntgen and Joffé [1913] published the first (known) observations of induced currents in certain solids. Röntgen [1921] continued the efforts, as did many other enthusiasts such as Schiller [1926] and Jaffé [1932]. Yet, their choices of materials were unfortunate, being mainly quartz, mica, rocksalt, glass, and other electrically insulating materials. Hence, the results were poor mainly caused by the very small induced currents, inadequate amplification electronics, crude counting methods, and time-dependent material polarization.

Scintillators, materials that emit visible light when irradiated with energetic particles or photons, offered another method to produce solid-state detectors. Scintillation materials were known since Röntgen's initial discovery of x rays with the $BaPt(CN)_4$-coated plate, yet a number of problems prevented the realization of a practical device for decades, mainly (1) that the scintillators used had poor light yield efficiency and (2) that there were then no practical devices available to measure or amplify the scintillation light output. Two major developments allowed scintillators to become practical and useful radiation detectors and spectrometers, namely the development of the photomultiplier tube (PMT) and the discovery of scintillating thallium-doped sodium iodide (NaI:Tl). There is evidence that Leonid A. Kubetsky [Lubsandorzhiev 2006] developed an electron amplifier that utilized secondary emission. Known as "Kubetsky tubes," the devices constitute an early version of the modern PMT. Independently, in 1935, a single-stage PMT was developed by RCA that had a gain of 8 [Burle 1980]. A multistage PMT was reported by Zworykin in 1936 that was operated by adjusting electric and magnetic fields but which proved to be impractical. Meanwhile, in 1937 Kubetsky published the descriptions of numerous photomultiplier designs with gains as high as 10^6. Within a few years, in 1941, RCA developed and commercialized the 931A PMT that had high electron signal gains, thereby providing a light amplification device that could be used with scintillators.

Various known organic scintillators were used in conjunction with the newly developed RCA 931A PMT with encouraging results. However, it is Hofstadter's discovery of NaI:Tl in 1947 that marks the beginning of a truly practical portable gamma-ray scintillation spectrometer [Hofstadter 1948; Hofstadter and McIntyre 1950]. NaI:Tl is a bright scintillator that emits approximately 43,000 visible light photons per MeV of energy absorbed, and the light yield as a function of energy is acceptably linear. Within a few years, commercial NaI:Tl gamma-ray spectrometer units were available.

Despite the success of NaI:Tl as a solid-state gamma-ray spectrometer, effort still continued to develop a solid-state version of an electron conduction device. Van Heerden [1945] demonstrated what is often referred

to as the first "practical" semiconductor radiation detector. In his Ph.D. dissertation, "The Crystal Counter," he decries the use of AgCl crystals cooled to low temperatures to detect alpha particles from a ^{210}Po source [see also Van Heerden and Milatz 1950]. Shortly thereafter, CdS crystals were used to observe pulses from gamma rays and beta particles (as reported by Frerichs and Warminsky [1946] and later by Goldsmith and Lark-Horovitz [1949]). In 1947, Wooldringe et al., followed by Jentschke 1948, reported induced electrical pulses from diamond samples.[10]

Although semiconductor detectors remained of interest, the development of NaI:Tl devices kept the status of semiconductor detectors, then referred to as "crystal counters," to little more than interesting gadgets. The main problem with semiconductor devices was the unfortunate high concentrations of defects in the crystals. The defects, which included impurities, dislocations, and intrinsic defects, caused severe problems with charge carrier collection from the devices. With the success of NaI:Tl, it appeared that crystal counters offered little hope for improvement, if any, to radiation spectroscopy.

Nevertheless, a variety of advances in semiconductor detectors began to occur after 1948 [see reviews by Hofstadter 1949a, 1949b; Chynoweth 1952; McGregor and Hermon 1997]. McKay [1949, 1951] developed a radiation detector using a point contact on a Ge semiconductor substrate. The rectifying point contact was irradiated with alpha particles from a Po source, and this detector yielded sizeable electronic pulses on the order of 8-12 millivolts at reverse biases between 2-10 volts. Soon after, various forms of diffused junction and "surface barrier" detectors were developed based on Ge and Si [Dearnaley and Northrop 1966]. However, the development that finally allowed semiconductor detectors to become serious devices for radiation detection and radiation spectroscopy was the introduction of Li ion drifting by Pell [1960]. Li ions were electrically drifted into Si and Ge crystals to nullify, or "compensate for," the effects of residual impurity dopants.

Originally, university and government researchers found it necessary to construct their own custom semiconductor detectors, and many techniques were developed and published to build surface barrier, *pn* junction, and Li-drifted detectors. However, with the success of Li drifting, a variety of semiconductor detectors became commercially available by 1964. Also by this time the traditional name of "crystal counter" was dropped and replaced with the more descriptive name "semiconductor detector." The semiconductor detectors enabled gamma-ray and particle energy identification with outstanding resolution, far better than that achieved with scintillation detectors [Bertolini and Coche 1968; Poenaru and Vilcov 1969; Deme 1971]. Lithium drifted Ge detectors, or Ge(Li) detectors, were of more use for gamma-ray spectroscopy than the Si(Li) detectors due to the greater atomic number of Ge (32) over Si (14), which gives Ge a higher absorption efficiency. Both Ge(Li) and Si(Li) detectors[11] needed to be operated at cryogenic temperatures near 77K to reduce thermal noise and leakage currents. This operating criterion was especially true for Ge(Li) devices for an added reason; if the detector warmed up, the Li would diffuse and redistribute in the crystal and the detector would be ruined [Dearnaley and Northrop 1966; Bertolini and Coche 1968]. Hence, Ge(Li) detectors had to be kept at cryogenic temperatures at all times, which is an obvious disadvantage.

Another method of dealing with the contaminant impurities is to remove them by various methods. Zone refinement, one such method, had already been used to purify and remove background impurity contaminants from a number of substances. Robert Hall at General Electric Co. (GE) suggested in 1968 that this method might be used to purify Ge to such levels that Li drifting would no longer be necessary. Two research groups, one at GE led by Robert Hall and another at Lawrence Berkeley Laboratory led by W.L. Hansen, developed a method of zone refinement for Ge [Yu and Cardona 1996]. Soon high-purity Ge (HPGe) detectors became commercially available, and over the years Ge(Li) detectors have been largely phased out for the preferable

[10] Jentschke references a diamond device that was reported by Stetter [1941], thereby predating Van Heerden's work. The device was used to observe pulses from an alpha particle source, yet the article is unclear on many aspects of the experiment, and the work was largely overlooked for many years.

[11] The traditional pronunciation is "jelly detector" for the Ge(Li) detector and "silly detector" for the Si(Li) detector.

HPGe detectors. HPGe detectors must still be cooled to cryogenic temperatures to prevent damage from excessive leakage currents; however, when not operating these detectors are no longer ruined if they are allowed to warm up. As explained in a later chapter, Si(Li) detectors currently remain important as x-ray spectrometers and are still commercially available.

Although Ge and Si have been established as important radiation detectors, the need for cryogenic cooling is inconvenient, especially in situations where a portable device is required. Hence, the search for semiconductor devices that can operate at room temperature remains a priority. Detectors made from gallium arsenide (GaAs), a wide band-gap semiconductor that can be operated at room temperature, were studied and reported as radiation counters in 1960. In 1970, Eberhardt, Ryan, and Tavendale demonstrated the first high energy resolution semiconductor room-temperature-operated gamma-ray spectrometer. The detector was fabricated from a high-purity, epitaxially grown GaAs crystal, and the active region of the device was only 80 microns thick. Since then, many other, and perhaps more promising, semiconductors have been studied. These include mercuric iodide, cadmium telluride, and cadmium zinc telluride. The main impediment to widespread use of compound semiconductors is the difficulty of producing quality detector crystals. It is much harder to produce defect-free compound semiconductors than it is to produce defect-free single-element semiconductors, of which only Si and Ge are practical materials.[12]

A timeline of the major developments in radiation detector inventions is shown in Figs. 1.16 and 1.17. This chart provides a snapshot up through 2010. However, this is not the end of detector history. Detector development actively continues today and the discipline is far from being exhausted, as evidenced by many new devices and designs produced in the past two decades. Novel approaches and designs, such as the gas electron multiplier (GEM), have expanded the use of gas-filled detectors. New scintillation materials, such as various lanthanide halides and elpasolites, have been developed that offer gamma-ray energy resolution that is much better than NaI:Tl. Also, new compact photomultiplier devices based on semiconductors have become available. Clever semiconductor detector designs have significantly reduced the effects of defects previously impeding progress with compound semiconductor detectors. Novel detector approaches using cryogenics have yielded devices with unprecedented energy resolution. Micro-machined semiconductors have produced the first high-efficiency semiconductor neutron detectors. All of these devices, amongst a myriad of other designs and technologies, some still in development, are described in chapters throughout this text.

[12] There are other single element semiconductors, such as C (diamond) and Te, but these materials have intrinsic properties that generally disqualify them. Because of its high melting point, diamond cannot be produced through traditional bulk crystal growth processes and is generally grown as thin chemical vapor deposition (CVD) films. Unfortunately, these diamond materials continue to have issues with defects. Further, with C having such a low Z number (6), they are simply not useful as gamma-ray spectrometers. However, there has been some effort investigating diamond as radiation-hard particle detectors. Te is a semiconductor, but its band gap (0.33 eV) is smaller than Ge (0.72 eV), hence such detectors would need to be operated at cryogenic temperatures, thereby offering no significant advantage over Ge detectors.

Chapter 2

Introduction to Nuclear Instrumentation

"...that a module be developed by the National Laboratories with the intent that the module will become standard in all of the National Laboratories and will be duplicated by many manufacturers."

U.S. National Bureau of Standards, 1963

Why is This Chapter Here?

In many ways this is an "orphan chapter" in that it does not discuss directly the theoretical principles or design of radiation detectors. Consequently, it could appear at the end of the book or even as an appendix. However, traditionally, courses designed to teach the principles of radiation detection and measurement usually have an associated laboratory component in which the actual detectors of various types are used to demonstrate radiation detection principles. The authors have learned that for such courses students must be introduced early to the various electronic devices they are going to use to make different radiation measurements. This early introduction is essential to minimize the many (often quite creative and destructive) ways students try to misuse the electronics to produce observable signals and measurements in the laboratory.

This chapter also serves as a historical view of how the electronics for various radiation detectors has evolved and become standardized over the past many decades. However, the reader may safely skip this chapter in the initial reading because little that follows critically depends on the information in this chapter.

2.1 Introduction

Nuclear instruments are designed to acquire and produce meaningful signals from radiation detectors. Almost all radiation detectors must have electrical power applied to them in some form or fashion and, hence, it is important to have a stable power supply.[1] Detectors that operate by producing electronic signals must have accompanying electronics that can accurately measure the magnitude of induced current or induced charge.

[1] Exceptions are detectors that use radiation to produce measurable chemical changes, e.g., photographic films, or changes in crystalline and chemical structures, e.g., color changes in crystals or material embrittlement.

Often the signal from the detector must be *shaped* and/or *amplified* so that it can be manipulated by other nuclear electronic instruments. Typically, there is also a user interface that allows one to easily interpret the data that is being accumulated or recorded. Such an interface can assume several forms, ranging from a simple analog meter up to a complex computer interface. The basic components for a radiation detection system are found in all such systems ranging from small portable hand-held devices to systems with sizes of hundreds of meters or kilometers that are used in high-energy physics experiments.

2.2 The Detector

The detector is the active element used to absorb radiation particles and subsequently produce a recognizable signal associated with each event. Detectors may rely upon measurable phenomena, such as electronic, thermal, or visual changes. Detector types are commonly categorized as gas-filled detectors, scintillation detectors, semiconductor detectors, and alternate detectors. Gas-filled detectors, as the name implies, are vessels filled with a gas, which may be under pressure or under a slight vacuum (and are covered in Chapters 9–11). Ionizing radiation interactions produce mobile charges in the gas, which, in turn, are usually identified as an induced current or voltage caused by the motion of these mobile charges. Scintillation detectors fluoresce when ionizing radiation interacts in the absorbing medium (see Chapters 13 and 14). These scintillation detectors are fashioned from solid, liquid, or gaseous materials that produce measurable light when stimulated by ionizing radiation particles. Semiconductor detectors are solid-state devices that change conductivity when radiation particles interact in the material, mainly due to the excitation of mobile charges to higher energy levels (see Chapters 15–16). Alternate detectors include devices that indicate the presence of radiation by acoustical changes, color changes, temperature changes, and variety of other phenomena (see Chapter 19).

Electronic detectors in a low-level radiation environment are usually operated in pulse mode, whereas detectors in a high radiation environment are usually operated in current mode. To understand the difference, shown in Fig. 2.1 is a common electronics arrangement for pulse mode counting. Radiation particles interacting in the detector produce an electronic signal which can be sensed and amplified by the preamplifier circuit. The signal from the preamplifier is then shaped and amplified further, where it either is rejected or accepted by discriminating electronics. Afterwards, the count rate or energy spectrum is recorded and displayed. The advantage of this method is that small currents can be converted into large voltage pulses through the pulse shaping and amplification stages. However, the entire process involves some finite amount of time, especially in the pulse processing stage, which defines the resolving (dead) time of the system. Radiation particles entering the detector at a higher rate than can be processed result in dead time losses; hence an alternate measurement method must be used when particles interact in the detector at a rate faster than the pulses can be processed.

In current mode, the current produced in a detector is directly measured with a current meter, usually by measuring the voltage across a load resistor through which the induced current flows. Unfortunately, these currents for a single ionizing event can range from tens of picoamperes to a few nanoamperes. Hence, current mode measurements are usually reserved for high radiation environments in which the signal is a result of many, nearly simultaneous, ionizing events.

Some radiation detectors must be used in pulse mode rather than current mode. For instance, the gas-filled ion chamber can be operated in either pulse mode or current mode, but other gas-filled detectors, such as Geiger-Müller counters can only be operated in pulse mode. There are many other examples that are covered in later chapters.

The detector for any single radiation measurement must be carefully chosen for the specific application. No single device can provide all of the desired aspects of a radiation detector. When selecting a detector, the operator must consider the radiation being measured (gamma-rays, neutrons, charged-particles, etc.),

the radiation exposure rate, and the information sought (energy, count rate, etc.). Some detectors are best suited for energy identification, others are best suited for high interaction efficiency, while still others may provide a more economical but satisfying result. Hence, the operator must choose a detector that provides the required information for a measurement, often from many possible sensors.

2.3 Nuclear Instrumentation

Instrumentation for the nuclear industry was specified in a 1964 report TID-20893 to the U.S. Atomic Energy Commission (now, after many reincarnations, the Department of Energy) to what are referred to as Nuclear Instrument Modules (NIM). Several revisions to the standard were submitted over the following years, eventually established in the 4th revision of 1974 (TID-20893-REV-4), with an updated version described in the 1990 report DOE/ER-0457T. The standard defines the dimensions, standard connections, and power requirements for modular nuclear electronic components, as well as the cabinet or bin into which these components are inserted. The NIM standard is a flexible and simple system that can incorporate many useful detection tools, such as amplifiers, analog-to-digital converters (ADCs), counting and timing electronics, discriminators, and power supplies. The NIM standard provides a common footprint for electronic modules (amplifiers, ADCs, discriminators, etc.), all of which plug into a larger chassis (NIM bin). This bin must supply ± 12 and ± 24 volts DC power to the modules via a backplane; the standard also specifies ± 6 V DC and 220 V or 110 V AC pins; however, not all NIM bins provide these other voltages. Shown in Fig. 2.1 is a block diagram of components commonly used in a pulse-mode counting system, and shown in Fig. 2.2 is a NIM bin with common components described in Section 2.5.

2.4 History of NIM Development

Early nuclear instruments were composed of vacuum tube circuits within a standardized 19-inch wide chassis. The components each had their own DC power supply and each connected directly to AC power. These components easily installed in standard 19-inch wide instrument racks. Hence, there was no issue with interchangeability between components, mainly because each unit operated independently.

The invention of the transistor in 1948 later allowed the electronics to be built much more compactly. Further, the overall efficiency and heat load was significantly less for transistorized components. Yet, these early transistorized nuclear instruments were built in a similar fashion as were their vacuum-tube counterparts, designed for large 19-inch wide containers. It was eventually realized, however, that these transistorized electronic components could be built as smaller and more efficient modular units, thereby eliminating the need for a single 19-inch wide chassis. Many independent laboratories and commercial companies began designing and constructing various different modular electronic component systems.

Two such systems, advanced at the time, were the systems developed by the European Organization for Nuclear Research (CERN) and the United Kingdom Atomic Energy Research Establishment. The European Standards community on Nuclear Electronics (ESONE), founded in 1961, also began working on a new standardized modular system. Along with these systems, numerous commercial companies began working on various modular nuclear electronics systems. Further, the independent U.S. national laboratories began developing modular nuclear electronics systems for their own purposes. As a result, numerous different nuclear electronics systems were under development, none of which was compatible with any of the other systems. Overall, research at nuclear laboratories was seriously limited by the compatibility of instruments, and researchers were forced to invest in numerous different modular nuclear components.

To remedy this divergent development of nuclear modules, the U.S. National Bureau of Standards (NBS),[2] in a 1963 report to the U.S. Atomic Energy Commission (AEC), recommended that the U.S. national

[2]The National Bureau of Standards is now the National Institute of Standards and Technology (NIST).

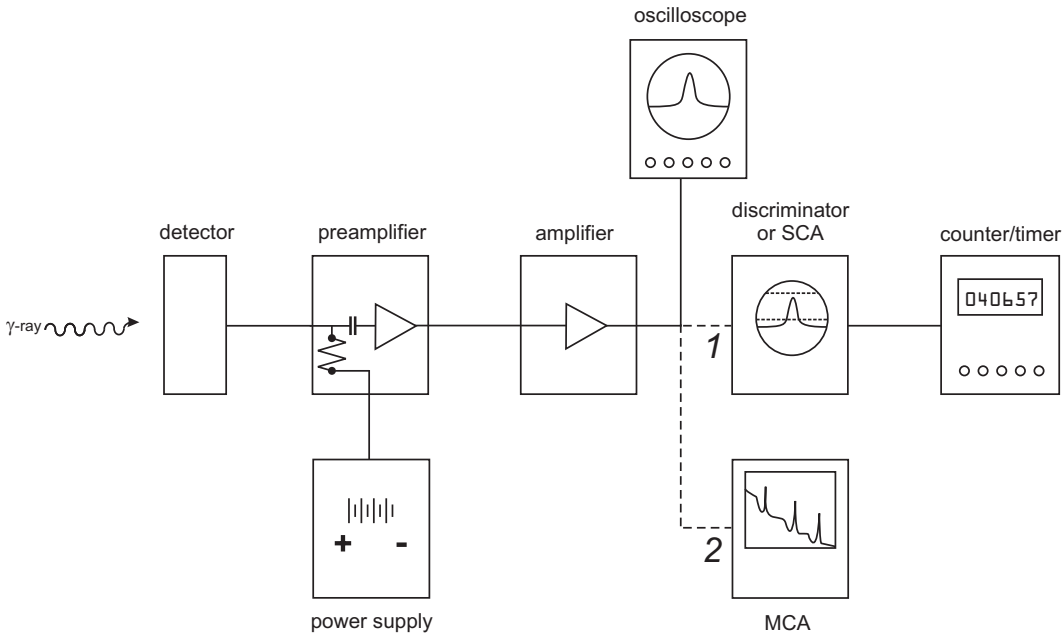

Figure 2.1. The basic components of a pulse-mode electronic detection system. A detector is powered by a bias supply or power supply usually through the preamplifier. The induced electronic signal from the detector is shaped and amplified through the preamplifier and amplifier circuits. The signal can be observed and monitored with an oscilloscope. When used as a basic counter, the shaped signal pulse is routed through a discriminator or single channel analyzer (SCA) and then into a counter/timer (route 1). When used as a spectrometer, the shaped signal pulse is routed into a multichannel analyzer (MCA) in which the pulse amplitudes are sorted and categorized according to the pulse heights (route 2).

laboratories develop a modular system to be duplicated by commercial manufacturers. The U.S. AEC convened a meeting of representatives from several national laboratories on Feb. 26, 1964 to determine if such a task was of interest to the laboratories. In agreement, the AEC Committee on Nuclear Instrument Modules was established, composed of members from all AEC national laboratories and a few other prominent nuclear laboratories.

The first NIM Committee meeting was held on March 17, 1964, with follow-up meetings over several ensuing months. The committee studied the advantages and shortcomings of the existing modular systems, and a system similar to the CERN design was eventually developed. The prototype bins were manufactured by Oak Ridge National Laboratory (ORNL), Lawrence Radiation Laboratory in Berkeley and Lawrence Radiation Laboratory in Livermore.[3] These early prototypes were studied at later meetings of the NIM Committee, eventually leading to a recommended design. Final details were resolved by the NIM Executive Committee with representatives from the U.S. NBS, ORNL, Lawrence Radiation Laboratory in Berkeley, and with later added members from Princeton-Pennsylvania Accelerator and Brookhaven National Laboratory (BNL). The final specifications were published in July 1964, and later updated versions of the specifications were published in 1966, 1968, 1969, and 1974. The standard was well received, with the first commercial NIM components being available by November 1964. During 1965, numerous more NIM instruments became

[3]The Lawrence Radiation Laboratory in Berkeley is now the Lawrence-Berkeley National Laboratory and the Lawrence Radiation Laboratory in Livermore is now the Lawrence-Livermore National Laboratory.

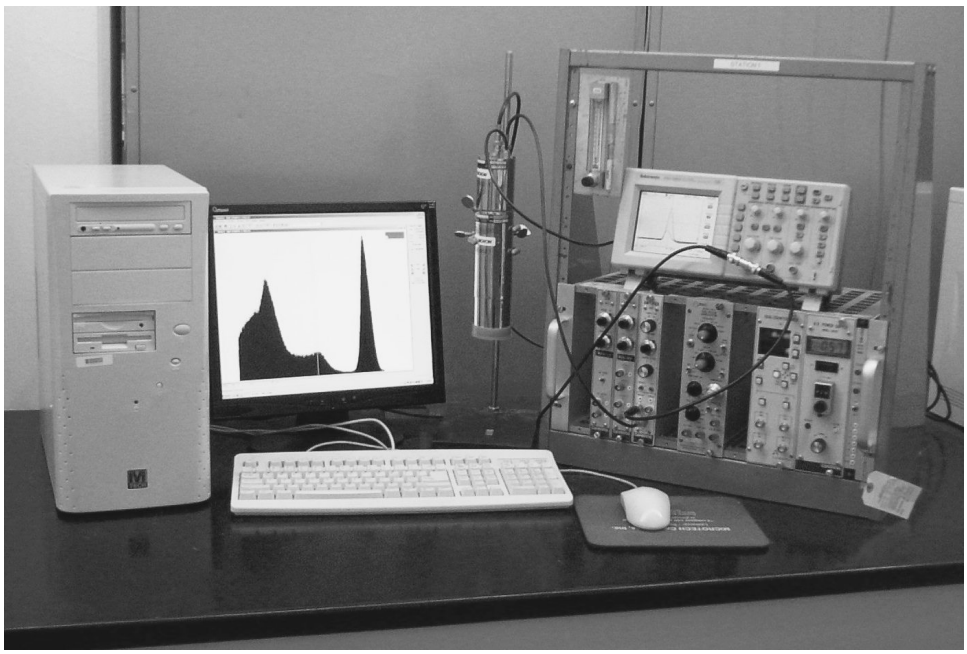

Figure 2.2. A typical measurement system in which various NIM components are installed into a NIM bin shown to the right. This NIM bin contains several nuclear instrument modules, including a power supply, a pulser, an amplifier, an SCA, and a counter/timer. The detector, to the left of the NIM bin, is a NaI:Tl device with the preamplifier attached to the detector back. The system is also attached to an oscilloscope, shown on top of the NIM bin. The detector is also connected to a computer-based MCA, which shows a spectrum of ^{137}Cs gamma rays on the monitor, behind the keyboard. The ^{137}Cs gamma ray check source is located directly beneath the NaI:Tl detector.

available, and NIM components accounted for over 95% of all modular nuclear instruments produced in the U.S. in the immediate years following 1967. The NIM standard was again revised in 1990, to make the standard compatible with existent technology and manufacturing processes, as described in Department of Energy (DOE) document DOE/ER-0457T.

2.5 NIM Components

Commercial manufacturers offer a variety of NIM components for radiation detection applications. Many of these modules are versatile and can be used for general radiation counting applications. There are also special NIM modules optimized for narrowly applied or special applications. Overall, the list of common NIM components include a NIM bin and power supply, a detector voltage supply, preamplifier, amplifier, discriminator, counter, timer, and often a data analyzer. Described in the following sections are the basic properties of these components. Further details on the design and operation of NIM components and other nuclear electronics can be found in Chapter 22.

2.5.1 The NIM Bin

The container for NIM components is traditionally referred to as a NIM bin. The NIM bin is used as the power supply docking port for most NIM components, except for a few high voltage power supplies that

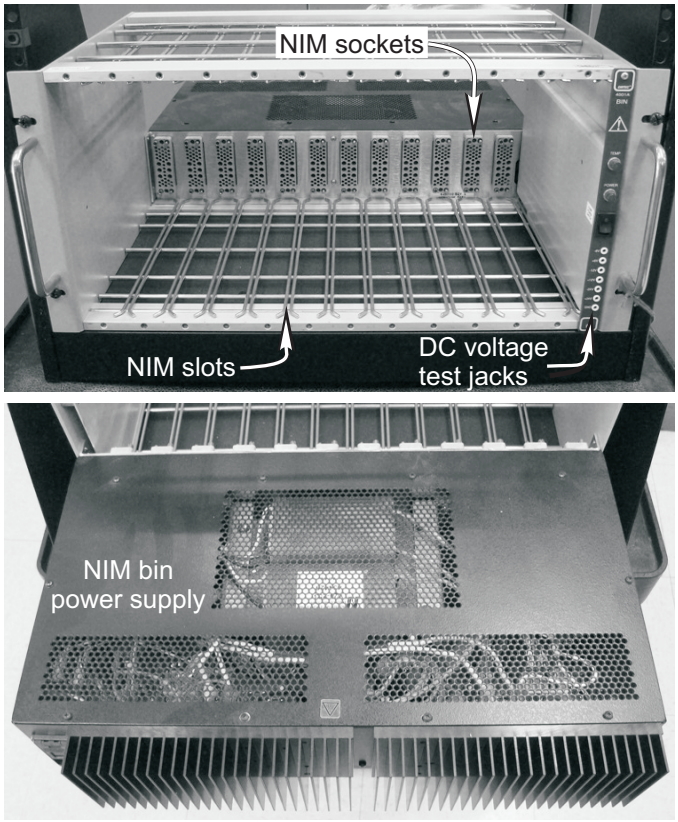

Figure 2.3. (top) Front view of a NIM bin, showing the NIM slots and power sockets. (bottom) Back view of a NIM bin, showing the power supply.

plug directly into a 120 VAC wall socket. The most common NIM bin size, shown in Fig. 2.3, has space for 12 single-width NIM components, as specified by DOE/ER-0457T. There are also more compact NIM bins with only 4 single width slots. These smaller NIM bins are typically used for portable measurement situations that require only a few NIM instruments. A power supply is placed behind the instrument slots in a NIM bin. This unit provides ±6 volts DC, ±12 volts DC, and ±24 volts DC to the NIM sockets and voltage jacks,[4] as well as 117 volts AC. Power is commonly rated between 150–160 W for the larger power supplies, although lower power models rated at ∼95 W are available (usually for models that do not offer the ±6 volt DC option). The NIM bin sockets and pin assignments conform to the specifications outlined in DOE/ER-0457T. Test jacks in the front of the NIM bin provide convenient access to monitor the DC voltage, and can also be used to conveniently supply power to custom electronics. Modern power supplies are filtered from electromagnetic interference (EMI), are short-circuit proofed, thermally protected, and provide stable power required for NIM components. Usually NIM bins have warning indicators that inform the operator if the power supply is approaching the temperature limit.

2.5.2 Detector Power Supplies

Detectors that operate with the NIM system typically produce an electronic output and, therefore, require a power supply of their own. Traditionally, the majority of such NIM power supplies for detectors apply a high voltage to the detectors.[5] Stability of the supply voltage is of particular importance in high-resolution measurements systems. High-voltage power supplies are used to operate detectors that do not suffer changes in capacitance as a function of voltage, such as gas-filled and scintillation detectors. High-voltage bias supplies are usually used for semiconductor detectors, in which the operating voltage can affect the detector capacitance.

High Voltage Power Supply

The high voltage power supply, as the name implies, supplies high voltage to the detection device, and can supply it with either positive or negative polarity. Typically, the voltage is applied to the detector

[4] Some models provide only ±12 VDC and ±24 VDC.

[5] Recently, there has been a move toward special detector systems based on semiconductor photon detectors that operate on lower voltages. These detectors, such as avalanche photodiodes, are discussed in Chapter 14.

Figure 2.4. (left) A common all-purpose HV power supply used for gas-filled and scintillation detectors. (right) A dual source DC bias supply used for smaller semiconductor detectors, such as silicon surface barrier detectors.

across a load resistor with the connection routed through the preamplifier unit. Also, a power supply often has a meter indicating the applied voltage, which is reasonably accurate because the detector resistance is typically much greater than the preamplifier load resistance. HV power supplies are available with the maximum voltages exceeding 3.5 kV. Because PMTs and gas-filled devices need relatively high power, a HV power supply is plugged directly into a wall socket, although many models have rails that allow the power supply to slip into a NIM bin for convenience. A HV power supply is shown in the left-hand side of Fig. 2.4.

High Voltage Bias Supply

For semiconductor detectors, the power supply is generally referred to as a "bias supply." As with a HV power supply, the bias supply provides a choice of positive or negative high voltage to the detector. However, this power supply does not have a meter, but rather only a dial indicator for the total applied voltage to the system.

Because the system includes load resistances in series with the detector, there is a voltage drop across this resistance, which reduces that applied to the detector. Thus, a meter indicating total voltage would be misleading. Instead jacks are provided that allow determination of the bias current. Because the series load resistance is known, the voltage applied to the detector, which is less than the total, can also be determined. Bias supplies are available for which the maximum allowable voltages can exceed 5 kV. Because typical

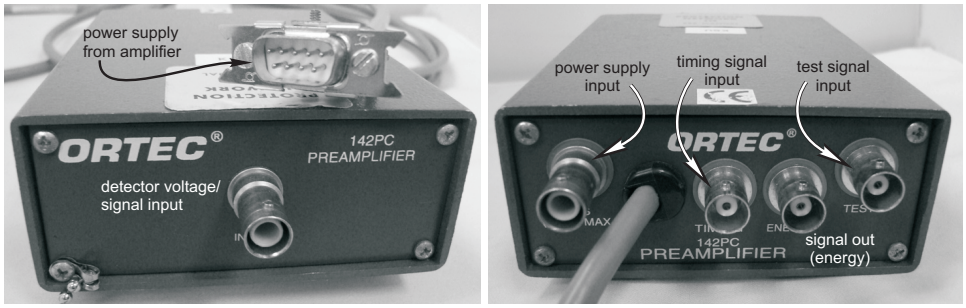

Figure 2.5. (left) Front view of a common charge-sensitive preamplifier, showing the safe high voltage (SHV) connector for the detector and the nine pin D-subminiature connector for the preamplifier power. (right) Back view of a the same charge-sensitive preamplifier, showing the connector terminals for the power supply, pulser input, timing input, and the output signal.

detectors are highly resistive and draw little current, the power requirement of the bias supply is low and, consequently, most bias supplies are plugged directly into the NIM bus for power, unlike the HV power supply. A HV bias NIM module is shown in the right-hand side of Fig. 2.4.

2.5.3 Preamplifier

A preamplifier unit has two basic purposes, namely (1) to provide low noise coupling of the detector to the string of amplifier and readout electronics, and (2) to produce a first stage of signal amplification. The preamplifier thus acts as a filter against objectionable line noise that may alter the input signal. Preamplifiers are designed to be either current sensitive, voltage sensitive, or charge sensitive. Optimum detector performance is obtained when the user selects the proper preamplifier matched to the type and characteristics of the detector and the analysis electronics. The general application of these preamplifiers are described here, with details on the design and operation reserved for Chapter 22.

Voltage-Sensitive Preamplifiers

Voltage-sensitive preamplifiers are so named because they tend to respond to and linearly amplify the voltage input from the detector into the preamplifier circuit. As discussed in Chapter 8, the voltage input V_{in} into the preamplifier from the detector is generally an inverse function of the detector capacitance, $V_{in} \approx Q_i/C_d$, where Q_i is the charge induced by the motion of electrons and ions excited in the detector by a radiation interaction event and C_d is the combined capacitance of the detector and coupling cables. The preamplifier output is usually defined by the feedback resistors, where for a typical inverting configuration $V_{out} \approx -(R_f/R_L)V_{in}$, where R_f is the feedback resistance and R_L is the input load resistance.

For many detectors, the capacitance remains constant for different applied operating voltages V_o; hence the preamplifier output V_{out} is mostly linear with respect to the charge excited in the detector regardless of the voltage applied to the detector. Examples include gas-filled detectors and scintillation detectors that are coupled to photo-multiplier tubes.

Charge-Sensitive Preamplifiers

There are some detectors that change capacitance as voltage is applied, particularly semiconductor diode detectors. These semiconductor detectors have active regions that increase with applied operating voltage, which, in turn, causes the capacitance C_d to decrease with increasing voltage. As a result, the preamplifier output changes with a varying operating voltage for identical induced charge Q_i. By redesigning the preamplifier feedback circuit, the capacitive component of the detector C_d can be minimized compared to

the feedback capacitance C_f of the preamplifier, thereby, effectively rendering the preamplifier output almost entirely dependent upon the induced charge Q_i. Hence, for semiconductor diode detectors, the voltage output V_{out} is largely dependent only upon the induced charge Q_i and feedback capacitance C_f, where $V_{out} \approx -AV_{in} \approx -Q_i/C_f$, where A is the preamplifier gain. Commercial charge sensitive preamplifiers are designed for optimum performance when matched to specific ranges of detector capacitance. Hence, it is advised that the user consult the preamplifier specification sheets to properly match detectors to preamplifiers. A common commercial charge sensitive preamplifier is shown in Fig. 2.5.

Current-Sensitive Preamplifiers

As the name implies, a current-sensitive preamplifier is designed to measure the instantaneous current flowing from a detector. The configuration is seldom used for most detector applications; however, on rare occasions a preamplifier with a fast rise time for timing applications is needed, and a current sensitive preamplifier is required. The current sensitive configuration requires that the input impedance be low and the preamplifier gain A be large. These conditions can be realized by using the general design of a voltage sensitive preamplifier and reducing the load resistance at the input of the preamplifier. Note that the *Johnson noise*[6] can be high unless the feedback resistor in the preamplifier circuit is $R_f \geq 10^9\ \Omega$. If the preamplifier input impedance is $50\ \Omega$, the current sensitive preamplifier will convert the input current I_{in} to an output voltage V_{out} described by $V_{out} = I_{in}(50\Omega)$ A.

2.5.4 Amplifier

The amplifier unit has two main purposes, namely, (1) pulse shaping and (2) pulse height amplification. The pulse at the output of the preamplifier typically has a fast rise time with a slower falling tail with the timing characteristics determined by the leading and trailing time constants. This pulse is then integrated and shaped by the amplifier to provide a Gaussian-like pulse that is far easier to manipulate with counting electronics that are placed further down in the pulse processing system. The amplifier, depending on its design, may allow the user to change rise times, decay times, and pulse width. Further, the gain on an amplifier has both course and fine adjustments, important features needed when calibrating the system. Lastly, the NIM standard allows for a 10-volt maximum output from the amplifier, i.e., any pulses whose amplitude is larger than 10 volts is "clipped" at 10 volts. Hence, it is wise to adjust the amplifier gain so that the largest expected output pulses are less than 10 volts; otherwise, the clipped signal may not be recognized or counted.

2.5.5 Oscilloscope

Although an oscilloscope is not part of the NIM system of instruments, it is a fundamental and important piece of equipment with which all NIM users should become familiar. The oscilloscope allows the user to determine how the system is manipulating the electronic pulses at every stage of the system by simply hooking into that portion of the pulse processing system with a "tee" connector. It can be used to measure pulse heights, pulse widths, repetition rates, pulse symmetry and variety of other values that allow for trouble-shooting and system calibration.

2.5.6 Pulse Discriminators

A simple discriminator is used to reject pulses outside set pulse-amplitude boundaries, thereby passing only pulses of certain voltages that are of interest. The electronic pulses emerging from the amplifier are indicative of the amount of energy deposited within the detector, typically linear with energy in well-designed systems. Hence, once calibrated, the final signal pulse height is a measure of the energy absorbed in the detector.

[6] Johnson noise is the electronic noise generated by the thermal agitation of the charge carriers inside an electrical conductor.

The discriminator allows the user to select a voltage at a lower level discriminator (LLD) threshold, below which pulses are rejected. In older discriminators, any signal above the LLD is passed. However, some newer systems reject pulses that exceed the 10-volt upper limit. Often a "discriminator" unit has only an LLD, whereas the single channel analyzer (SCA) has both an LLD and an upper level discriminator (ULD). The ULD rejects signal pulses that exceed the set threshold. Hence, the SCA allows the user to pick a voltage region (or energy region) of interest defined by lower and upper energy thresholds, and pass only those signal pulses that fall within those boundaries.

2.5.7 Counter/Timer

Voltage pulses that pass through the discriminator or SCA are usually routed to a counter/timer. The function of the counter/timer is to record the number of radiation induced pulses within a predetermined amount of time. Hence, a count rate from a radiation source can be determined. Most counter/timers can be set to automatically count for a preset amount of time and stop so as to reveal the number of pulses or counts obtained within that time period. Conversely, they can be set to record a certain number of counts and stop when that limit is obtained to reveal the time required for the measurement. Counter/timers are common instruments used for radiation measurement and dosimetry.

2.5.8 Pulse Generator

A valuable piece of equipment that assists with calibration of the radiation counting system is the pulse generator, and is commonly referred to as a *pulser*. Pulsers provide accurate voltage test pulses into the radiation detection system. The pulses can be set to have different shapes (tail pulse being the most common), decay times, pulse frequencies, and amplitudes in order to calibrate the amplifier, MCA, SCA, or counter/timers. The test pulses can also be used to help determine system dead times and system electronic noise. Although not necessary to operate a radiation counting system, they are quite valuable when first configuring the system and calibrating it for radiation measurements. Further, it is typical that a pulser be operating during spectroscopic radiation measurements in order to have a comparison peak for system noise determination. Typically the pulser peak is set to an MCA channel that does not interfere with the accumulated radiation spectrum.

2.5.9 Coincidence Modules

There are many applications that require the measurement of events that occur in two separate detectors within a given time interval Δt. Examples include identifying the simultaneous arrival of photon-photon or photon-particle events, positron lifetime studies, decay scheme studies. Such measurements are commonly referred to as *coincidence measurements*. By contrast there are some measurements that require the opposite condition, i.e., when two radiation events are recorded within Δt are rejected. Such measurements are referred to as *anti-coincidence* measurements. Regardless, the main function of a coincidence module is to discern the arrival of two or more radiation particles in separate detectors within some preset time interval Δt.

In practice it is not possible to analyze coincidence events with 100% confidence due to the uncertainties associated with the statistical nature of radiation emissions. Statistical timing errors may occur from the detection process and uncertainties in the electronics resulting from timing jitter, amplitude walk, and noise, all of which lead to statistically variable time delays between processed events. A simple coincidence circuit solves this problem by essentially summing the two input pulses, passing the resultant sum pulse through a discriminator level, and generating an output pulse when the two input pulses overlap.

The period of time in which the two input pulses can be accepted is defined as the coincidence resolving time, and is determined by the width of the pulses, τ, such that the resolving time is equal to 2τ. A coincidence analyzer produces a logic pulse output when the input pulses, on the active inputs, occur within

the resolving time window selected on the front panel. Because detector events occur at random times, accidental coincidences can occur between two pulses which produce background in the coincidence counting. The rate of accidental or random coincidences r_R is given by

$$r_R = r_1 r_2 (2\tau), \tag{2.1}$$

where r_1 and r_2 are the count rates observed by the two detectors.

The number of counts in the detectors depends upon the experiment and the detectors, so the best way to reduce accidental coincidences is to make the resolving time as small as possible. However, the resolving time cannot be reduced below the amount of time jitter in the detector pulses without losing true coincidences, so the type of detector determines the minimum useful resolving time.

2.5.10 Time-to-Amplitude Converters

There are some radiation measurements in which the time interval between two separate events is sought. A time-to-amplitude converter (TAC) measures the time delay between two events Δt and converts it into a voltage output between 0–10 volts. The magnitude of the output voltage is linearly proportional to Δt. These pulses can be displayed as a pulse height spectrum, thereby yielding the average delay and the timing resolution defined as the full width at half maximum (FWHM) of the pulse height spectrum.

2.5.11 Analog-to-Digital Converters

An analog-to-digital converter (ADC) generates a digital "word" proportional to the amplitude of an input pulse. In nuclear applications, ADCs are used to digitize the output signals from spectroscopy amplifiers. Because these amplifiers generate output pulses whose amplitudes are directly proportional to the energies of the incident radiation, the ADC can be used with an amplifier and a multichannel analyzer (MCA) to generate energy distributions (spectra) of the radiation emitted by radioactive samples.

2.5.12 Photomultiplier Tube Base

The photomultiplier tube (PMT) base is a separate electronic unit and not a NIM bin module and is used to supply voltage to a PMT. PMTs are vacuum tubes commonly coupled to a scintillating detection medium, which might be a solid, liquid, or gas. Scintillation light excited by radiation absorbed in the scintillator detector may strike the photosensitive cathode of the PMT and eject an electron into the tube. Beyond the light sensitive cathode, a series of metal plates or meshes, called dynodes, are biased with voltage in order to attract and accelerate electrons. These electrons strike the dynode and knock off more secondary electrons than were incident on the dynode, thereby amplifying the signal that increases with the number of dynodes in the PMT. The PMT base divides the applied voltage evenly among these dynodes, with ten stage dividers being common amongst commercial vendors. The output of the PMT base can be coupled to a preamplifier or, in some models, the preamplifier may be incorporated within the PMT base. Some PMT bases allow adjustment of the gain and applied bias in order to achieve optimal detector performance.

2.5.13 Multichannel Analyzer

The multichannel analyzer (MCA) measures the pulse heights emerging from the amplifier with high precision for many pulses, one after the other, and creates a histogram of small voltage intervals or bins along the abscissa (x-axis) and number of observed pulse heights within each interval along the ordinate (y-axis). In the NIM standard the maximum pulse height is 10 volts so the amplifier gain must be set so that no pulse heights of interest exceed this limit. The voltage measurement is made with a quick analog-to-digital converter and the subsequent manipulation and storage is today done with conventional computer code and memory. Because the underlying analog-to-digital converters and computer hardware are binary, the

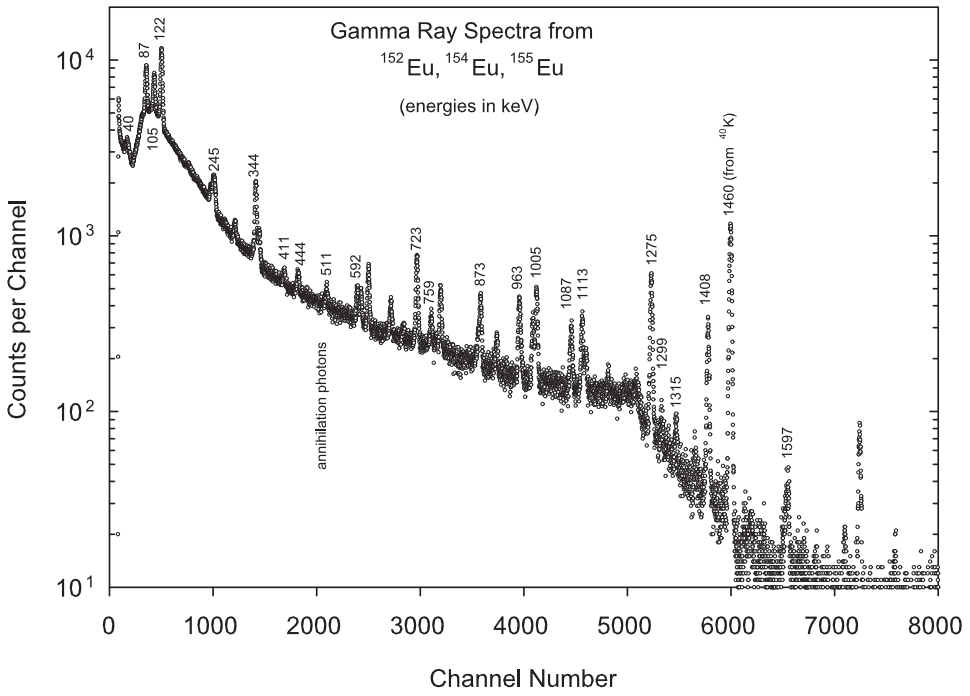

Figure 2.6. Differential pulse height spectrum of gamma rays emitted by the radioactive decay of ^{152}Eu, ^{154}Eu, and ^{155}Eu as measured by a high purity germanium (HPGe) semiconductor detector.

first MCAs divided the ten-volt span into a selectable number of bins that are increasing powers of 2 and this approach is still used. The bins are called channels that range from as low as 128 in number to 4096 or even more. For typical scintillation or gas filled detectors 1024 or 2048 channels are sufficient, but for higher resolution semiconductor detectors pulses are typically collected in 4096 or 8192 bins. The *pulse height spectrum* that is formed from radiation induced pulses forms a histogram on the MCA output display, usually a computer screen. The histogram represents the voltage distribution of pulse height amplitudes provided by the detector, where the voltage pulses are linearly related to the radiation energy absorbed by the detector for each event. Hence, the pulse height spectrum is a relative measure of the spectroscopic energy distribution absorbed in the detector. Overall, the MCA performs the function of numerous SCAs in series as well as a counter/timer. Modern MCAs can be set with over 16000 channels spread over 10 volts, a requirement for radiation spectroscopy applications with ultra-high resolution. Shown in Fig. 2.6 is a MCA differential pulse height spectrum of a mixed Eu source (^{152}Eu, ^{154}Eu,^{155}Eu) as taken with a high purity Ge (HPGe) detector. Details of various types of MCAs are reserved for Chapter 22.

2.5.14 Other NIM Components

Although the main NIM (or CAMAC) components commonly used in a detecting system are listed above, there are many other NIM components that can be used for special counting purposes. Such units include timing modules, coincidence modules, delay lines, time-to-amplitude converters (TAC), and analog-to-digital converters. There are also many variations of those NIM components discussed in the previous sections. The user should consult the specifications regarding the NIM components to determine which modules are best suited for the experiments or measurements to be made.

2.6 CAMAC

For more complex detection systems, as may be encountered at large research facilities and high-energy accelerator centers, there is another international standard for modularized electronics, namely, Computer Automated Measurement And Control (CAMAC), which defines a standard bus for data acquisition and control. The interface system, upon which this standard is based, was developed by the ESONE Committee of European Laboratories with the collaboration of the NIM Committee of the US Department of Energy (DOE) [ESONE, 1964; CAMAC, 1972]. This standard is based on ERDA Reports TID-25875, July 1972 (corresponding to ESONE Report EUR 4100e) and TID-25877. The standard defines the mechanical construction and electrical dataway for the modules. The CAMAC also includes the IEEE standards of 583 (the basic CAMAC design), 595 (serial highway system), 596 (parallel branch highway system), 675 (auxiliary crate controller), 683 (block transfer specifications), 726 (real-time BASIC computer language) and 758 (FORTRAN computer language subroutines for CAMAC).

The container for instrumentation modules is referred to as a 'crate' or 'CAMAC crate.' The CAMAC bus allows data exchange between plug-in modules (up to 24 in a single crate) and a crate controller, which then interfaces to a PC or to a VME-CAMAC interface. The original standard was capable of one 24-bit data transfer every μs. Later a revision to the standard was released to support shorter cycles which allow a datum transfer every 450 ns. A follow-up on upwardly compatible standard Fast CAMAC allows the crate cycle time to be tuned to the capabilities of the modules in each slot. Typically, CAMAC components are significantly more costly than NIM components, and are best used when computer automation is necessary. Regardless of the standard, both NIM and CAMAC systems use basic components to operate and manipulate data from radiation detectors.

2.7 Nuclear Instruments other than NIM or CAMAC

Although NIM electronics are popular and still in widespread use, most of the systems that use NIM electronics are not considered portable. However, there are integrated components available as handheld or totable instruments. Many of these instruments, or survey meters, consist of a battery-operated unit with a detachable detector (see Fig. 2.7). The monitoring unit may have an analog or digital display that conveys information regarding the radiation exposure or the energy signature, and often has a dial selectable radiation exposure range feature.

Portable instrumentation is available for gas-filled, scintillation, and semiconductor detectors, and range in complexity from simple radiation counters to cryogenically cooled high-resolution energy spectrometers. Some relatively new instrumentation that has become available include miniature Geiger-Müller counters the size of key-chain holders, compact solid state VLSI[7] detector packages, to sophisticated 3-dimensional imaging devices capable of identifying radioactive sources by energy and location.

Although these devices may have special operating electronics and features, the same basic pulse processing and signal recognition electronics described available for NIM components are usually a part of the detector package. For instance, a handheld rate meter will typically have a power supply, amplification and shaping, pulse discrimination, and a visual output much like a NIM system, but instead in a compact handheld platform. Some examples of these systems are presented in many of the following chapters on detectors.

2.8 Cables and Connectors

The proper choice of cables and connectors used with nuclear instrumentation is influenced by signal velocity, instrument impedance, operation temperature, radiation environment, and mechanical environment.

[7] Very large scale integration.

Figure 2.7. Two commercial handheld portable gas-filled detectors. The detector on the left is an ion chamber manufactured by Eberline, and the detector on the right is a Geiger-Müller counter attached to a rate meter, both manufactured by Ludlum.

Although numerous variations exist, there are a few standard choices for cables and connectors used in the nuclear industry. Briefly described here are some of those choices. For a more detailed discussion on cables and connectors for nuclear measurements, the reader is referred to Chapter 22.

2.8.1 Cables

Signal transmission of voltage pulses is most often done with coaxial cables. Such cables have a central conductor, around which is an insulating dielectric material. A second conducting layer is wrapped around the dielectric, over which a protective insulator is often applied. Common dielectric materials include polyethylene and Teflon^{TM}. For special radiation environments, cables with mineral dielectrics may be a wise choice.

The propagation speed v of a signal in a cable is dependent upon the dielectric and magnetic properties of the internal insulating materials separating the central conductor from the outer conductor, and is given by

$$v = \frac{1}{\sqrt{\mu\epsilon}} = \frac{1}{\sqrt{\mu_r\epsilon_r\epsilon_0\mu_0}} = \frac{c}{\sqrt{\mu_r\epsilon_r}}, \tag{2.2}$$

where ϵ_r is the relative permittivity, μ_r is the relative permeability and, by definition, $\epsilon_0\mu_0 = c^{-2}$. Most often, $\mu_r \approx 1$, hence the wave propagation speed becomes primarily dependent upon the relative permittivity. Electric waves propagate as transverse electro-magnetic (TEM) waves, meaning that the electrical and magnetic fields are perpendicular to the direction of wave propagation. At some "cutoff" frequency, other modes can propagate, those being transverse magnetic (TM) and transverse electric (TE), which do not

necessarily travel at the same wave velocity, thereby potentially causing undesirable interference. Hence, it is best to operate within the specified bandwidth of the cable.

Historically, conductor investigations indicated that wave attenuation is minimum at characteristic impedances of 77 ohms, the breakdown voltage is greatest at 60 ohms and the power-carrying capacity is maximized at 30 ohms. The widespread use of 75 ohm and 50 ohm cables comes from a compromise of these properties. "Radio Guide" (RG) cable is named from the defunct military specification for cable identification, but is commercially still in common use. RG cables have typical characteristic impedances between 50 and 93 ohms. A table of values for various cables can be found in Chapter 22.

Finally, the perils of mixing connectors that are mechanically different is fairly obvious while mixing cables of components of different impedances is more subtle, but can be equally problematic.

2.8.2 Delay Lines

Under some circumstances it is necessary to delay the signal from a detector before it enters the analyzing electronics. For instance, a coincidence measurement may be desired for two different types of detectors, but the signal processing times are different for the two devices. A delay line can be used to retard the progression of the faster signal, thereby allowing coincident events to arrive at the same time. A simple delay line consists of a long coaxial cable where the propagation time per unit length of cable is

$$t_d = \frac{1}{v} = \frac{\sqrt{\mu_r \epsilon_r}}{c} = \sqrt{\frac{LC}{d^2}}, \tag{2.3}$$

where d is the cable length, L is the cable inductance, and C cable capacitance. For typical coaxial cables that have polyethylene as the insulating filling ($\epsilon_r \simeq 2.25$), the delay time is approximately 5 nanoseconds per meter. There are special cables designed as delay lines that have spiral conductors to increase the time delay per unit length, thereby shortening the required cable.

Delay lines not only cause a delay in the arrival time of a signal, but also can attenuate the signal as it travels down the cable. If the delay line is purposely shorted at the output terminal, then the signal can be reflected back, inverted in form, towards the input terminal. As a result, the combined attenuation and reflection of the original signal can be used to alter the final output electronic signal to a desirable outcome, referred to as single delay line pulse shaping. The method is discussed in more detail in Chapter 22.

2.8.3 Connectors

Bayonet Neill-Concelman connectors, most often referred to as BNC connectors, are quick disconnect RF connectors designed for use with coaxial cables (see Fig. 2.8). Cables commonly used with BNC connectors for nuclear measurements are RG-58 and RG-59. BNC connectors can be acquired with a characteristic impedance of 50 ohms or 75 ohms, where it is important to match the impedance of the connector to that of cable impedance to minimize signal reflection. Although typically rated for voltage applications below 500 V, some BNC connectors can be acquired with ratings up to 900 V.

Miniature High Voltage (MHV) connectors are RF connectors for coaxial cable (see Fig. 2.9). They have a similar appearance to BNC connectors, except that the insulation around the male pin protrudes slightly out of the MHV connector, whereas the insulation around the male pin of a BNC connector does not. BNC and MHV connectors do not match. MHV and BNC connectors are not interchangeable, and damage could occur if a BNC connector is mated to a MHV connector.[8]

MHV connectors have potential ratings up to 5000 V DC at 3 A. MHV connectors were at one time popular for detectors requiring applied voltages exceeding that of BNC specifications. Although still in

[8] One author discovered the aftermath of a student's amazing feat of forcing a male MHV connector onto a female BNC connector, a result that rivals spot welding as a process to permanently fuse electrical connectors together.

Figure 2.8. Male and Female BNC connectors.

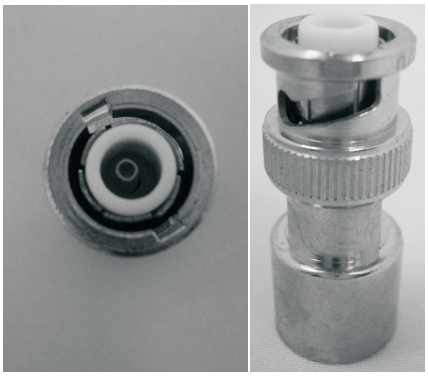

Figure 2.9. Male MHV connectors. Notice the slight insulator protrusion.

use, a MHV connector has design issues, namely, a user can be exposed to ungrounded high voltage during disconnection; hence, SHV connectors (discussed below) have largely displaced the once popular MHV connectors.

Safe High Voltage (SHV) connectors are RF connectors designed for use with coaxial cables. Similar in design to a BNC and/or an MHV connector, the male SHV connector has the distinctive feature of a shielded insulator protruding significantly from the connector body (see Fig. 2.10). The protruding insulator on a male SHV connector remedies the safety issues of an MHV connector by preventing contact with the high voltage conductor. Further, the design eliminates the chance of mismatching a high voltage line to a low voltage connector, as can happen by misidentifying an MHV as a BNC. Most SHV connectors are rated for 5000 V and 5 A.

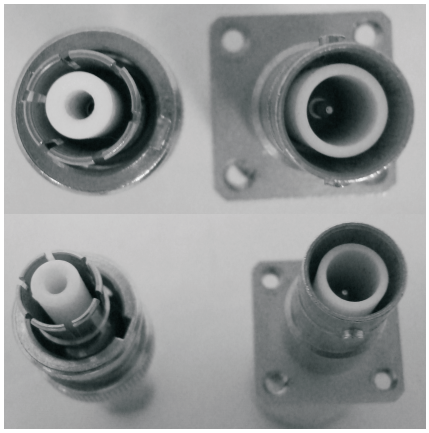

Figure 2.10. Male (left) and female (right) SHV connectors.

Figure 2.11. Female (left) and male (right) N-type connectors, showing (top) 75 Ω and (bottom) 50 Ω variants.

The "N" connector, named after Paul Neill of Bell Laboratories, is a weatherproof RF connector for use with coaxial cables (see Fig. 2.11). The connector is somewhat rugged with a threaded system rather than a bayonet connection system. N connectors can be used with RG-8, RG-58, RG-141, and RG-225 cables. N connectors come in 50 ohm and 75 ohm variants, and are typically rated for 1000–1500 V. In general, 50 ohm and 75 ohm variants are not interchangeable, and damage can occur if a 50 ohm N connector is mated to a 75 ohm N connector.

The "C" connector, presumably named after inventor Carl Concelman of Amphenol Corp., is a bayonet style RF connector that resembles that of a BNC connector, but is considerably larger in size (see Figs. 2.12 and 2.13). C connectors are relatively weatherproof and are often employed with portable survey instrumentation. C connectors have either 50 ohm or 75 ohm impedance, and are typically rated up to 1500 V and 2 A. The actual insulator resistance is greater than 5 GΩ. C-type 50 ohm connectors can be used with 75 ohm cable with little loss at frequencies below 300 MHz. The recommended operating temperature range is between −65°C and 165°C.

The High-Voltage N-Type (HN) connectors are threaded weatherproof coaxial connectors designed to withstand temperature and mechanical stresses. The connectors typically are designed with a characteristic impedance of 50 ohms with a voltage rating of 1500 V. Operational temperature range is −65°C to +165°C. HN connectors are often employed with detector instrumentation used for nuclear reactor power monitoring.

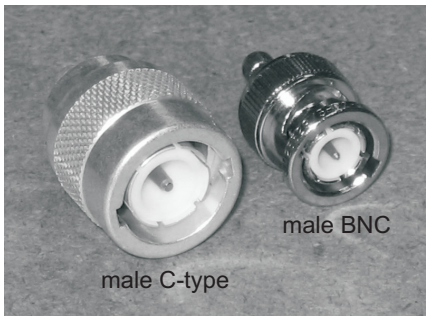

Figure 2.12. Comparison of a C-type connector with a BNC connector.

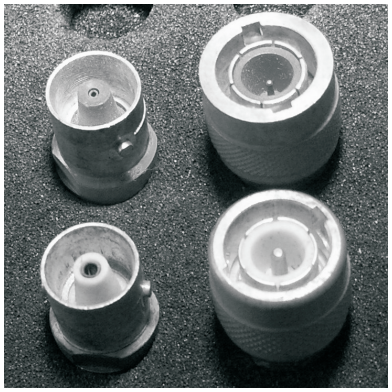

Figure 2.13. Female and male C-type connectors, showing (top) 75 Ω and (bottom) 50 Ω variants.

LEMO connectors, named after company founder Léon Mouttet, are push-pull miniature coaxial connectors with significantly smaller diameters than BNC or other common coaxial connectors. These compact connectors can be employed for instrumentation where little space is available for multiple connectors. The 50 ohm LEMO 00 series connectors are rated at voltages above 2000 V with limit of 4 A, and they are often used in conjunction with NIM and CAMAC instrumentation.

PROBLEMS

1. Explain the purpose behind implementing the NIM system.

2. Common RG-58/U cable has a characteristic impedance of 50 ohms per meter and characteristic capacitance of 93.5 pF per meter. Calculate the length of cable required to delay a signal by 0.5 microseconds.

3. What is the upper limit for signal voltage in a NIM system? What happens if a signal greater than the limit passes into a NIM component such as a SCA?

4. If the standard for the upper limit for signal voltage were 10 mV, rather than the 10 V of the NIM standard, then only a preamplifier would be necessary to provided any needed signal amplification and, thus, would eliminate the need for an additional amplifier. Why is this low voltage limit not a good idea?

5. What is the voltage width of each bin in a MCA with (a) 128 channels and with (b) 4096 channels?

6. Although Oliver Heaviside invented and patented the coaxial cable in 1880, almost all early work on the development of radiation detectors and the important atomic-level discoveries in the first half of the twentieth century, simply used wires (often bare!) for making electrical connections. So why are coaxial cables so important in today's detector techology?

7. Today with ultra-large-scale integrated circuits, tens of billions of electronic components can be placed on a small chip of silicon. Indeed a complete PC, no larger than the tip of a finger, has been fabricated. Why have electronics for radiation detectors not experienced a similar revolutionary reduction in size?

Chapter 3

Basic Atomic and Nuclear Physics

I claim that relativity and the rest of modern physics is not complicated. It can be explained very simply. It is only unusual or, put another way, it is contrary to common sense.

Edward Teller

The main topic of this book is radiation detection and measurement; however, in order to understand the principles involved in this discipline it is necessary to comprehend the basic ideas of *modern* physics upon which these principles are based. It is not the intent in this and the next few chapters to present a detailed derivation of the many topics addressed by atomic and nuclear physics. Rather, several topics important for radiation detection are reviewed. Such a review does not go into great detail about the derivation of the results, mainly because there are many excellent and thorough treatments already published such as books by Kaplan [1962], Evans [1955], and Griffiths [2004, 2005]. It should also be noted that much of the material in this and the next chapter have been extracted from Shultis and Faw [2008].

In this chapter, the important concepts of special relativity, wave-particle duality, and quantum mechanics are reviewed. Then brief descriptions of the constituents of matter, atomic and nuclear models and the energetics of nuclear interactions are provided. Finally, a review of radioactivity and its dynamics are discussed.

3.1 Modern Physics Concepts

During the first three decades of the twentieth century, our understanding of the physical universe underwent tremendous changes. Although the results of this revolution in physics are now called "modern" physics, they are now almost a century old. Three of these modern physical concepts are (1) Einstein's theory of special relativity, which extended Newtonian mechanics; (2) wave-particle duality, which says that both electromagnetic waves and atomic particles have dual wave and particle properties; and (3) quantum mechanics, which revealed that the microscopic atomic world is far different from our everyday macroscopic world. The results and insights provided by these three advances in physics are fundamental to an understanding of nuclear science and technology.

3.1.1 The Special Theory of Relativity

The classical laws of dynamics as developed by Newton were believed, for over 200 years, to describe all motion in nature. Students still spend considerable effort mastering the use of these laws of motion. For example, Newton's second law, in the form originally stated by Newton, says the rate of change of a body's

momentum $\mathbf{p}$ equals the force $\mathbf{F}$ applied to it, i.e.,

$$\mathbf{F} = \frac{d\mathbf{p}}{dt} = \frac{d(m\mathbf{v})}{dt}. \tag{3.1}$$

For a constant mass m, as assumed by Newton, this equation immediately reduces to the modern form of the second law, $\mathbf{F} = m\mathbf{a}$, where $\mathbf{a} = d\mathbf{v}/dt$, the acceleration of the body.

In 1905 Einstein discovered that classical mechanics could not describe properly the behavior of an object traveling near the speed of light and he found the necessary correction. In his theory of special relativity,[1] Einstein showed that Eq. (3.1) is still correct, but that the mass of a body is not constant, but increases with the body's speed v. The form $\mathbf{F} = m\mathbf{a}$ is thus incorrect. Specifically, Einstein showed that m varies with the body's speed as

$$m = \frac{m_o}{\sqrt{1 - v^2/c^2}}, \tag{3.2}$$

where m_o is the body's "rest mass," i.e., the body's mass when it is at rest, and c is the speed of light ($\simeq 3 \times 10^8$ m/s). The validity of Einstein's correction was immediately confirmed by observing that the electron's mass did indeed increase as its speed increased in precisely the manner predicted by Eq. (3.2).

Most fundamental changes in physics arise in response to experimental results that reveal an old theory to be inadequate. However, Einstein's correction to the laws of motion was produced theoretically before being confirmed experimentally. This is perhaps not too surprising since in our everyday world the difference between m and m_o is incredibly small. For example, a satellite in a circular earth orbit of 7100 km radius moves with a speed of 7.5 km/s. For this satellite the mass correction factor $\sqrt{1 - v^2/c^2} = 1 - 0.31 \times 10^{-9}$, i.e., relativistic effects change the satellite's mass only in the ninth significant figure or by less than one part in a billion! Thus for practical engineering problems in our macroscopic world, relativistic effects can safely be ignored. However, at the atomic and nuclear level, these effects can be very important.

3.1.2 Principle of Relativity

The principle of relativity is older than Newton's laws of motion. In Newton's words (actually translated from Latin) "The motions of bodies included in a given space are the same amongst themselves, whether the space is at rest or moves uniformly forward in a straight line." This means that experiments made in a laboratory in uniform motion (e.g., in a non-accelerating train) produce the same results as when the laboratory is at rest. Indeed, this principle of relativity is widely used to solve problems in mechanics by shifting to moving frames of reference to simplify the equations of motion.

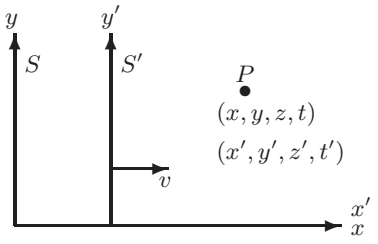

Figure 3.1. Two inertial coordinate systems.

The relativity principle is a simple intuitive and appealing idea. But do all the laws of physics indeed remain the same in all non-accelerating (*inertial*) coordinate systems? Consider the two coordinate systems shown in Fig. 3.1. System S is at rest, while system S' is moving uniformly to the right with speed v. At $t = 0$, the origin of S' is at the origin of S. The coordinates of some point P are (x, y, z) in S and (x', y', z') in S'. Clearly, the primed and unprimed coordinates are related by

$$x' = x - vt; \quad y' = y; \quad z' = z; \quad \text{and} \quad t' = t. \tag{3.3}$$

If these coordinate transformations are substituted into Newton's laws of motion, the equations are unchanged. For example, consider a force in the x-direction, F_x, acting on some mass m. Then the second

[1] In 1915 Einstein published the general theory of relativity, in which he generalized his special theory to include gravitation.

law in the S' moving system is $F_x = m\,d^2x'/dt'^2$. Now transform this law to the stationary S system. For v constant, one finds

$$F_x = m\frac{d^2x'}{dt'^2} = m\frac{d^2(x-vt)}{d(t)^2} = m\frac{d^2x}{dt^2}.$$

Thus the second law has the same form in both systems. Since the laws of motion are the same in all inertial coordinate systems, it follows that it is impossible to tell, from results of mechanical experiments, whether or not the system is moving.

In the 1870s, Maxwell introduced his famous laws of electromagnetism. These laws explained all observed behavior of electricity, magnetism, and light in a uniform system. However, when Eqs. (3.3) are used to transform Maxwell's equations to another inertial system, they assume a different form. Thus from optical experiments in a moving system, one should be able to determine the speed of the system. For many years Maxwell's equations were thought to be somehow incorrect, but 20 years of research only continued to reconfirm them. Eventually, some scientists began to wonder if the problem lay in the Galilean transformation of Eqs. (3.3). Indeed, Lorentz observed in 1904 that if the transformation

$$x' = \frac{x-vt}{\sqrt{1-v^2/c^2}}; \quad y' = y; \quad z' = z; \quad t' = \frac{t-vx/c^2}{\sqrt{1-v^2/c^2}} \tag{3.4}$$

is used, Maxwell's equations become the same in all inertial coordinate systems. Poincaré, about this time, even conjectured that *all* laws of physics should remain unchanged under the peculiar looking Lorentz transformation. The Lorentz transformation is indeed strange, since it indicates that space and time are not independent quantities. Time in the S' system, as measured by an observer in the S system, is different from the time in the observer's system.

3.1.3 Results of the Special Theory of Relativity

It was Einstein who, in 1905, showed that the Lorentz transformation was indeed the correct transformation relating all inertial coordinate systems. He also showed how Newton's laws of motion must be modified to make them invariant under this transformation.

Einstein based his analysis on two postulates:

- The laws of physics are expressed by equations that have the same form in all coordinate systems moving at constant velocities relative to each other.
- The speed of light in free space is the same for all observers and is independent of the relative velocity between the source and the observer.

The first postulate is simply the principle of relativity, while the second states that light is observed to move with speed c even if the light source is moving with respect to the observer. From these postulates, Einstein demonstrated several amazing properties of our universe.

1. The laws of motion are correct, as stated by Newton, if the mass of an object is made a function of the object's speed v, i.e.,

$$m(v) = \frac{m_o}{\sqrt{1-v^2/c^2}}. \tag{3.5}$$

   This result also shows that no material object can travel faster than the speed of light since the relativistic mass $m(v)$ must always be real. Further, an object with a rest mass ($m_o > 0$) cannot even travel at the speed of light; otherwise, its relativistic mass would become infinite and give it an infinite kinetic energy.

2. The length of a moving object in the direction of its motion appears smaller to an observer at rest, namely,
$$L = L_o\sqrt{1 - v^2/c^2}. \tag{3.6}$$
where L_o is the "proper length" or length of the object when at rest.

3. The passage of time appears to slow in a system moving with respect to a stationary observer. The time t required for some physical phenomenon (e.g., the interval between two heart beats) in a moving inertial system appears to be longer (dilated) than the time t_o for the same phenomenon to occur in the stationary system. This phenomenon is called *time dilation*. The relation between t and t_o is
$$t = \frac{t_o}{\sqrt{1 - v^2/c^2}}. \tag{3.7}$$

4. Perhaps the most famous result from special relativity is the demonstration of the equivalence of mass and energy by the well-known equation $E = mc^2$. By using Eqs. (3.1) and (3.2), Einstein showed that the kinetic energy T of a particle is given by $T = mc^2 - m_oc^2$. Thus it is seen that the kinetic energy is associated with the increase in the mass of the particle. Equivalently, this result can be written as $mc^2 = m_oc^2 + T$. The quantity mc^2 can be interpreted as the particle's "total energy" E, which equals its rest-mass energy plus its kinetic energy. If the particle was also in some potential field, for example, an electric field, the total energy would also include the potential energy. Thus it follows that
$$\boxed{E = mc^2.} \tag{3.8}$$
This well-known equation is the cornerstone of nuclear energy analyses. It shows the equivalence of energy and mass. One can be converted into the other in precisely the amount specified by $E = mc^2$.

The derivation of these important results can be found, for example, in Shultis and Faw [2008].

Relation Between Kinetic Energy and Momentum

Both classically and relativistically, the momentum p of a particle is given by
$$p = mv. \tag{3.9}$$
In classical physics, a particle's kinetic energy T is given by
$$T = \frac{mv^2}{2} = \frac{p^2}{2m},$$
which yields
$$p = \sqrt{2mT}. \tag{3.10}$$

For relativistic particles, the relationship between momentum and kinetic energy is not as simple. Square Eq. (3.5) to obtain
$$m^2\frac{c^2 - v^2}{c^2} = m_o^2,$$
or, upon rearrangement,
$$p^2 \equiv (mv)^2 = (mc)^2 - (m_oc)^2 = \frac{1}{c^2}[(mc^2)^2 - (m_oc^2)^2].$$

Because $T = mc^2 - m_o c^2$, the above result reduces to

$$p^2 = \frac{1}{c^2}\left[(T + m_o c^2)^2 - (m_o c^2)^2\right] = \frac{1}{c^2}\left[T^2 + 2Tm_o c^2\right]. \tag{3.11}$$

Thus for relativistic particles

$$\boxed{p = \frac{1}{c}\sqrt{T^2 + 2Tm_o c^2}.} \tag{3.12}$$

Relativistic Particles

For most moving objects encountered in engineering analyses, the classical expression for kinetic energy can be used. Only if an object has a speed near c must relativistic expressions be used. If the changeover from classical to relativistic mechanics is associated with a specific relativistic mass increase, 0.1% for example, the associated speed can be calculated from Eq. (3.5), which, for this example, yields $1.001 = 1/\sqrt{1 - v^2/c^2}$. Solving this result for v gives the relativistic speed threshold as $v = 0.045c$. Listed in Table 3.1 for several important atomic particles are the rest mass energies and the kinetic energies required for a 0.1% mass change.

Table 3.1. Rest mass energies and kinetic energies for a 0.1% relativistic mass increase for four particles.

Particle	rest mass energy $m_o c^2$	kinetic energy for a 0.1% increase in mass
electron	0.511 MeV	511 eV $\simeq$ 0.5 keV
proton	938 MeV	938 keV $\simeq$ 1 MeV
neutron	940 MeV	940 keV $\simeq$ 1 MeV
α-particle	3751 MeV	3.8 MeV $\simeq$ 4 MeV

3.2 Highlights in the Evolution of Atomic Theory

The concept of the atom is ancient. The Greek philosophers Leucippus and his pupil Democritus in the fifth century BC conjectured that all matter was composed of indivisible particles or *atoms* (lit. "not to be cut"). Unfortunately, Aristotle, whose ideas were more influential far into the Middle Ages, favored the "fire, air, earth, and water" theory of Empedocles. According to the Roman poet Lucretius (100 B.C.), who wrote at length about the nature of the universe in *De Rerun Natura*, the philosopher Epicurus (300 B.C.) tried to revive the atomistic idea but little came from his effort because, of course, the idea was beyond any experimental verification test at that time.

The modern concept of the atom had its origin in the observations of chemical properties made by eighteenth and nineteenth century alchemists. Lavoisier first discovered that mass was conserved in chemical reactions, and shortly after Gay-Lussac found that gases combined in simple ratios by volume. These observations prompted chemist Dalton in the period 1803–1808 to develop an explanation for the observations. Dalton proposed his atomic hypothesis that stated: (1) each element consists of a large number of identical particles (called atoms) that cannot be subdivided and that preserve their identity in chemical reactions; (2) a compound's mass equals the sum of the masses of the constituent atoms; and (3) chemical compounds are formed by the combination of atoms of individual elements in simple proportions (e.g., 1:1, 1:2, etc.). This atomic hypothesis explained chemical reactions and the distinct ratios in which elements combined to form compounds. However, Dalton made no statement about the structure of an atom.

At the beginning of the twentieth century, a wealth of experimental evidence allowed scientists to develop ever more refined models of the atom, until our present model of the atom was essentially established by the 1940s. The structure of the nucleus of an atom has now also been well developed qualitatively and is supported by a wealth of nuclear data. However, work still continues on developing more refined mathematical models to quantify the properties of nuclei and atoms.

In this section, a brief historical summary of the development of atomic models is presented. The emphasis of the presentation is on the novel ideas that were developed, and little discussion is devoted to the many experiments that provided the essential data for model development. Those interested in more detail, especially about the seminal experiments, should refer to any modern physics text.

3.2.1 Radiation as Waves and Particles

For many phenomena, radiant energy can be considered as electromagnetic waves. Indeed Maxwell's equations, which describe very accurately interactions of long wave-length radiation, readily yield a wave equation for the electric and magnetic fields of radiant energy. Phenomena such as diffraction, interference, and other related optical effects can be described only by a wave model for radiation.

However, near the beginning of the twentieth century, several experiments involving light and x rays were performed that indicated that radiation also possessed particle-like properties. Today it is understood, through quantum theory, that matter (e.g., electrons) and radiation (e.g., x rays) both have wave-like and particle properties. This dichotomy, known as the *wave-particle duality principle*, is a cornerstone of modern physics. For some phenomena, a wave description works best; for others, a particle model is appropriate.

3.2.2 Early Observations

In 1887, Heinrich Hertz observed that when ultraviolet light was illuminated upon one contact of a high voltage circuit that an electric spark would issue a longer distance than when the contact was not exposed to the light. J.J. Thomson demonstrated that the effect was caused by a negative charge being produced on the contact surface by the ultraviolet light, referred to as the "photo-electric" effect. Later, in 1897, J.J. Thomson correctly explained that cathode rays, which had been observed for decades, were actually accelerated negative particles, which he referred to as "electrons", as was correctly predicted by Benjamin Franklin in 1746 with his Leyden jar experiments.[2]

3.2.3 The Photoelectric Effect

According to a classical (wave theory) description of light, the light energy was absorbed by the metal surface, and when sufficient energy was absorbed to free a bound electron, a photoelectron would "boil" off the surface. If light were truly a wave, one would expect the following observations:

- Photoelectrons should be produced by light of all frequencies.
- At low intensities, a time lag would be expected between the start of irradiation and the emission of a photoelectron since it takes time for the surface to absorb sufficient energy to eject an electron.
- As the light intensity (i.e., wave amplitude) increases, more energy is absorbed per unit time and, hence, the photoelectron emission rate should increase.
- The kinetic energy of the photoelectron should increase with the light intensity since more energy is absorbed by the surface.

[2] Franklin was first to give the positive and negative designations to electricity, and he was the first to discover the principle of conservation of charge. The cgs unit of electric charge was named after him, where one franklin (Fr) is equal to one statcoulomb.

However, experimental results differed dramatically from these predictions. It was observed:

- For each metal there is a minimum light frequency below which no photoelectrons are emitted, no matter how high the intensity.
- There is no time lag between the start of irradiation and the emission of photoelectrons, no matter how low the intensity.
- The intensity of the light affects only the emission *rate* of photoelectrons.
- The kinetic energy of the photoelectron depends only on the frequency of the light and not on its intensity. The higher the frequency, the more energetic is the photoelectron.

Einstein's Explanation of the Photoelectric Effect

In 1905 Einstein introduced a new light model which explained all these observations.[3] Einstein assumed that light energy consists of *photons* or "quanta of energy," each with an energy $E = h\nu$, where h is Planck's constant (6.626×10^{-34} J s) and ν is the light frequency. He further assumed that the energy associated with each photon interacts as a whole, i.e., either all the energy is absorbed by an atom or none is. With this "particle" model, the maximum kinetic energy of a photoelectron would be

$$E = h\nu - A, \tag{3.13}$$

where A is the amount of energy (the so-called *work function*) required to free an electron from the metal. Thus if $h\nu < A$, no photoelectrons are produced. Increasing the light intensity only increases the number of photons hitting the metal surface per unit time and, thus, the rate of photoelectron emission.

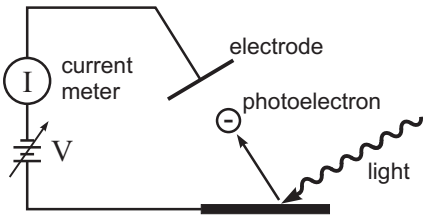

Figure 3.2. A schematic illustration of the experimental arrangement used to verify photoelectric effect.

Although Einstein was able to explain qualitatively the observed characteristics of the photoelectric effect, it was several years later before Einstein's prediction of the maximum energy of a photoelectron, Eq. (3.13), was verified quantitatively using the experiment shown schematically in Fig. 3.2. Photoelectrons emitted from freshly polished metallic surfaces were absorbed by a collector causing a current to flow between the collector and the irradiated metallic surface. As an increasing negative voltage was applied to the collector, fewer photoelectrons had sufficient kinetic energy to overcome this potential difference and the photoelectric current decreased to zero at a critical voltage V_o at which no photoelectrons had sufficient kinetic energy to overcome the opposing potential. At this voltage, the maximum kinetic energy of a photoelectron, Eq. (3.13), equals the potential energy $V_o q_e$ the photoelectron must overcome, i.e.,

$$V_o q_e = h\nu - A,$$

or

$$V_o = \frac{h\nu}{q_e} - \frac{A}{q_e}, \tag{3.14}$$

[3] It is an interesting historical fact that Einstein received the Nobel prize for his photoelectric research and not for his theory of relativity, which he produced in the same year.

where q_e is the electron charge (1.602×10^{-19} C).[4] In 1912 Hughes showed that, for a given metallic surface, V_o was a linear function of the light frequency ν. In 1916 Millikan, who had previously measured the electron charge q_e, verified that plots of V_o versus ν for different metallic surface had a slope of h/q_e, from which h could be evaluated. Millikan's value of h was in excellent agreement with the value determined from measurements of black-body radiation, in whose theoretical description Planck first introduced the constant h.

The prediction by Einstein and its subsequent experimental verification clearly demonstrated the quantum nature of radiant energy. Although the wave theory of light explained diffraction and interference phenomena, scientists saw that the energy of electromagnetic radiation was in the form of individual quanta, each with the same energy $E = h\nu$. A quantum of energy could then be transferred to a single atomic electron. This quantization occurs no matter how weak the radiant energy.

3.2.4 Compton Scattering

Other experimental observations showed that light, besides having quantized energy characteristics, must have another particle-like property, namely, momentum. According to the wave model of electromagnetic radiation, radiation should be scattered from an electron with no change in wavelength. However, in 1922 Compton observed that x rays scattered from electrons had an increase in the wavelength $\Delta\lambda = \lambda' - \lambda$ proportional to $(1 - \cos\theta_s)$ where θ_s was the scattering angle (see Fig. 3.3). To explain this observation, it was necessary to treat x rays as particles with a linear momentum $p = h/\lambda$ and energy $E = h\nu = pc$.

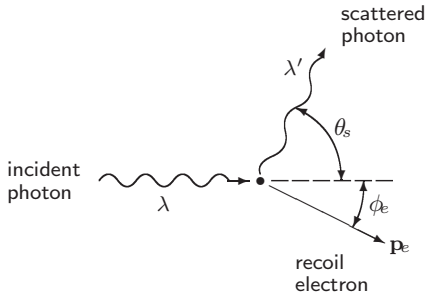

Figure 3.3. A photon with wavelength λ is scattered by an electron. After scattering, the photon has a longer wavelength λ' and the electron recoils with an energy T_e and momentum $\mathbf{p}_e$.

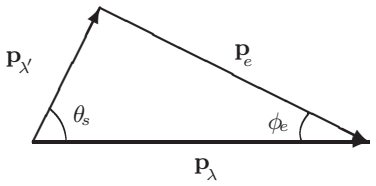

Figure 3.4. Conservation of momentum requires the initial momentum of the photon p_λ equal the vector sum of the momenta of the scattered photon and recoil electron.

In an x-ray scattering interaction, the energy and momentum before scattering must equal the energy and momentum after scattering. Conservation of linear momentum requires the initial momentum of the incident photon (the electron is assumed to be initially at rest) to equal the vector sum of the momenta of the scattered photon and the recoil electron. This requires the momentum vector triangle of Fig. 3.4 to be

[4] Historically, the unit charge of an electron is denoted by 'e', which is also the SI symbol. Unfortunately, 'e' is also used as Euler's number

$$e = \lim_{n\to\infty}\left(1 + \frac{1}{n}\right)^n = \sum_{n=0}^{\infty}\frac{1}{n!}.$$

Hence, to avoid confusion the authors chose to designate the symbol q_e as the magnitude for the unit charge $1.602\,176\,565 \times 10^{-19}$ coulombs.

closed, i.e.,

$$\mathbf{p}_\lambda = \mathbf{p}_{\lambda'} + \mathbf{p}_e \tag{3.15}$$

or from the law of cosines

$$p_e^2 = p_\lambda^2 + p_{\lambda'}^2 - 2p_\lambda p_{\lambda'} \cos\theta_s. \tag{3.16}$$

The conservation of energy requires

$$p_\lambda c + m_e c^2 = p_{\lambda'} c + mc^2 \tag{3.17}$$

where m_e is the rest-mass of the electron before the collision when it has negligible kinetic energy, and m is its relativistic mass after scattering the photon. This result, combined with Eq. (3.11) (in which $m_e \equiv m_o$), can be rewritten as

$$p_\lambda + m_e c - p_{\lambda'} = \sqrt{p_e^2 + (m_e c)^2}. \tag{3.18}$$

Substitute for p_e from Eq. (3.16) into Eq. (3.18), square the result, and simplify to obtain

$$\frac{1}{p_{\lambda'}} - \frac{1}{p_\lambda} = \frac{1}{m_e c}(1 - \cos\theta_s). \tag{3.19}$$

Because $\lambda = h/p$, this result gives the increase in the wavelength of the scattered electron as

$$\lambda' - \lambda = \frac{h}{m_e c}(1 - \cos\theta_s), \tag{3.20}$$

where $h/(m_e c) = 2.431 \times 10^{-6}\mu$m. Thus, Compton was able to predict the wavelength change of scattered x rays by using a particle model for the x rays, a prediction which could not be obtained with a wave model.

This result can be expressed in terms of the incident and scattered photon energies, E and E', respectively. With the photon relations $\lambda = c/\nu$ and $E = h\nu$, Eq. (3.20) gives

$$\boxed{\frac{1}{E'} - \frac{1}{E} = \frac{1}{m_e c^2}(1 - \cos\theta_s).} \tag{3.21}$$

3.2.5 Electromagnetic Radiation: Wave-Particle Duality

Electromagnetic radiation assumes many forms encompassing radio waves, microwaves, visible light, x rays, and gamma rays. Many properties are described by a wave model in which the wave travels at the speed of light c and has a wavelength λ and frequency ν, which are related by the wave speed formula

$$c = \lambda\nu. \tag{3.22}$$

The wave properties account for many phenomena involving light such as diffraction and interference effects.

However, as Einstein and Compton showed, electromagnetic radiation also has particle-like properties, namely, the light energy being carried by discrete quanta or packets of energy called *photons*. Each photon has an energy $E = h\nu$ and interacts with matter (atoms) in particle-like interactions (e.g., in the photoelectric interactions described above).

Thus, light has both wave-like and particle-like properties. The properties or model to use depend on the wavelength of the radiation being considered. If, for example, the electromagnetic radiation is visible or infrared, radar or radio, with wavelengths upwards of $\sim 10^{-6}$ m and thus much greater than atom dimensions, the wave model is usually most useful. However, if the electromagnetic radiation consists of ultraviolet, x rays or gamma rays, with wavelengths $\lesssim 10^{-8}$ m or less, the corpuscular or photon model is usually used. This is the model generally used throughout this book on radiation detection, because the radiation of concern is usually penetrating short-wavelength electromagnetic radiation.

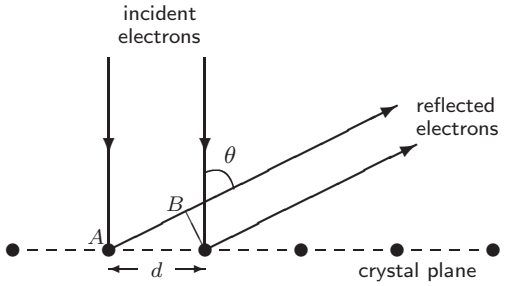

Figure 3.5. Electrons scattering from atoms on a crystalline plane interfere constructively if the distance AB is a multiple of the electron's de Broglie wavelength.

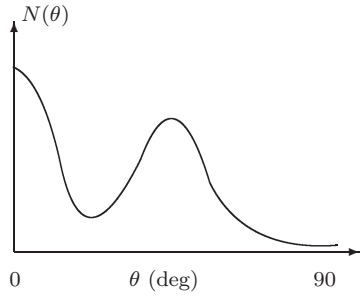

Figure 3.6. Observed number of electrons $N(\theta)$ scattered into a fixed cone or directions about an angle θ by the atoms in a nickel crystal.

Photon Properties

Some particles must always be treated relativistically. For example, photons, by definition, travel with the speed of light c. From Eq. (3.5), one might think that photons have an infinite relativistic mass, and hence, from Eq. (3.12), infinite momentum. This is obviously not true since objects, when irradiated with light, are not observed to jump violently. This apparent paradox can easily be resolved if the rest mass of the photon is exactly zero, although its relativistic mass is finite. In fact, the total energy of a photon, $E = h\nu$, is due strictly to its motion. Equation (3.12) immediately gives the momentum of a photon (with $m_o \equiv 0$) as

$$p = \frac{E}{c} = \frac{h\nu}{c} = \frac{h}{\lambda}. \tag{3.23}$$

From Eq. (3.8), the photon's relativistic mass is $mc^2 = E = h\nu$ or

$$m = \frac{h\nu}{c^2}. \tag{3.24}$$

3.2.6 Electron Scattering

In 1924 de Broglie postulated that, since light had particle properties, then for symmetry (physicists love symmetry!), particles should have wave properties. Because photons had a discrete energy $E = h\nu$ and momentum $p = h/\lambda$, de Broglie suggested that a particle, because of its momentum, should have an associated wavelength $\lambda = h/p$.

Confirmation of Matter Waves

Davisson and Germer in 1927 confirmed that electrons did indeed behave like waves with de Broglie's predicted wavelength. In their experiment, shown schematically in Fig. 3.5, Davisson and Germer illuminated the surface of a Ni crystal by a perpendicular beam of 54-eV electrons and measured the number of electrons $N(\theta)$ reflected at different angles θ from the incident beam. According to the particle model, electrons should be scattered by individual atoms isotropically and $N(\theta)$ should exhibit no structure. However, $N(\theta)$ was observed to have a peak near 50° (see Fig. 3.6). This observation could only be explained by recognizing the peak as a constructive interference peak — a wave phenomenon. Specifically, two reflected electron waves are in phase (constructively interfere) if the difference in their path lengths AB in Fig. 3.5 is an integral number of wavelengths, i.e., if $d \sin\theta = n\lambda,\ n = 1, 2, \ldots$ where d is the distance between atoms of the crystal.

In the following year, G.P. Thomson used a beam of more energetic electrons to pass through a thin foil of a polycrystalline material. Film behind the foil clearly showed diffraction circles as a result of constructive and destructive interference of the electron waves. In 1930 Estermann and Stern [1930] used a similar method

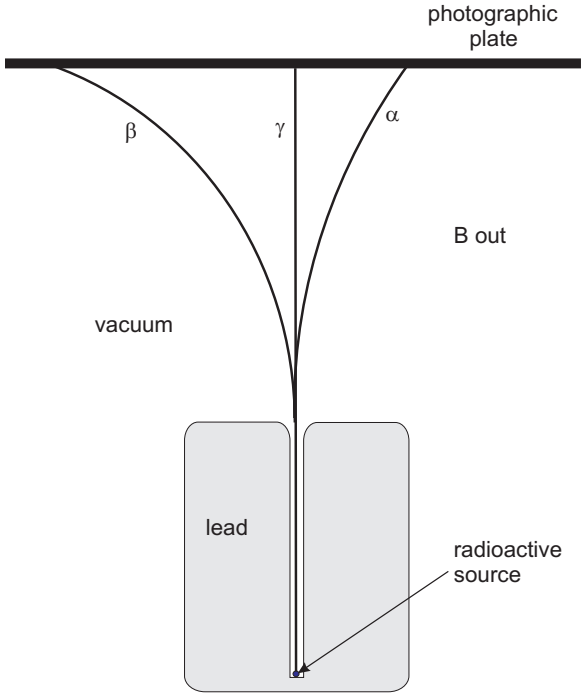

Figure 3.7. Deflection of α, β, and γ rays by a magnetic field out of and perpendicular to the page.

to demonstrate that helium atoms also exhibit wave characteristics. These experiments and many similar ones clearly demonstrated that electrons (and other particles such as atoms) have wave-like properties.

3.3 Development of the Modern Atom Model

In the first half of the twentieth century, the efforts to develop a model of an atom also provided additional evidence that orbital electrons must have wave-like properties. In this section the historical development of atomic models is reviewed.

3.3.1 Discovery of Radioactivity

In 1896, Becquerel discovered that uranium salts emitted rays similar to x rays in that they also fogged photographic plates. Becquerel's discovery was followed by isolation of two other radioactive elements, radium and polonium, by the Curies in 1898. The radiation emission rate of radium was found to be more than a million times that of uranium, for the same mass.

Experiments in magnetic fields showed that three types of radiation could be emitted from naturally occurring radioactive materials. The identification of these radiations was made by the experimental arrangement shown in Fig. 3.7. Radioactive material was placed in a lead enclosure and the emitted radiation collimated in the upward direction by passing through the collimator. The entire chamber was evacuated and a magnetic field was applied perpendicularly and directed outwardly from the plane of the page. With this arrangement, Becquerel found three distinct spots at which radiation struck the photographic plate used as a detector. The three different types of radiation, whose precise nature was then unknown, were called *alpha*, *beta*, and *gamma* rays.

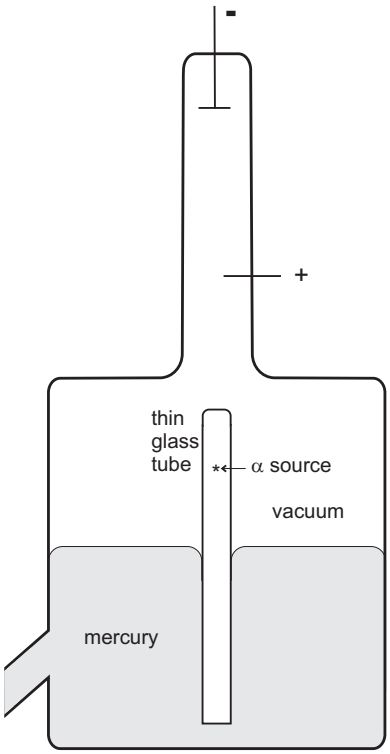

Figure 3.8. Experimental arrangement used to identify the identity of α particles.

The beta rays, which were deflected to the left, were obviously negatively charged particles, and were later found to be the same as the "cathode" rays seen in gas discharge tubes. These rays were identified by J.J. Thomson in 1898 as electrons. The gamma rays were unaffected by the magnetic field and hence had to be uncharged. Today, we know that gamma rays are high frequency electromagnetic radiation whose energy is carried by particles called photons. The alpha particles, being deflected to the right, had positive charge. They were deflected far less than were the beta rays, an indication that the alpha particles have a charge-to-mass ratio q_e/m far less than that of beta particles. Either the positive charge of the alpha particle was far less than the negative charge of beta particles and/or the alpha particle's mass was far greater than that of a beta particle.

A quantitative analysis of the deflection of alpha particles showed that their speeds were of the order of 10^7 m/s. The charge-to-mass ratio was found to be 4.82×10^7 C kg^{-1}. By contrast, the charge-to-mass ratio for the hydrogen ion is twice as large, namely, 9.59×10^7 C kg^{-1}. Thus, if the alpha particle had the same charge as the hydrogen ion, its mass would have to be twice that of the hydrogen ion. If the alpha particle were doubly charged, its mass would be four times as large and would correspond to that of the helium atom. That an alpha particle is an ionized helium atom was demonstrated by Rutherford who used the experimental arrangement of Fig. 3.8. The alpha particles from the radioactive source penetrate the thin-walled glass tube and are collected in the surrounding evacuated chamber. After slowing, the α particles capture ambient electrons to form neutral helium atoms. The accumulated helium gas is then compressed so that an electrical discharge occurs when a high voltage is applied between the electrodes. The emission spectrum from the excited gas atoms was found to have the same wavelengths as that produced by an ordinary helium-filled discharge tube. Therefore, the alpha particle must be a helium ion. The mass of the alpha particle is four times the mass of hydrogen, but the charge on the alpha particle is only twice the charge on a hydrogen ion.

3.3.2 Thomson's Atomic Model: The Plum Pudding Model

The discovery of radioactivity by Becquerel in 1896 and Thomson's discovery of the electron in 1898 provided a basis for the first theories of atomic structure. In radioactive decay, atoms are transformed into different atoms by emitting positively charged or negatively charged particles. This led to the view that atoms are composed of positive and negative charges. If correct, the total negative charge in an atom must be an integral multiple of the electronic charge and, since atoms are electrically neutral, the positive and negative charges must be numerically equal.

The emission of electrons from atoms under widely varying conditions was convincing evidence that electrons exist as such inside atoms. The first theories of atomic structure were based on the idea that atoms were composed of electrons and positive charges. There was no particular assumption concerning the nature of the positive charges because the properties of the positive charges from radioactive decay and from gas discharge tubes did not have the q_e/m consistency that was shown by the negative charges (electrons).

At the time of Thomson's research on atoms, there was no information about the way that the positive and negative charges were distributed in the atom. Thomson proposed a model, simple but fairly accurate, considering the lack of information about atoms at that time. He assumed that an atom consisted of a sphere of positive charge of uniform density, throughout which was distributed an equal and opposite charge in the form of electrons. The atom was like a "plum pudding," with the negative charges dispersed like raisins or plums in a dough of positive electricity (see Fig. 3.9). The diameter of the sphere was of the order of 10^{-10} m, the magnitude found for the size of the atom.

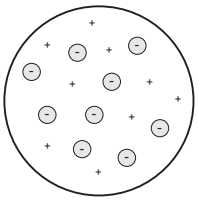

Figure 3.9. Thomson's plum-pudding model of the atom.

This model explained three important experimental observations: (1) an ion is just an atom from which electrons have been lost, (2) the charge on a singly ionized atom equals the negative of the charge of an electron, and (3) the number of electrons in an atom approximately equals one-half of the atomic weight of the atom, i.e., if the atom's mass doubles, the number of electrons double.

Also it was known that the mass of the electron was known to be about one eighteen hundredth the mass of the hydrogen atom. Therefore, the total mass of the electrons in an atom is a very small part of the total mass of the atom, and, hence, practically all of the mass of an atom is associated with the positive charge of the "pudding."

3.3.3 The Rutherford Atomic Model

At the beginning of the twentieth century, Geiger and Marsden used alpha particles from a radioactive source to irradiate a thin gold foil. According to the Thomson plum-pudding model, for a gold foil 4×10^{-5} cm in thickness, the probability an alpha particle scatters at least by an angle ϕ was calculated to be $\exp(-\phi/\phi_m)$, where $\phi_m \simeq 1^\circ$. Thus, the probability that an alpha particle scatters by more than 90° should be about 10^{-40}. In fact, it was observed that one alpha particle in 8000 was scattered by more than 90°!

To explain these observations, Rutherford in 1911 concluded that the positively charged mass of an atom must be concentrated within a sphere of radius about 10^{-12} cm. The electrons, therefore, must revolve about a massive, small, positively charged nucleus in orbits with diameters of the size of atoms, namely, about 10^{-8} cm. With such a model of the nucleus, the predicted deflection of alpha particles by the gold foil fit the experimental data very well.

3.3.4 The Bohr Atomic Model

The Rutherford model of an atom was quickly found to have serious deficiencies. In particular, it violated classical laws of electromagnetism. According to classical theory, an accelerating charge (the electrons in circular orbits around a nucleus) should radiate away their kinetic energy within about 10^{-9} s and spiral into the nucleus.[5]

But obviously atoms do not collapse. Were they to do so, the electromagnetic radiation emitted by the collapsing electrons should be continuous in frequency, since as the electrons collapse, they should spiral ever faster around the nucleus and hence experience increasing central accelerations. When atoms are excited by an electrical discharge, for example, atoms are observed to emit light not in a continuous wavelength spectrum but with very discrete wavelengths characteristic of the element. For example, part of the spectrum of light emitted by hydrogen is shown in Fig. 3.10.

[5] This radiation produced by an accelerated electric charge explains how radio waves are generated. Electrons are accelerated back and forth along a wire (antenna) by an alternating potential with a well-defined frequency, namely that of the radio waves that are emitted from the wire.

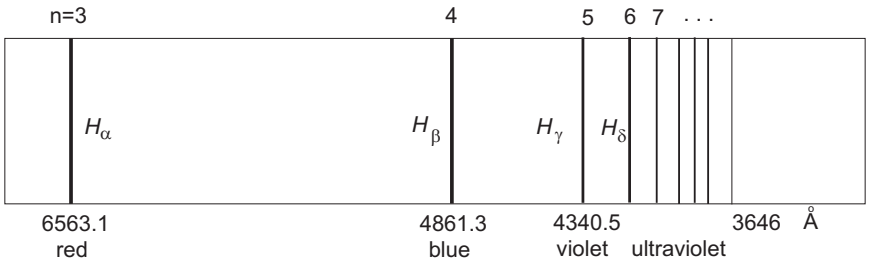

Figure 3.10. Diagram of the lines of the Balmer series of atomic hydrogen. After Kaplan [1963].

Table 3.2. Various hydrogen spectral series.

n_o	Series name	Spectrum location
1	Lyman	ultraviolet
2	Balmer	visible and near ultraviolet
3	Paschen	infrared
4	Brackett	infrared
5	Pfund	infrared

It was found empirically that the wavelength of light emitted by hydrogen (excited by electrical discharges) could be described very accurately by the simple equation

$$\frac{1}{\lambda} = R_H \left[\frac{1}{n_o^2} - \frac{1}{n^2} \right] \tag{3.25}$$

where n_o, n are positive integers with $n > n_o$ and R_H is the Rydberg constant found empirically to have the value $R_H = 10\,967\,758\ \mathrm{m}^{-1}$. The integer n_o defines a series of spectral lines discovered by different researchers identified in Table 3.2.

The observed discrete-wavelength nature of light emitted by excited atoms was in direct conflict with Rutherford's model of the atom. In a series of papers published between 1913 and 1915, Bohr developed an atomic model which predicted very closely the observed spectral measurements in hydrogen. Bohr visualized an atom much like the Rutherford model with the electrons in orbits around a small dense central nucleus. However, his model included several non-classical constraints. Bohr postulated:

1. An electron moves in a circular orbit about the nucleus obeying the laws of classical mechanics.
2. Instead of an infinity of orbits, only those orbits whose angular momentum L is an integral multiple of $h/2\pi$ are allowed.
3. Electrons radiate energy only when moving from one allowed orbit to another. The energy $E = h\nu$ of the emitted radiation is the difference between characteristic energies associated with the two orbits. These characteristic energies are determined by a balance of centripetal and Coulombic forces.

Consider an electron of mass m_e moving with speed v in a circular orbit of radius r about a central nucleus with charge Zq_e. From postulate (1), the centripetal force on the electron must equal the Coulombic attractive force, i.e.,

$$\frac{m_e v^2}{r} = \frac{Z q_e^2}{4\pi\epsilon_o r^2}, \tag{3.26}$$

where ϵ_o is the *permittivity* of free space and q_e is the charge of the electron. From postulate (2)

$$L \equiv m_e v r = n\frac{h}{2\pi}, \quad n = 1, 2, 3, \ldots. \tag{3.27}$$

Solution of these relations for r and v yields

$$v_n = \frac{Z q_e^2}{2\epsilon_o n h} \quad \text{and} \quad r_n = \frac{n^2 h^2 \epsilon_o}{\pi m_e Z q_e^2}, \quad n = 1, 2, 3, \ldots \tag{3.28}$$

For $n = 1$ and $Z = 1$, these expressions yield $r_1 = 5.293 \times 10^{-11}$ m and $v_1 = 2.187 \times 10^6$ m/s $\ll c$, indicating that our use of non-relativistic mechanics is justified.

The electron has both potential energy[6] $V_n = -Zq_e^2/(4\pi\epsilon_o r_n)$ and kinetic energy $T_n = \frac{1}{2}m_e v_n^2$ or, from Eq. (3.26), $T_n = \frac{1}{2}[Zq_e^2/(4\pi\epsilon_o r_n)]$. Thus, the electron's total energy $E_n = T_n + V_n$ or, with Eq. (3.28),

$$E_n = T_n + V_n = \frac{1}{2}\left(\frac{Zq_e^2}{4\pi\epsilon_o r_n}\right) - \left(\frac{Zq_e^2}{4\pi\epsilon_o r_n}\right) = -\frac{1}{2}\frac{Zq_e^2}{4\pi\epsilon_o r_n} = -\frac{m_e(Zq_e^2)^2}{8\epsilon_o^2 n^2 h^2}. \tag{3.29}$$

For the ground state of hydrogen ($n = 1$ and $Z = 1$), this energy is $E_1 = -13.606$ eV, which is the experimentally measured ionization energy for hydrogen.

Finally, by postulate (3), the frequency of radiation emitted as an electron moves from an orbit with "quantum number" n to an orbit denoted by $n_o < n$ is given by

$$h\nu_{n\to n_o} = E_n - E_{n_o} = \frac{m_e Z^2 q_e^4}{8\epsilon_o^2 h^2}\left[\frac{1}{n_o^2} - \frac{1}{n^2}\right]. \tag{3.30}$$

Since $1/\lambda = \nu/c$, the wavelength of the emitted light is thus

$$\frac{1}{\lambda_{n\to n_o}} = \frac{m_e Z^2 q_e^4}{8\epsilon_o^2 c h^3}\left[\frac{1}{n_o^2} - \frac{1}{n^2}\right] = R_\infty\left[\frac{1}{n_o^2} - \frac{1}{n^2}\right], \quad n > n_o. \tag{3.31}$$

Example 3.1: What is the energy (in eV) required to remove the electron in the ground state from singly ionized helium?

Solution:

For the helium nucleus $Z = 2$ and the energy of the ground state (n=1) is, from Eq. (3.29),

$$E_1 = -\frac{m_e(2q_e^2)^2}{8\epsilon_o^2 h^2}.$$

From Table A.1 in Appendix A, one finds $h = 6.626\times10^{-34}$ J s, $m_e = 9.109\times10^{-31}$ kg, $q_e = 1.6022\times10^{-19}$ C, and $\epsilon_o = 8.854 \times 10^{-12}$ F m^{-1} (= C^2 J^{-1} m^{-1}). Substitution of these values into the above expression for E_1 yields

$$E_1 = -8.720 \times 10^{-18}\left(\frac{\text{kg}}{\text{m}^{-2}\ \text{s}^2}\right) = -8.720 \times 10^{-18}\text{J}$$
$$= (-8.720 \times 10^{-18}\text{J})/(1.6022 \times 10^{-19}\text{J/eV}) = -54.43 \text{ eV}.$$

Thus, it takes 54.43 eV of energy to remove the electron from singly ionized helium.

Equation (3.31) has the same form as the empirical Eq. (3.25). However, in the present analysis it has been implicitly assumed that the proton is infinitely heavy compared to the orbiting electron so that the electron moves in a circular orbit about a stationary proton. The Rydberg constant in the above result (with $Z = 1$) is thus denoted by R_∞, and is slightly different from R_H for the hydrogen atom. In reality, the proton and electron revolve about each other. To account for this, the electron mass in

[6] The potential energy is negative because of the attractive Coulombic force, with energy required to extract the electron from the atom. The zero reference for potential energy is associated with infinite orbital radius.

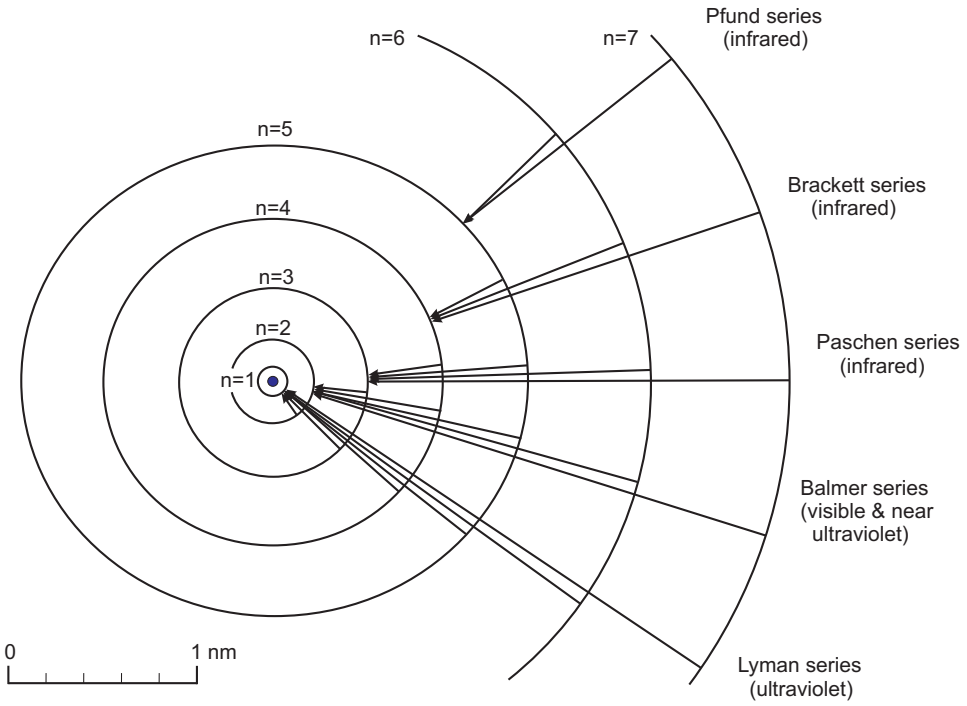

Figure 3.11. Bohr orbits for the hydrogen atom showing the deexcitation transitions that are responsible for the various spectral series observed experimentally. After Kaplan [1963].

Eq. (3.31) should be replaced by the electron's *reduced* mass $\mu_e = m_e m_p/(m_e + m_p)$ [Kaplan 1963]. This is a small correction since $\mu_e = 0.999445568\, m_e$, nevertheless an important one. With this correction, $R_H = \mu_e q_e^4/(8\epsilon_o^2 ch^3) = 10\,967\,758\ \mathrm{m}^{-1}$, which agrees with the observed value to eight significant figures!

The innermost orbits of the electron in the hydrogen atom are shown schematically in Fig. 3.11 to scale. The electronic transitions that give rise to the various emission series of spectral lines are also shown. The Bohr model, with its excellent predictive ability, *quantizes* the allowed electron orbits. Each allowed orbit is defined by the *quantum number* n introduced through Bohr's second postulate, a postulate whose justification is that the resulting predicted emission spectrum for hydrogen is in amazing agreement with the observation.

3.3.5 Extension of the Bohr Theory: Elliptic Orbits

The Bohr theory was very successful in predicting with great accuracy the wavelengths of the spectral lines in hydrogen and singly ionized helium. Shortly after Bohr published his model of the atom, there was a significant improvement in spectroscopic resolution. Refined spectroscopic analysis showed that the spectral lines were not simple, but consisted of a number of lines very close together, a so-called *fine structure*. In terms of energy levels, the existence of a fine structure means that instead of a single electron energy level for each quantum number n, there are actually a number of energy levels lying close to one another. Sommerfeld partly succeeded in explaining some of the lines in hydrogen and singly ionized helium by postulating elliptic orbits as well as circular orbits (see Fig. 3.12). These elliptical orbits required the introduction of another quantum number ℓ to describe the angular momentum of orbits with varying eccentricities.

Sommerfeld showed that, in the case of a one-electron atom, the fine structure could be partially explained. When the predictions of Sommerfeld's model were compared to experimental results on the resolution of the Balmer lines for He^+, the theory predicted more lines than were observed in the fine structure. Agreement

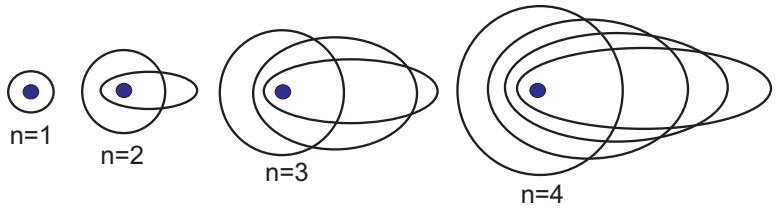

Figure 3.12. Relative positions and dimensions of the elliptical orbits corresponding to the first four values of the quantum number n in Sommerfeld's modification for the hydrogen atom. After Kaplan [1963].

between theory and experiment required the new quantum number ℓ to be constrained by an empirical or *ad hoc* selection rule which limited the number of allowed elliptical orbits and the transitions between the orbits.

For two-electron atoms, difficulties arose in the further refinement of Bohr's theory. To account for the observed splitting of the spectral lines in an applied magnetic field, it was necessary to introduce a third quantum number m, related to the orientation of the elliptical orbits in space. In the presence of a magnetic field, there is a component of the angular momentum in the direction of the field. This modification again led to the prediction of more spectral lines than were experimentally observed, and a second set of selection rules had to be empirically introduced to limit the number of lines.

Further difficulties arose when the model was applied to the spectrum of more complicated atoms. In the spectra of more complicated atoms, multiplet structure is observed. Multiplets differ from fine structure lines in that lines of a multiplet can be widely separated. The lines of sodium with wavelengths of 589.593 nm and 588.996 nm are an example of a doublet. Triplets are observed in the spectrum of magnesium.

These difficulties (and others) could not be resolved by further changes of the Bohr theory. It became apparent that these difficulties were intrinsic to the model. An entirely different approach was necessary to solve the problem of the structure of the atom and to avoid the need to introduce empirical selection rules.

3.3.6 The Quantum Mechanical Model of the Atom

From the *ad hoc* nature of quantum numbers and their selection rules used in refinements of the basic Bohr model of the atom, it was apparent an entirely different approach was needed to explain the details of atomic spectra. This new approach was introduced in 1925 by Schrödinger who brought wave or quantum mechanics to the world. Here, only a brief summary is given. Schrödinger's new theory (or model) showed that there were indeed three quantum numbers (n, ℓ, m) analogous to the three used in the refined Bohr models. Further, the values and constraints on these quantum numbers arose from the theory naturally—no *ad hoc* selection rules were needed.

To explain the multiple fine-line structure in the observed optical spectra from atoms and the splitting of some of these lines in a strong magnetic field (the *anomalous Zeeman effect*), the need for a fourth quantum number m_s was needed. This quantum number accounted for the inherent angular momentum of the electron equal to $\pm h/2\pi$. In 1928, Dirac showed that this fourth quantum number also arises from the wave equation if it is corrected for relativistic effects.

In the quantum mechanical model of the atom, the electrons are no longer point particles revolving around the central nucleus in orbits. Rather, each electron is visualized as a standing wave around the nucleus. The amplitude of this wave (called a *wave function*) at any particular position gives the probability that the electron is in that region of space. Example plots of these wave functions for the hydrogen atom are given in Fig. 3.16. Each electron wave function has a well-defined energy which is specified uniquely by the four quantum numbers defining the wave function.

3.3.7 Wave-Particle Duality

The fact that particles can behave like waves and that electromagnetic waves can behave like particles seems like a paradox. What really is a photon or an electron? Are they waves or particles? The answer is that entities in nature are more complex than is often thought, and they have, simultaneously, both particle and wave properties. Which properties dominate depends on the object's energy and mass. The de Broglie wavelength is given by

$$\lambda = \frac{h}{p} = \frac{hc}{\sqrt{T^2 + 2Tm_oc^2}} \tag{3.32}$$

For a classical object ($T^2 \ll 2Tm_oc^2$), the wavelength is given by $\lambda = h/\sqrt{2m_oT}$. However, as the object's speed increases, its behavior eventually becomes relativistic ($T \gg 2m_oc^2$) and the wavelength varies as $\lambda = hc/T$, the same as that for a photon. When the wavelength of an object is much less than atomic dimensions ($\sim 10^{-10}$ m), it behaves more like a classical particle than a wave. However, for objects with longer wavelengths, wave properties tend to be more apparent than particle properties.

3.4 Quantum Mechanics

The demonstration that particles (point objects) also had wave properties led to another major advance of modern physics. Because a material object such as an electron has wave properties, it should obey some sort of wave equation. Indeed, Schrödinger in 1925 showed that atomic electrons could be well described as standing waves around the nucleus. Further, the electron associated with each wave could have only a discrete energy. The branch of physics devoted to this wave description of particles is called *quantum mechanics* or *wave mechanics*.

3.4.1 Schrödinger's Wave Equation

To illustrate Schrödinger's wave equation, consider an analogy to the standing waves produced by a plucked string of length L anchored at both ends. The wave equation that describes the displacement $\Psi(x,t)$ as a function of position x from one end of the string, which has length L, and at time t is [Riley et al. 2006]

$$\frac{\partial^2\Psi(x,t)}{\partial x^2} = \frac{1}{u^2}\frac{\partial^2\Psi(x,t)}{\partial t^2}. \tag{3.33}$$

Here u is the wave speed. There are infinitely many discrete solutions to this homogeneous partial differential equation, subject to the boundary condition $\Psi(0,t) = \Psi(L,t) = 0$, namely,

$$\Psi(x,t) = A\sin\left(\frac{n\pi x}{L}\right)\sin\left(\frac{n\pi ut}{L}\right), \quad n = 1, 2, 3\ldots \tag{3.34}$$

That this is the general solution can be verified by substitution of Eq. (3.34) into Eq. (3.33). The frequencies ν of the solutions are also discrete. The time for one cycle is $t_c = 1/\nu$ so that $n\pi ut_c/L = 2\pi$; thus

$$\nu = \frac{nu}{2L}, \quad n = 1, 2, 3, \ldots.$$

Notice that the solution of the wave equation Eq. (3.34) is *separable*, i.e., it has the form $\Psi(x,t) = \psi(x)T(t) = \psi(x)\sin(2\pi\nu t)$. Substitution of this separable form into Eq. (3.33) yields

$$\frac{d^2\psi(x)}{dx^2} + \frac{4\pi^2\nu^2}{u^2}\psi(x) = 0$$

or, since $u = \lambda\nu$,

$$\frac{d^2\psi(x)}{dx^2} + \frac{4\pi^2}{\lambda^2}\psi(x) = 0. \tag{3.35}$$

To generalize to three-dimensions, the operator d^2/dx^2 is replaced by $\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2 \equiv \nabla^2$ giving

$$\nabla^2\psi(x,y,z) + \frac{4\pi^2}{\lambda^2}\psi(x,y,z) = 0. \tag{3.36}$$

Now apply this wave equation to an electron bound to an atomic nucleus. The positively charged nucleus produces an electric field and an attractive electric force on the electron. The electron with (rest) mass m has a total energy E, kinetic energy T, and a potential energy U such that $T = E - U$. The wavelength of the electron is $\lambda = h/p = h/\sqrt{2mT} = h/\sqrt{2m(E-U)}$ (assuming the electron is non-relativistic). Substitution for λ into Eq. (3.36) gives

$$\boxed{-\frac{h^2}{8\pi^2 m}\nabla^2\psi(x,y,z) + U(x,y,z)\psi(x,y,z) = E\psi(x,y,z).} \tag{3.37}$$

This equation is known as the steady-state *Schrödinger's wave equation*, and is the fundamental equation of quantum mechanics. This is a homogeneous equation in which everything on the left-hand side is known except, of course, $\psi(x,y,z)$; but on the right-hand side the electron energy E is not known. Such an equation generally has only the trivial null solution ($\psi = 0$); however, non-trivial solutions can be found if E has very precise and discrete values[7] $E = E_n, n = 0, 1, 2, \ldots$. This equation then says that an electron around a nucleus can have only very discrete values of $E = E_n$, a fact well verified by experiment. Moreover, the wave solution of $\psi_n(x,y,z)$ associated with a given energy level E_n describes the amplitude of the electron wave. The interpretation of ψ_n is discussed below.

3.4.2 The Wave Function

The non-trivial solution $\psi_n(x,y,z)$ of Eq. (3.37) when $E = E_n$ (an eigenvalue of the equation) is called a *wave function*. In general, this is a complex quantity which extends over all space, and may be thought of as the relative amplitude of a wave associated with the particle described by Eq. (3.37). Further, because Eq. (3.37) is a homogeneous equation, then, if ψ' is a solution, so is $\psi = A\psi'$, where A is an arbitrary constant. It is usual to choose A so that the integral of $\psi\psi^* = |\psi|^2$ over all space equals unity, i.e.,[8]

$$\iiint \psi(x,y,z)\psi^*(x,y,z)\,dV = 1. \tag{3.38}$$

Just as the square of the amplitude of a classical wave defines the intensity of the wave, the square of the amplitude of the wave function $|\psi|^2$ gives the probability of finding the particle at any position in space. Thus, the probability that the particle is in some small volume dV around the point (x,y,z) is

$$\text{Prob} = |\psi(x,y,z)|^2\,dV = \psi(x,y,z)\psi^*(x,y,z)\,dV.$$

From this interpretation of ψ, the normalization condition of Eq. (3.38) requires that the particle be somewhere in space.

[7] Mathematicians call such an equation (subject to appropriate boundary conditions) an *eigenvalue* problem in which E_n is called the *eigenvalue* and the corresponding solution $\psi_n(x,y,z)$ the *eigenfunction*.

[8] Here ψ^* denotes the complex conjugate of ψ.

3.4.3 The Uncertainty Principle

With quantum/wave mechanics, it is no longer possible to say that a particle is at a particular location; rather, one can say only that the particle has a probability $\psi\psi^* \, dV$ of being in a volume dV. It is possible to construct solutions to the wave equation such that $\psi\psi^*$ is negligibly small except in a very small region of space. Such a wave function thus localizes the particle to the very small region of space. However, such localized *wave packets* spread out very quickly so that the subsequent path and momentum of the particle is known only within very broad limits. This idea of there being uncertainty in a particle's path and its speed or momentum was first considered by Heisenberg in 1927.

If one attempts to measure both a particle's position along the x-axis and its momentum, there will be an uncertainty Δx in the measured position and an uncertainty Δp in the momentum. Heisenberg's uncertainty principle says there is a limit to how small these uncertainties can be, namely,

$$\Delta x \, \Delta p \geq \frac{h}{4\pi}. \tag{3.39}$$

This limitation is a direct consequence of the wave properties of a particle. The uncertainty principle can be derived rigorously from Schrödinger's wave equation; however, a more phenomenological approach is to consider an attempt to measure the location of an electron with very high accuracy. Conceptually, one could use an idealized microscope, which can focus very short wavelength light to resolve points that are about 10^{-11} m apart. To "see" the electron, a photon must scatter from it and enter the microscope. The more accurately the position is to be determined (i.e., the smaller Δx), the smaller must be the light's wavelength (and the greater the photon's energy and momentum). Consequently, the greater is the uncertainty in the electron's momentum Δp since a higher energy photon, upon rebounding from the electron, will change the electron's momentum even more. *By observing a system, the system is necessarily altered.*

The limitation on the accuracies with which both position and momentum (speed) can be known is an important consideration only for systems of atomic dimensions. For example, to locate a mass of 1 g to within 0.1 mm, the minimum uncertainty in the mass's speed, as specified by Eq. (3.39), is about 10^{-26} m/s, far smaller than errors introduced by practical instrumentation. However, at the atomic and nuclear levels, the uncertainty principle provides a very severe restriction on how position and speed of a particle are fundamentally intertwined.

There is a second uncertainty principle (also by Heisenberg) relating the uncertainty ΔE in a particle's energy E and the uncertainty in the time Δt at which the particle had the energy, namely,

$$\Delta E \, \Delta t \geq \frac{h}{4\pi}. \tag{3.40}$$

This restriction on the accuracy of energy and time measurements is a consequence of the time-dependent form of Schrödinger's wave equation (not presented here), and is of practical importance only in the atomic world. In the atomic and subatomic world involving transitions between different energy states, energy need not be rigorously conserved during very short time intervals Δt, provided the amount of energy violation ΔE is limited to $\Delta E \simeq h/(2\pi\Delta t)$. This uncertainty principle is an important relation used to estimate the lifetimes of excited nuclear states.

3.4.4 Particle in a Potential Well

To illustrate a solution of the Schrödinger's wave equation, consider the case in which a particle is confined within a one-dimensional potential well of finite depth and width a, as shown in Fig. 3.13. The potential is constant at $U(x) = 0$ inside the well and is constant at a value labeled U_0 for all regions outside the well. A solution is sought for the three regions $x < 0$, $0 < x < a$, and $a < x$. To simplify the analysis, it is common to write Eq. (3.37) as

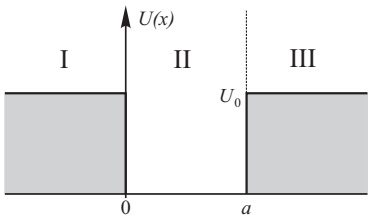

Figure 3.13. Finite square potential well in which the particle energy is less than the well potential.

$$\nabla^2\psi(x,y,z) - \frac{2m}{\hbar^2}[U(x,y,z) - E]\psi(x,y,z) = 0, \tag{3.41}$$

where $\hbar \equiv h/(2\pi)$. Equation (3.41) can then be written for this one-dimensional problem, under the the assumption that $E < U_0$, as

$$\frac{d^2\psi(x)}{dX^2} - k^2\psi(x) = 0 \qquad \text{for } x < 0 \text{ or } x > a, \tag{3.42}$$

and

$$\frac{d^2\psi(x)}{dX^2} + \phi^2\alpha^2\psi(x) = 0 \quad \text{for } 0 < x < a, \tag{3.43}$$

where $k^2 \equiv 2mE/\hbar^2$ and $\phi^2 \equiv 2m(U_0 - E)/\hbar^2$, both positive real numbers. From Eq. (3.42) one infers

$$\psi_1(x) = Ae^{kx} + Be^{-kx} \quad (x < 0) \tag{3.44}$$

and

$$\psi_3(x) = Fe^{kx} + Ge^{-kx} \quad (x > a). \tag{3.45}$$

The negative exponent term in region I and the positive exponent in region III must be excluded because $\psi(x)$ must not become infinite anywhere. Consequently, it is concluded that $B = F = 0$. From Eq. (3.43), one has

$$\psi_2(x) = C\sin(kx) + D\cos(kx), \tag{3.46}$$

the wave function in region II. A condition for the validity of Eq. (3.37) is that $\nabla^2\psi$ must exist and remain finite everywhere. Here this condition requires ψ and $d\psi/dx$ be continuous across all boundaries (and at infinity). From this requirement, values of the arbitrary constants A, G, C, and D can be determined. Beforehand, a special case will be considered.

Particle in a Box

As $U_0 \to \infty$ the parameter $\phi \to \infty$ so that $\psi_1(0)$ and $\psi_3(a)$ must vanish so the only non-zero values of $\psi(x)$ are to be found in region II. In other words, the particle must be confined inside the well. From Eq. (3.46) it is seen that

$$\psi_2(0) = 0 = D \qquad \text{and } \psi_2(x) = C\sin(kx). \tag{3.47}$$

Because $\psi_2(a) = 0 = C\sin(kx)$ to obtain non-trivial solutions the argument ka must assume discrete values (or *eigenvalues*)

$$k = \frac{n\pi}{a}, \quad n = \pm1,\ \pm2,\ \pm3,\ \ldots,. \tag{3.48}$$

so the wavefunctions have the form

$$\psi_n(x) = C\sin\left(\frac{n\pi x}{a}\right), \tag{3.49}$$

and the energy of the particles is restricted to discrete values

$$E_n = \frac{n^2h^2\pi^2}{2m} = \frac{1}{2m}\left(\frac{n\pi\hbar}{a}\right)^2. \tag{3.50}$$

Because the energy of the particle is quantized, so is its momentum. Consequently,

$$E_n = \frac{p_n^2}{2m} = \frac{\hbar^2 k_n^2}{2m} = \frac{n^2\pi^2\hbar^2}{2ma^2}. \tag{3.51}$$

Finally the constant C is determined by the normalization condition

$$\int_{\infty}^{\infty} \psi_n^*(x)\psi_n(x)\, dx = \int_0^a A_n^2 \sin^2\left(\frac{n\pi x}{a}\right) dx = 1. \tag{3.52}$$

Upon evaluation of the integral, it is found $A_n = \sqrt{2/a}$ so the wave functions for a particle in a box are

$$\psi_n(x) = \sqrt{\frac{2}{a}} \sin\left(\frac{n\pi x}{a}\right). \tag{3.53}$$

In Fig. 3.14 the wave function is shown for $n = 3$.

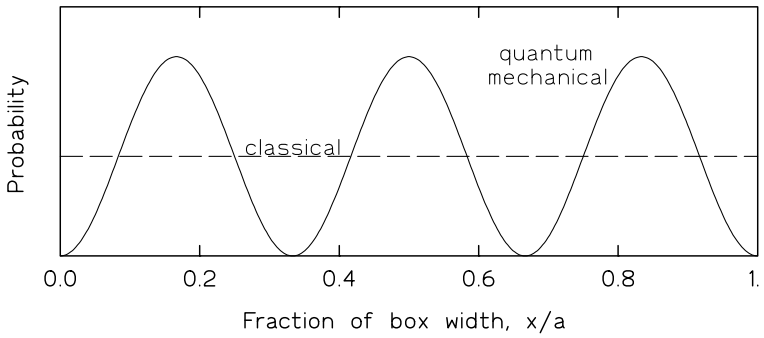

Figure 3.14. The probability distribution for finding a particle in quantum state $n = 3$ with energy E_3 at points in a one-dimensional box.

From this analysis two distinct differences between classical mechanics and wave mechanics are apparent. First, a particle confined to a box with rigid boundaries can have any speed, energy or linear momentum, whereas in wave mechanics these variables have very distinct discrete values. Second, classically the particle can be anywhere in the box with equal probability, whereas in wave mechanics the probability of observing the particle varies with position.

Particle in a Finite Potential Well

Now let us return to a particle in a finite potential well. The most general solution is given by Eqs. (3.44), (3.45), and (3.46), but now the boundary conditions are

$$\psi_1(-\infty) = 0\ ,\ \psi_3(\infty) = 0$$

$$\psi_1(0) = \psi_2(0)\ ,\ \psi_2(a) = \psi_3(a)$$

$$\left.\frac{d\psi_1}{dx}\right|_{x=0} = \left.\frac{d\psi_2}{dx}\right|_{x=0}\ ,\ \left.\frac{d\psi_2}{dx}\right|_{x=a} = \left.\frac{d\psi_3}{dx}\right|_{x=a}$$

From the first two boundary conditions, the coefficients B and F must be zero if the wave function disappears at $\pm\infty$. Hence, the wavefunctions reduce to

$$\psi_1(x) = Ae^{\phi x}, \qquad \psi_2(x) = C\sin(kx) + D\cos(kx), \qquad \psi_3(x) = Ge^{-\phi x}. \tag{3.54}$$

From the boundary conditions on $\psi_1(0)$ and $\psi_3(a)$ one finds $A = D$ and $\phi A = kC$ from which it follows that $D = kC/\phi$. Finally, the boundary conditions on the slope of the wave functions give

$$C\sin(ka) + D\cos(ka) = Ge^{-\phi a} \quad \text{and} \quad k(C\cos(ka) - D\sin(ka)) = -\phi G e^{-\phi a}. \tag{3.55}$$

Substitution of $D = kC/\phi$ into Eqs. (3.55) yields

$$C\sin(ka) + \frac{kC}{\phi}\cos(ka) = Ge^{-\phi a}, \tag{3.56}$$

and

$$\frac{k}{\phi}\left((\frac{kC}{\phi}\sin(ka) - C\cos(ka)\right) = Ge^{-\phi a} \quad . \tag{3.57}$$

Equating these two results and rearranging terms yields

$$C\left[(k^2 - \phi^2)\sin(ka) - 2\phi k\cos(ka)\right] = 0. \tag{3.58}$$

Here it is assumed that the wavefunction ψ and coefficient C are non-zero. Equation (3.58) can then be rewritten as

$$\tan(ka) = \frac{2\phi k}{k^2 - \phi^2}, \tag{3.59}$$

a relation that relates the allowable values of ϕ and k. With the following substitutions,

$$\phi_0 = \sqrt{\frac{2mU_0}{\hbar^2}}, \quad \xi = \frac{E}{U_0}, \quad \phi = \phi_0\sqrt{1-\xi}, \quad k = \phi_0\sqrt{\xi}, \tag{3.60}$$

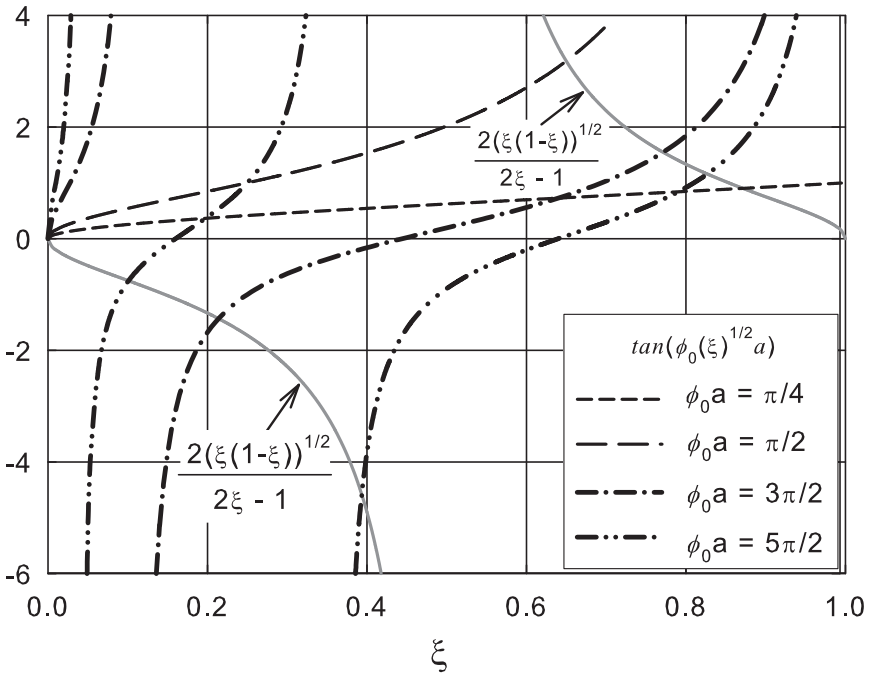

Figure 3.15. Solutions to the finite square well for different values of $\phi_0\alpha$.

Eq. (3.59) is reduced to the following

$$\tan(\phi_0\sqrt{\xi}a) = \frac{2\sqrt{\xi(1-\xi)}}{2\xi-1} \quad . \tag{3.61}$$

The solutions to Eq. (3.61) can be found by plotting both sides versus ξ and locating the intercepts, the results of which are shown in Fig. 3.15. The allowed energies are found by multiplying the intercept value of ξ by the potential energy U_0. The number of possible solutions, for a given value of $\phi_0 a$ is seen to be

$$\text{If } (n-1)\,\pi\ < \phi_0 a < n\pi \quad \text{there are } n \text{ solutions}, \quad n = 1, 2, 3, \ldots.$$

Each solution defines an allowed energy state in the well. Observe from Fig. 3.15 that more states appear as a is increased. Further, as a is decreased, the general trend is the solution for E (a function of ξ) increases in value. In conclusion, (1) the number of allowed states increases as the well dimension a increases, and (2) the allowed states are pushed upwards towards U_0 as the well dimension a decreases.

3.4.5 The Hydrogen Atom

The hydrogen atom, the simplest atom, can be considered as a system of two interacting point charges, the proton (nucleus) and an electron. The electrostatic attraction between the electron and proton is described by Coulomb's law. The potential energy of a bound electron is given by,

$$U(r) = -\frac{q_e^2}{r}, \tag{3.62}$$

where r is the distance between the electron and the proton.

The three-dimensional Schrödinger wave equation in spherical coordinates for the electron bound to the proton is [Griffiths 2005]

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial\psi}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2} + \frac{8\pi^2\mu}{h^2}\left[E - U(r)\right]\psi = 0, \tag{3.63}$$

where $\psi = \psi(r,\theta,\phi)$ and μ is the electron mass (more correctly the reduced mass of the system).

To solve this partial differential equation for the wave function $\psi(r,\theta,\phi)$, first replace it by three equivalent ordinary differential equations involving functions of only a single independent variable. To this end, the "separation of variables" method is used to seek a solution of the form

$$\psi(r,\theta,\phi) = R(r)\Theta(\theta)\Phi(\phi). \tag{3.64}$$

Substitute this form into Eq. (3.63) and multiply the result by $r^2\sin^2\theta/(R\Theta\Phi)$ to obtain

$$\frac{\sin^2\theta}{R(r)}\frac{d}{dr}\left(r^2\frac{dR(r)}{dr}\right) + \frac{1}{\Phi(\phi)}\frac{d^2\Phi(\phi)}{d\phi^2} + \frac{\sin\theta}{\Theta(\theta)}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta(\theta)}{d\theta}\right) + \frac{8\pi^2\mu}{h^2}r^2\sin^2\theta\left[E - U(r)\right] = 0. \tag{3.65}$$

The second term is only a function of ϕ, while the other terms are independent of ϕ. This term, therefore, must equal a constant, $-m^2$ say. Thus,

$$\frac{d^2\Phi(\phi)}{d\phi^2} = -m^2\Phi(\phi). \tag{3.66}$$

Equation 3.65, upon division by $\sin^2\theta$ and rearrangement becomes

$$\frac{1}{R(r)}\frac{d}{dr}\left(r^2\frac{dR(r)}{dr}\right) + \frac{8\pi^2\mu r^2}{h^2}\left[E - U(r)\right] = -\frac{1}{\sin\theta\Theta(\theta)}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta(\theta)}{d\theta}\right) + \frac{m^2}{\sin^2\theta} = 0. \tag{3.67}$$

Since the terms on the left are functions only of r and the terms on the right are functions only of θ, both sides of this equation must be equal to the same constant, β say. Thus two ordinary differential equations are obtained, one for $R(r)$ and one for $\Theta(\theta)$, namely,

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta(\theta)}{d\theta}\right) - \frac{m^2}{\sin^2\theta}\Theta(\theta) + \beta\Theta(\theta) = 0, \tag{3.68}$$

and

$$\frac{1}{r^2}\frac{d}{dr}\left[r^2\frac{dR(r)}{dr}\right] + \frac{\beta}{r^2}R(r) + \frac{8\pi^2\mu}{h^2}\left[E - U(r)\right]R(r) = 0. \tag{3.69}$$

Thus Eq. (3.63) is reduced to three ordinary, homogeneous, differential equations [Eq. (3.66), Eq. (3.68), and Eq. (3.69)], whose solutions, when combined, give the entire wave function $\psi(r,\theta,\phi) = R(r)\Theta(\theta)\Phi(\phi)$. Each of these equations is an eigenvalue problem which yields "quantum numbers." These quantum numbers are used to describe the possible electron configurations in a hydrogen atom. The solutions also yield relationships between the quantum numbers. The solution details are omitted—see any book on quantum mechanics for the explicit solutions, for example Griffiths [2005]. The present discussion is restricted to the essential features that arise from each equation.

The most general solution of Eq. (3.66) is

$$\Phi(\phi) = A\sin m\phi + B\cos m\phi, \tag{3.70}$$

where A and B are arbitrary. However, it is required $\Phi(0) = \Phi(2\pi)$ since $\phi = 0$ and $\phi = 2\pi$ are the same azimuthal angle. This boundary condition then requires m to be an integer, i.e., $m = 0, \pm1, \pm2, \ldots$. For each *azimuthal* quantum number m, the corresponding solution is denoted by $\Phi_m(\phi)$.

Equation (3.68) in θ has normalizable solutions only if the separation constant has the form $\beta = \ell(\ell+1)$ where ℓ is a positive integer or zero, and is called the *angular momentum* quantum number. Moreover, the azimuthal quantum number m must be restricted to $2\ell+1$ integer values, namely, $m = 0, \pm1, \pm2, \ldots, \pm\ell$. The corresponding solutions of Eq. (3.68) are denoted by $\Theta_{\ell m}(\theta)$ and are known to mathematicians as the associate Legendre functions of the first kind; however, these details are not of concern here.

Finally, the solution of Eq. (3.69) for the radial component of the wave function, with $\beta = \ell(\ell+1)$ and $U(r) = -q_e^2/r$, has normalizable solutions only if the electron's energy has the (eigen)value

$$E_n = -\frac{2\pi^2\mu q_e^2}{h^2 n^2}, \quad \text{where } n = 1, 2, 3, \ldots \tag{3.71}$$

The integer n is called the *principal* quantum number. Moreover, to obtain a solution, the angular quantum number ℓ must be no greater than $n-1$, i.e., $\ell = 0, 1, 2, \ldots, (n-1)$. The corresponding radial solution is denoted by $R_{n\ell}(r)$ and mathematically is related to the associated Laguerre function.

Thus, the wave functions for the electron bound in the hydrogen atom have only very discrete forms $\psi_{n\ell m}(r,\theta,\phi) = R_{n\ell}(r)\Theta_{\ell m}(\theta)\Phi_m(\phi)$. For the hydrogen atom, the energy of the electron is given by Eq. (3.71) and is independent of the angular moment or azimuthal quantum numbers m and ℓ (this is not true for multielectron atoms).

Special Notation for Electron States

A widely used, but strange, notation has been of long standing in describing the n and ℓ quantum numbers of particular electron states. The letters s, p, d, f, g, h, and i are used to denote values of the angular momentum quantum number ℓ of 0, 1, 2, 3, 4, 5, and 6, respectively. The value of n is then used as a prefix to the angular moment letter. Thus a bound electron designated as $5f$ refers to an electron with $n = 5$ and $\ell = 3$.

Examples of Wave Functions for Hydrogen

In Fig. 3.16, density plots of $|\psi_{n\ell m}|^2 = \psi^*_{n\ell m}\psi_{n\ell m}$ are shown for different electron states in the hydrogen atom. These plots are slices through the three-dimensional $|\psi|^2$ in a plane perpendicular to the x-axis and through the atom's center. Because $|\psi|^2$ is the probability of finding the electron in a unit volume, the density plots directly show the regions where the electron is most likely to be found. The s states ($\ell = 0$) are spherically symmetric about the nucleus, while all the others have azimuthal and/or polar angle dependence.

Electron Energy Levels in Hydrogen

For hydrogen, the energy of the bound electron is a function of n only (see Eq. (3.71)). Thus, for $n > 1$, the quantum numbers ℓ and m may take various values without changing the electron energy, i.e., the allowed electron configurations fall into sets in which all members of the set have the same energy. Thus, in Fig. 3.16, an electron has the same energy in any of the four $4f$ electron states or the three $4d$ states, even though the distribution of the electron wave function around the nucleus is quite different for each state. Such states with the same electron binding energy are said to be *degenerate*.

The Spin Quantum Number

It was found, first from experiment and later by theory, that each quantum state (specified by values for n, ℓ, and m) can accommodate an electron in either of two spin orientations. The electron, like the proton and neutron, has an inherent angular momentum with a value of $\frac{1}{2}h/(2\pi)$. In a bound state (defined by n, ℓ, and m) the electron can have its spin "up" or "down" with respect to the z-axis used to define angular momentum. Thus, a fourth quantum number $m_s = \pm\frac{1}{2}$ is needed to unambiguously define each possible electron configuration in an atom.

Dirac showed in 1928 that when the Schrödinger wave equation is rewritten to include relativistic effects, the spin quantum number m_s is inherent in the solution along with the quantum numbers n, ℓ, and m, which were also inherent in the wave function solution of the non-relativistic Schrödinger's wave equation [Schiff 1968].

3.4.6 Energy Levels for Multielectron Atoms

The solution of Schrödinger's equation for the hydrogen atom can be obtained analytically, but the solution for a multielectron system cannot. This difficulty arises because of the need to add a repulsive component to the potential energy term to account for the interactions among the electrons. To obtain a solution for a multielectron atom, numerical approximation techniques must be used together with high speed computers. Such a discussion is far beyond the scope of this text.

There is, however, one important result for multielectron atoms that should be described here. The energies of the electronic levels in atoms with more than one electron are functions of both n and ℓ. The energy degeneracy in the angular momentum quantum number disappears. Thus states with the same n but different ℓ values have slightly different energies, and there is a significant reordering of the electron energy levels compared to those in the hydrogen atom.

Electron energy levels with the same value of n and ℓ but different values of m are still degenerate in energy; however, this degeneracy is removed in the presence of a strong external magnetic field (the Zeeman effect). An electron moving about a nucleus creates a magnetic dipole whose strength of interaction with an external magnetic field varies with the quantum numbers ℓ and m.

The Electronic Structure of Atoms

Each electron in an atom can be characterized by its four quantum numbers n, ℓ, m, and m_s. Further, according to Pauli's exclusion principle (1925), no two electrons in an atom can have the same quantum numbers. An assignment of a set of four quantum numbers to each electron in an atom, no sets being alike in all four numbers, then defines a quantum state for an atom as a whole. For ground-state atoms, the

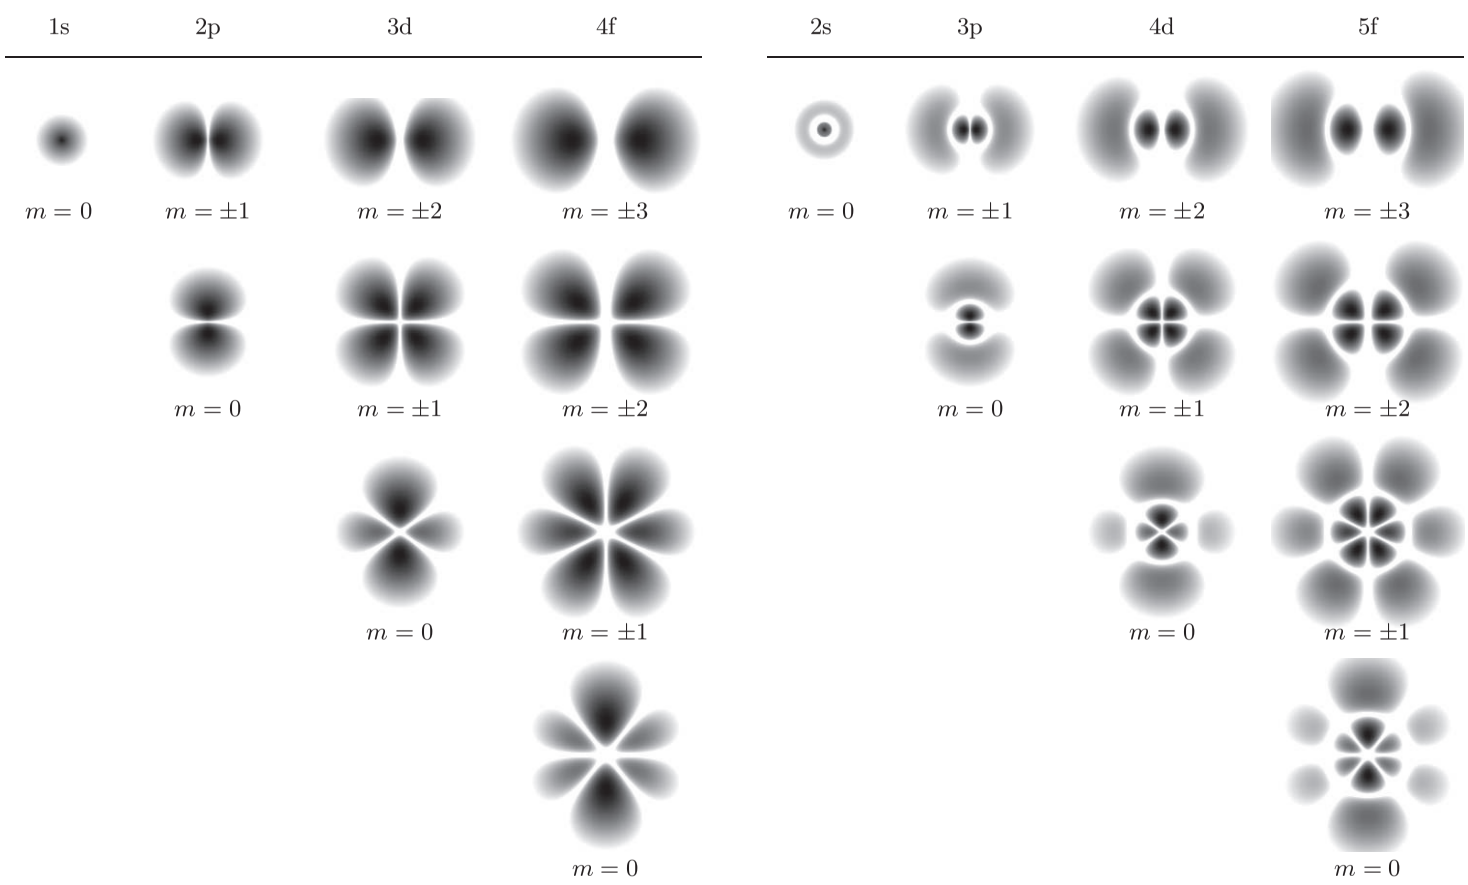

Figure 3.16. Density plots of $\psi^*\psi$ for different electron eigenstates in the hydrogen atom. Plots are sectional views of the probability density in a plane containing the polar axis, which is vertical and in the plane of the paper. Scale of the right group is about 15% bigger than that of the left group. After: R.B. Leighton, *Principles of Modern Physics*, McGraw Hill, New York, 1959.

electrons are in the lowest energy electron states. For an atom in an excited state, one or more electrons are in electron states with energies higher than some vacant states. Electrons in excited states generally drop very rapidly ($\sim 10^{-7}$ s) into vacant lower energy states. During these spontaneous transitions, the difference in energy levels between the two states must be emitted as a photon (*fluorescence* or *x rays*) or be absorbed by other electrons in the atom (thereby causing them to change their energy states).

Crucial to the chemistry of atoms is the arrangement of atomic electrons into various electron *shells*. All electrons with the same n number constitute an *electron shell*. For $n = 1, 2, \ldots, 7$, the shells are designated $K, L, M, \ldots, Q$.

Consider electrons with $n = 1$ (K shell). Since $\ell = 0$ (s state electrons), then $m = 0$ and $m_s = \pm\frac{1}{2}$. Hence, there are only 2 $1s$ electrons, written as $1s^2$, in the K shell. In the L shell ($n = 2$), $\ell = 0$ or 1. For $\ell = 0$, there are two $2s$ electrons (denoted by $2s^2$), and for $\ell = 1$ ($m = -1, 0, 1$), there are six $2p$ electrons (denoted by $2p^6$). Thus in the L shell there are a total of eight electrons ($2s^2 2p^6$). Electrons with the same value of ℓ (and n) are referred to as a *subshell*. For a given subshell, there are $(2\ell + 1)$ m values, each with two m_s values, giving a total of $2(2\ell + 1)$ electrons per subshell, and $2n^2$ electrons per shell. A shell or subshell containing the maximum number of electrons is said to be *closed*.

The Periodic Table of Elements can be described in terms of the possible number of electrons in the various subshells. The number of electrons in an atom equals its atomic number Z and determines its position in the Periodic Table. The chemical properties are determined by the number and arrangement of the electrons. Each element in the table is formed by adding one electron to that of the preceding element in the Periodic Table in such a way that the electron is most tightly bound to the atom. The arrangement of the electrons for the elements with electrons in only the first four shells is shown in Table 3.3.

3.4.7 Success of Quantum Mechanics

Quantum mechanics has been an extremely powerful tool for describing the energy levels and the distributions of atomic electrons around a nucleus. Each energy level and configuration is uniquely defined by four quantum numbers: n the principal quantum number, ℓ the orbital angular momentum quantum number, m_ℓ the z-component of the angular momentum, and $m_s = \pm 1/2$, the electron spin number. These numbers arise naturally from the analytical solution of the wave equation (as modified by Dirac to include special relativity effects) and thus avoid the *ad hoc* introduction of orbital quantum numbers required in earlier atomic models.

Inside the nucleus, quantum mechanics is also thought to govern. However, the nuclear forces holding the neutrons and protons together are much more complicated than the electromagnetic forces binding electrons to the nucleus. Consequently, much work continues in the application of quantum mechanics (and its more general successor quantum electrodynamics) to predicting energy and configuration states of nucleons. Nonetheless, the fact that electronic energy levels of an atom and nuclear excited states are discrete with very specific configurations is a key concept in modern physics. Moreover, when one state changes spontaneously to another state, energy is emitted or absorbed in specific discrete amounts.

3.5 The Fundamental Constituents of Ordinary Matter

Throughout this book, atoms, neutrons, and protons are treated as the only "fundamental" entities of interest. Indeed, for the energies involved in practical nuclear and atomic interactions, this view is well justified. However, at kinetic energies produced in particle accelerators or found in some cosmic rays, the microscopic structure of matter is found to be much more complicated. This fine structure is not of practical importance, however, in understanding radiation detectors; but for completeness, a brief overview of the constituents of ordinary matter is presented here.

Although neutrons and protons are often considered "fundamental" particles, it is now known that they are composed of other smaller particles called *quarks* held together by the exchange of massless particles

Table 3.3. Electron shell arrangement for the lightest elements.

Element	Z	shell and electron designation

called *gluons*, which are the carriers of the nuclear force. The protons and neutrons are bound together in a nucleus by the residual interactions of the gluons in the neutrons and protons.

From studies of nuclear interactions produced by energetic cosmic rays and by particle accelerators, it is believed that there are six different types or "flavors" of quarks with the fanciful names of up (u), down (d), strange (s), charm (c), top (t), and bottom (b). For each quark there exists an antiquark, denoted by $\bar{u}$, $\bar{d}$, etc. Each quark has a charge that is a fraction of the electron charge, namely the u, d, c, s, t, and b quarks have charge $2/3, -1/3, 2/3, -1/3, 2/3$, and $-1/3$, respectively. An antiquark has the same mass and angular momentum, but opposite charge, as its real quark counterpart.

With the quarks and antiquarks two types of composite particles are formed. *Baryons* are composed of 3 quarks; for example, the neutron is a (ddu) composite (with a net charge of $-1/3 - 1/3 + 2/3 = 0$) and the proton is a (uud) composite (with a net charge of $2/3 + 2/3 - 1/3 = 1$). *Mesons* are composed of a quark-antiquark pair; for example, a π^+ meson is a (u,$\bar{d}$) pair and a π^- meson is a ($\bar{u}$,d) pair.

In addition to the quarks, there is another class of fundamental particles, called *leptons* consisting of the electron, muon, and tau particles, each with an associated neutrino. Each of the leptons also has an antiparticle. The quarks and leptons are exceedingly small with sizes less than about 10^{-19} m and are indeed fundamental particles, i.e., not composite particles.

"Ordinary" matter is mostly composed of neutrons, protons, electrons, and neutrinos, each of which has an angular momentum of $\pm h/(2\pi)$ (or a "spin" of 1/2) and, as such, are called *fermions*. Most of the possible composite baryons and mesons are extremely unstable, with the heavier quarks decaying rapidly to less massive ones by the forces mitigated by *bosons*, such as the photon or $W^{\pm}$ boson, all of which have spin = 1. For example, a free neutron can decay to a proton when a d quark changes to an u quark by emitting a W^- boson, which almost instantly decays to an electron (e^-) and an electron antineutrino ($\overline{\nu}_e$). The known "fundamental" particles with their mass and charge are shown in Table 3.4. Whether there are additional fundamental particles or even whether these particles are themselves composite particles made from even more complex structures are unknown and are presently topics of great interest to high energy physicists.

However, in this work the electron, neutron, and proton are treated as fundamental indivisible particles, because the composite nature of nucleons becomes apparent only under extreme conditions, such as those encountered during the first second after the creation of the universe (the "big bang") or in high energy particle accelerators. Such gigantic energies are not addressed in this book. Rather, the energy of radiation considered in this work is sufficient only to rearrange or remove the electrons in an atom or the neutrons and protons in a nucleus.

3.5.1 Dark Matter and Energy

In our universe all *ordinary* matter is composed of electrons, neutrinos, and up and down quarks which are bound together in protons and neutrons. However, over the past several decades, it has become apparent that the gravitational forces from ordinary matter are insufficient to explain (1) the motion of stars near the center of galaxies, (2) the filigreed distribution of galaxies in the universe, and (3) the accelerating expansion of the universe itself. To explain these observations, astrophysicists have come to accept that there must be vast amounts of *dark matter* to provide extra gravitational forces on stars in a galaxy and between galaxies. Further, the amount of dark matter must be about five times that of ordinary matter. Although dark matter can exert gravitational forces, it does not interact with light and, hence, is invisible to us. The fundamental particles of dark matter are unknown and are the subject of much current speculation.

Astrophysicists have also had to postulate the existence of something called *dark energy* that must pervade the universe in order to explain the observed accelerated expansion of our universe. Again, what constitutes dark energy is unknown, but the amount of dark energy represents about 70% of the total mass/energy of our universe!

Table 3.4. The fundamental particles that make up "ordinary" matter. Each fermion has a corresponding antiparticle with the same mass but of opposite charge. Data are from Yao et al. [2006]

Fermions (spin = 1/2)					
quarks			**leptons**		
flavor	mass ($\mathrm{GeV/c^2}$)	charge (q_e)	type	mass ($\mathrm{GeV/c^2}$)	charge (q_e)

3.5.2 Atomic and Nuclear Nomenclature

The identity of an atom is uniquely specified by the number of neutrons N and protons Z in its nucleus. For an electrically neutral atom, the number of electrons equals the number of protons Z, which is called the *atomic number*. All atoms of the same *element* have the same atomic number. Thus, all oxygen atoms have 8 protons in the nucleus while all uranium atoms have 92 protons. The nucleus of an atom with a unique N and A numbers is often referred to as a *nuclide*. There are about 3200 known nuclides.

However, atoms of the same element may have different numbers of neutrons in the nucleus. Atoms of the same element, but with different numbers of neutrons, are called *isotopes*. The symbol used to denote a particular isotope is

$$\boxed{{}^{A}_{Z}\mathrm{X}}$$

where X is the chemical symbol and $A \equiv Z + N$, which is called the *mass number*. For example, two uranium isotopes are ${}^{235}_{92}\mathrm{U}$ and ${}^{238}_{92}\mathrm{U}$. The use of both Z and X is redundant because one specifies the other. Consequently, the subscript Z is often omitted, so that one may write, for example, simply ${}^{235}\mathrm{U}$ and ${}^{238}\mathrm{U}$.[9]

Because isotopes of the same element have the same number and arrangement of electrons around the nucleus, the chemical properties of such isotopes are nearly identical. Only for the lightest isotopes (e.g., hydrogen ${}^{1}\mathrm{H}$, deuterium ${}^{2}\mathrm{H}$, and tritium ${}^{3}\mathrm{H}$) are small differences observed. For example, light water ${}^{1}\mathrm{H_2O}$

[9] To avoid superscripts, which were hard to make on old-fashioned typewriters, the simpler form U-235 and U-238 was often employed. However, with modern word processing, this form should no longer be used.

freezes at 0°C, while heavy water ^2H_2O (or D_2O since deuterium is often given the chemical symbol D) freezes at 3.82°C.

3.5.3 Relative Atomic Masses

The *relative atomic mass* $\mathcal{A}$ of any particular isotope, a dimensionless physical quantity, is the ratio of the mass of one atom of the isotope to 1/12 the mass of an atom of ^{12}C. It is equivalent to the older term *atomic weight*.[10]

The relative atomic mass of an element (typically composed of several isotopes) is slightly more involved. The relative atomic mass of an element is ratio of the *average* mass of atoms in a sample of the element to 1/12 the mass of an atom of ^{12}C. Thus the elemental relative atomic mass can vary depending on the source of the sample. For example, elemental samples from different geological, biological, or extraterrestrial sources often have different relative atomic masses because of their different isotopic compositions. In a similar manner, the relative molecular weight is the average mass of molecules in a sample of the molecules to 1/12 the mass of an atom of ^{12}C.

Most naturally occurring elements are composed of two or more isotopes. The *isotopic abundance* γ_i of the i-th isotope in a given element is the fraction of the atoms in the element that are that isotope. As with the elemental relative atomic mass, the isotopic abundances of a sample depends on the origins of the sample. For a specified element, the *elemental atomic weight* is the weighted average of the atomic weights of all naturally occurring isotopes of the element, weighted by the isotopic abundance of each isotope, i.e.,

$$\mathcal{A} = \sum_i \frac{\gamma_i(\%)}{100} \mathcal{A}_i, \tag{3.72}$$

where the summation is over all the isotopic species comprising the element.

Both the terms relative atomic mass and atomic weight are often loosely used to refer to a *standard* atomic weight. The elemental standard atomic weight is the average mass of the atoms in a *normal* sample of the element to 1/12 the mass of an atom of ^{12}C. A normal sample is one from any reasonable source of the element or its compounds used in commerce for industry and one that has not undergone significant isotopic modification. These values are widely published in books and on wall charts of the Periodic Table.

3.5.4 The Atomic Mass Unit

Closely related to the concept of the relative atomic mass is the *unified atomic mass unit*,[11] abbreviated as u, defined such that the mass of a neutral atom of ^{12}C atom is 12 u. Equivalently, the mass of Avogadro's number of ^{12}C atoms (Avogadro's number = 1 mole) is 0.012 kg. Thus, the SI unit for 1 u equals $(1/12)(0.012\ \text{kg}/N_a) = 1.660\,538\,7 \times 10^{-27}$ kg. An alternative and useful value of 1 u is $931.494\,043/c^2$ MeV. Masses of the different atomic nuclides are available in many compilations, e.g., Shultis and Faw [2008]. It then follows that the mass M of an atom measured in atomic mass units numerically equals the atom's relative atomic mass $\mathcal{A}$. The atomic weight of a nuclide almost equals (within less than one percent) the atomic mass number A of the nuclide. Thus for approximate calculations, one can usually assume $\mathcal{A} \simeq A$.

[10] The continued use of "atomic weight" and "relative atomic mass" has caused much controversy since the 1960s, primarily because of the distinction in physics between "weight" and "mass."

[11] Previously called the *atomic mass unit* and abbreviated *amu*, it was based on ^{16}O rather than ^{12}C. This older metric and terminology are obsolete. In terms of today, *unified atomic mass unit* and *atomic mass unit* are often casually interchanged, but both refer to 'u' based on ^{12}C.

3.5.5 Avogadro's Number

Avogadro's constant is the key to the atomic world since it relates the number of microscopic entities in a sample to a macroscopic measure of the sample. Specifically, Avogadro's constant $N_a \simeq 6.022 \times 10^{23}$ equals the number of atoms in 12 grams of ^{12}C. Few fundamental constants need be memorized, but an approximate value of Avogadro's constant should be.

The importance of Avogadro's constant lies in the concept of the mole. A *mole* (abbreviated mol) of a substance is defined to contain as many "elementary particles" as there are atoms in 12 g of ^{12}C. In older texts, the mole was often called a "gram-mole" but is now called simply a mole. The "elementary particles" can refer to any identifiable unit that can be unambiguously counted. One can, for example, speak of a mole of stars, persons, molecules, or atoms.

Because the atomic weight of ^{12}C is defined to be 12 and because 12 g of ^{12}C is defined to contain 1 mol of atoms, it follows that the mass *in grams* of any atomic species that numerically equals the dimensionless atomic weight of the species must also contain 1 mole of atoms. The mass in grams of a substance that equals the dimensionless atomic or molecular weight is sometimes called the *gram atomic weight* or *gram molecular weight*. Thus, one gram atomic or molecular weight of any substance represents one mole of the substance and contains as many atoms or molecules as there are atoms in one mole of ^{12}C, namely, N_a atoms or molecules. That one mole of any substance contains N_a entities is known as *Avogadro's law* and is the fundamental principle that relates the microscopic world to the everyday macroscopic world. Table 3.5 illustrates how Avogadro's number N_a, together with the atomic weight $\mathcal{A}$, is the key to transforming between macroscopic masses and the number of atoms.

Table 3.5. Use of Avogadro's constant N_a (atoms/mol) and the atomic weight $\mathcal{A}$ (g/mol) to move between the atomic and macroscopic worlds.

Macroscopic World	Transformation $\longleftrightarrow$			**Microscopic World**
m (g)	$\xrightarrow{\div\mathcal{A}}$	$\frac{m}{\mathcal{A}}$ (mols)	$\xrightarrow{\times N_a}$	$\frac{m}{\mathcal{A}}N_a$ (atoms)
$m = \frac{N}{N_a}\mathcal{A}$ (g)	$\xleftarrow{\times\mathcal{A}}$	$\frac{N}{N_a}$ (mols)	$\xleftarrow{\div N_a}$	N (atoms)
$\rho\ \left(\frac{\text{g}}{\text{cm}^3}\right)$	$\xrightarrow{\div\mathcal{A}}$	$\frac{\rho}{\mathcal{A}}\ \left(\frac{\text{mol}}{\text{cm}^3}\right)$	$\xrightarrow{\times N_a}$	$\frac{\rho N_a}{\mathcal{A}}\ \left(\frac{\text{atoms}}{\text{cm}^3}\right)$
$m = \frac{\mathcal{A}}{N_a}\ \left(\frac{\text{g}}{\text{atom}}\right)$	$\xleftarrow{\times\mathcal{A}}$	$\frac{1}{N_a}$ (mol)	$\xleftarrow{\div N_a}$	1 (atom)

3.5.6 Mass of an Atom

With Avogadro's number, many basic properties of atoms can be inferred. For example, the mass of an individual atom can be found. Since a mole of a group of identical atoms (with a mass of $\mathcal{A}$ grams) contains N_a atoms, the mass of an individual atom is

$$M\,(\text{g/atom}) = \mathcal{A}/N_a \simeq A/N_a. \tag{3.73}$$

The approximation of $\mathcal{A}$ by A is usually quite acceptable for all but the most precise calculations.

3.5.7 Number Density of Atoms and Isotopes

Avogadro's number also determines the atom density (number of atoms per cm^3) of a substance. For a homogeneous substance of a single species and with mass density ρ g/cm^3, 1 cm^3 contains $\rho/\mathcal{A}$ moles of the

substance and $\rho N_a/\mathcal{A}$ atoms. The atom density N is thus

$$\boxed{N \text{ (atoms/cm}^3) = \frac{\rho}{\mathcal{A}} N_a.} \tag{3.74}$$

In radiation detection the number density of a particular isotope of an element is often of interest. To find the atom density N_i of isotope i of an element with atom density N, simply multiply N by the fractional isotopic abundance $\gamma_i/100$ for the isotope, i.e., $N_i = (\gamma_i/100)N$.

The same manner the atom density can be found of a particular element contained in a homogeneous substance composed entirely of a certain molecule. In this case, N in Eq. (3.74) is the molecular density and $\mathcal{A}$ the gram molecular weight. The number of atoms of a particular type, per unit volume, is found by multiplying the molecular density by the number of the atoms of interest per molecule.

The composition of a mixture such as air is often specified by the mass fraction w_i of each constituent. If the mixture has a mass density ρ, the mass density of the ith constituent is $\rho_i = w_i\rho$. The density N_i of the ith component is thus

$$N_i = \frac{\rho_i N_a}{\mathcal{A}_i} = \frac{w_i \rho N_a}{\mathcal{A}_i}. \tag{3.75}$$

If the composition of a substance is specified by a chemical formula, such as $\mathrm{X}_n\mathrm{Y}_m$, the molecular weight of the mixture is $\mathcal{A} = n\mathcal{A}_X + m\mathcal{A}_Y$ and the mass fraction of component X is

$$w_X = \frac{n\mathcal{A}_X}{n\mathcal{A}_X + m\mathcal{A}_Y}. \tag{3.76}$$

Finally, as a general rule of thumb, it should be remembered that atom densities in solids and liquids are usually between 10^{21} and 10^{23} atoms cm^{-3}. Gases at standard temperature and pressure are typically less by a factor of 1000.

3.5.8 Size of an Atom

For a substance with an atom density of N atoms/cm^3, each atom has an associated volume of $V = 1/N$ cm^3. If this volume is considered a cube, the cube's width is $V^{1/3}$. For ^{238}U, the cubical size of an atom is thus $1/N^{1/3} = 2.7 \times 10^{-8}$ cm. Measurements of the size of atoms reveal a diffuse electron cloud about the nucleus. Although there is no sharp edge to an atom, an effective radius can be defined such that outside this radius, an electron is very unlikely to be found. Almost all atoms with $Z > 10$ have radii between 1×10^{-8} and 2×10^{-8} cm. As Z increases, i.e., as more electrons and protons are added, the size of the electron cloud changes little, but simply becomes more dense. Hydrogen, the lightest element, is also the smallest with a radius of about 0.5×10^{-8} cm.

3.5.9 Nuclear Dimensions

Size of a Nucleus

If each proton and neutron in the nucleus has the same volume, the volume of a nucleus should be proportional to A. This has been confirmed by many measurements that have explored the shape and size of nuclei. Nuclei, to a first approximation, are spherical or very slightly ellipsoidal with a somewhat diffuse surface. In particular, it is found that an effective spherical nuclear radius is

$$R = R_o A^{1/3}, \qquad \text{with } R_o \simeq 1.25 \times 10^{-13} \text{ cm}. \tag{3.77}$$

The associated volume is

$$V_{\text{nucleus}} = \frac{4}{3}\pi R^3 \simeq 7.25 \times 10^{-39} A \quad \text{cm}^3. \tag{3.78}$$

Since the atomic radius of about 2×10^{-8} cm is 10^5 times greater than the nuclear radius, the nucleus occupies only about 10^{-15} of the volume of an atom. If an atom were to be scaled to the size of a large concert hall, then the nucleus would be the size of a very small gnat!

Nuclear Density

Since the mass of a nucleon (neutron or proton) is much greater than the mass of electrons in an atom ($m_n \simeq 1837\ m_e$), the mass density of a nucleus is

$$\rho_{\text{nucleus}} = \frac{m_{\text{nucleus}}}{V_{\text{nucleus}}} = \frac{A/N_a}{(4/3)\pi R^3} = 2.4 \times 10^{14}\ \text{g/cm}^3.$$

This is the density of the earth if it were compressed to a ball 200 m in radius.

3.6 Nuclear Reactions

Nuclear reactions play a very important role in many areas of nuclear science and engineering, because it is through such reactions that various types of radiation are produced. The detection of such radiation is the focus of this book. There are two main categories of nuclear reactions.

In the first category, the initial reactant X is a single atom or nucleus that spontaneously changes by emitting one or more particles, i.e.,

$$X \longrightarrow Y_1 + Y_2 + \cdots.$$

Such a reaction is called *radioactive decay*. Of the over 3200 known nuclides (an atom whose nucleus has a unique number neutron and protons), all but 266 are radioactive. The variation in the number of radioactive atoms over time and the different types of radioactive decay are addressed in the next section. Radioactive decay is a particular type of nuclear reaction that, because it occurs spontaneously, must necessarily be exothermic; i.e., mass must decrease in the decay process and energy must be emitted, usually in the form of the kinetic energy of the reaction products.

The second broad category of nuclear reactions are *binary reactions* in which *two* nuclear particles (nucleons, nuclei or photons) interact to form different nuclear particles.

$$X + x \longrightarrow Y_1 + Y_2 + \cdots.$$

The most common types of such nuclear reactions are those in which some nucleon or nucleus x moves with some kinetic energy and strikes and interacts with a nucleus X to form a pair of product nuclei y and Y, i.e.,

$$x + X \longrightarrow Y + y.$$

As a shorthand notation, such a reaction is often written as $X(x, y)Y$ where x and y are usually the lightest of the reaction pairs.

3.6.1 Q-Value for a Reaction

In any nuclear reaction, energy must be conserved, i.e., the total energy, including rest-mass energy, of the initial particles must equal the total energy of the final products, i.e.,

$$\sum_i [E_i + m_i c^2] = \sum_i [E_i' + m_i' c^2] \tag{3.79}$$

where E_i (E_i') is the kinetic energy of the ith initial (final) particle with a rest mass m_i (m_i').

Any change in the total kinetic energy of particles before and after the reaction must be accompanied by an equivalent change in the total rest mass of the particles before and after the reaction. To quantify this change in kinetic energy or rest-mass change in a reaction, a so-called Q-value is defined as

$$Q = (\text{KE of final particles}) - (\text{KE of initial particles}). \tag{3.80}$$

Thus, the Q-value quantifies the amount of kinetic energy gained in a reaction. Equivalently, from Eq. (3.79), this gain in kinetic energy must come from a decrease in the rest mass, i.e.,

$$Q = (\text{rest mass of initial particles})c^2 - (\text{rest mass of final particles})c^2. \tag{3.81}$$

The Q-value of a nuclear reaction may be either positive or negative. If the rest masses of the reactants exceed the rest masses of the products, the Q-value of the reaction is positive with the decrease in rest mass being converted into a gain in kinetic energy. Such a reaction is exothermic.

Conversely, if Q is negative, the reaction is endothermic. For this case, kinetic energy of the initial particles is converted into rest-mass energy of the reaction products. The kinetic energy decrease equals the rest-mass energy increase. Such reactions cannot occur unless the colliding particles have at least a certain amount of kinetic energy.

Binary Reactions

For the binary reaction $x + X \rightarrow Y + y$, the Q-value is given by

$$Q = (E_y + E_Y) - (E_x + E_X) = [(m_x + m_X) - (m_y + m_Y)]c^2. \tag{3.82}$$

For most binary nuclear reactions, the number of protons is conserved so that the same number of electron masses may be added to both sides of the reactions and, neglecting differences in electron binding energies, the Q-value can be written in terms of atomic masses as

$$Q = (E_y + E_Y) - (E_x + E_X) = [(M_x + M_X) - (M_y + M_Y)]c^2. \tag{3.83}$$

Radioactive Decay Reactions

For a radioactive decay reaction $X \rightarrow Y + y$, there is no particle x and the nucleus of X generally is at rest so $E_X = 0$. In this case

$$Q = (E_y + E_Y) = [m_X - (m_y + m_Y)]c^2 > 0. \tag{3.84}$$

Thus radioactive decay is always exothermic and the mass of the parent nucleus must always be greater than the sum of the product masses. In some types of radioactive decay (e.g., beta decay and electron capture), the number of protons is *not* conserved and care must be exercised in expressing the nuclear masses in terms of atomic masses. This nuance is discussed in Section 3.6.3.

3.6.2 Conservation of Charge and the Calculation of Q-Values

In all nuclear reactions, total charge must be conserved. Sometimes this is not clear when writing the reaction and subtle errors can be made when calculating the Q-value from Eq. (3.81). Consider, for example, the reaction ${}^{16}_{8}\mathrm{O}(n,p){}^{16}_{7}\mathrm{N}$ or

$${}^{1}_{0}\mathrm{n} + {}^{16}_{8}\mathrm{O} \longrightarrow {}^{16}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{p}. \tag{3.85}$$

One might be tempted to calculate the Q-value as

$$Q = \{m_n + M(^{16}_{8}\mathrm{O}) - M(^{16}_{7}\mathrm{N}) - m_p\}c^2.$$

However, this is incorrect because the number of electrons is not conserved on both sides of the reaction. On the left side there are 8 electrons around the $^{16}_{8}$O nucleus, while on the right there are only 7 electrons in the product atom $^{16}_{7}$N. In reality, when the proton is ejected from the $^{16}_{8}$O nucleus by the incident neutron, an orbital electron is also lost from the resulting $^{16}_{7}$N nucleus. Thus, the reaction of Eq. (3.85), to conserve charge, should be written as

$$^{1}_{0}\mathrm{n} + {}^{16}_{8}\mathrm{O} \longrightarrow {}^{16}_{7}\mathrm{N} + {}^{0}_{-1}\mathrm{e} + {}^{1}_{1}\mathrm{p}. \tag{3.86}$$

The released electron can now be conceptually combined with the proton to form a neutral atom of $^{1}_{1}$H, the electron binding energy to the proton being negligible compared to the reaction energy. Thus, the reaction can be approximated by

$$^{1}_{0}\mathrm{n} + {}^{16}_{8}\mathrm{O} \longrightarrow {}^{16}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} \tag{3.87}$$

and its Q-value is calculated as

$$Q = \{m_n + M(^{16}_{8}\mathrm{O}) - M(^{16}_{7}\mathrm{N}) - M(^{1}_{1}\mathrm{H})\}c^2. \tag{3.88}$$

In any nuclear reaction, *in which the numbers of neutrons and protons are both conserved*, the Q-value is calculated by replacing any charged particle by its neutral-atom counterpart. Recall that 1 u is $931.494\,043/c^2$ MeV, a value that readily allows reaction Q-values to be calculated in units of MeV when the atomic masses are in atomic mass units.

3.6.3 Special Case for Changes in the Proton Number

The above procedure for calculating Q-values in terms of neutral-atom masses *cannot* be used when the number of protons and neutrons are not conserved, and a more careful analysis is required. Such reactions involve the so-called weak force that is responsible for changing neutrons into protons or vice versa. These reactions are recognized by the presence of a neutrino ν (or antineutrino $\overline{\nu}$) as one of the reactants or products. In such reactions, the conceptual addition of electrons to both sides of the reaction to form neutral atoms often results in the appearance or disappearance of an extra free electron.

3.7 Radioactivity

Radioactive nuclei and their radiations have properties that are the basis of many of the ideas and techniques of atomic and nuclear physics [Shultis and Faw 2008]. The spontaneous emission of alpha and beta particles led to the concept that atoms are composed of smaller fundamental units. Likewise, the scattering of alpha particles led to the idea of the nucleus, which is fundamental to the models used in atomic physics. The discovery of isotopes resulted from the analysis of the chemical relationships among the various radioactive elements. The bombardment of the nucleus by alpha particles caused the disintegration of nuclei and led to the discovery of the neutron and the present model for the composition of the nucleus.

The discovery of artificial, or induced, radioactivity started a new line of nuclear research and hundreds of artificial nuclei have been produced by many different nuclear reactions. The investigation of the emitted radiations from radionuclides has shown the existence of nuclear energy levels similar to the electronic energy levels. The identification and the classification of these levels are important sources of information about the structure of the nucleus.

A number of radioactive nuclides occur naturally on the earth. One of the most important is $^{40}_{19}$K, which has an isotopic abundance of 0.0118% and a half-life of 1.28×10^9 y. Potassium is an essential element needed

by plants and animals, and is an important source of human internal and external radiation exposure. Other naturally occurring radionuclides are of cosmogenic origin. Tritium ($^{3}_{1}$H) and $^{14}_{6}$C are produced by cosmic ray interactions in the upper atmosphere, and also can cause measurable human exposures. $^{14}_{6}$C (half-life 5730 y), which is the result of a neutron reaction with $^{14}_{7}$N in the atmosphere, is incorporated into plants by photosynthesis. By measuring the decay of ^{14}C in ancient plant material, the age of the material can be determined.

Other sources of terrestrial radiation are uranium, thorium, and their radioactive progeny. All elements with Z > 83 are radioactive. Uranium and thorium decay into daughter radionuclides, forming a series (or chain) of radionuclides that ends with a stable isotope of lead or bismuth. There are four naturally occurring radioactive decay series.

In all nuclear interactions, including radioactive decay, there are several quantities that are always conserved or unchanged by the nuclear transmutation. The most important of these conservation laws include:

- Conservation of charge, i.e., the number of elementary positive and negative charges in the reactants must be the same as in the products.
- Conservation of the number of nucleons, i.e., A is always constant. With the exception of EC and $\beta^{\pm}$ radioactive decay, in which a neutron (proton) transmutes into a proton (neutron), the number of protons and neutrons is also generally conserved.
- Conservation of mass/energy (total energy). Although, neither rest mass nor kinetic energy is generally conserved, the total (rest-mass energy equivalent plus kinetic energy) is conserved.
- Conservation of linear momentum. This quantity must be conserved in all inertial frames of reference.
- Conservation of angular momentum. The total angular momentum (or the *spin*) of the reacting particles must always be conserved.

3.7.1 Types of Radioactive Decay

There are several types of spontaneous changes (or *transmutations*) that can occur in radioactive nuclides. In each transmutation, the nucleus of the parent atom $^{A}_{Z}$P is altered in some manner and one or more particles are emitted. If the number of protons in the nucleus is changed, then the number of orbital electrons in the daughter atom D must subsequently also be changed, either by releasing an electron to or absorbing an electron from the ambient medium. The most common types of radioactive decay are summarized in Table 3.6.

3.7.2 Radioactive Decay Diagrams

Detailed descriptions of radioactive decay involve a considerable amount of information. One convenient method for presenting such data is through a radioactive decay diagram. In Fig. 3.17 the hypothetical decay of a radionuclide $^{A}_{Z}$X is shown.

In a radioactive decay diagram, also sometimes called a *nuclear-level diagram*, the y-axis represents the masses (or energy equivalents) of the nuclides involved and the x-axis shows the atomic number of the nuclides. At the highest energy is the radionuclide of interest, the parent, whose ground state energy is denoted by the bold horizontal line. The radioactive parent may decay in several ways to produce different daughter nuclides. Decay that leads to daughters with lower atomic number than that of the parent have daughter states shown to the left of the parent, with thin horizontal lines denoting excited states and a bold line for the ground state. Daughters with increased atomic numbers are shown to the right of the parent.

Because all radioactive decays are exoergic, the mass of the daughter states must always be less than the mass of the parent. Thus, the various decay modes (shown by descending arrows) always proceed from the parent nuclide at the top of the diagram to daughter states below the parent, i.e., to states with less mass.

Table 3.6. Summary of important types of radioactive decay. The parent atom is denoted as P and the product or daughter atom by D.

Decay Type	Reaction	Description
gamma (γ)	${}^{A}_{Z}\mathrm{P}^{*} \longrightarrow {}^{A}_{Z}\mathrm{P} + \gamma$	An excited nucleus decays to its ground state by the emission of a gamma photon.
alpha (α)	${}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A-4}_{Z-2}\mathrm{D} + \alpha$	An α particle is emitted leaving the daughter with 2 fewer neutrons and 2 fewer protons than the parent.
negatron (β^{-})	${}^{A}_{Z}\mathrm{P} \longrightarrow {}_{Z+1}{}^{A}\mathrm{D} + \beta^{-} + \overline{\nu}$	A neutron in the nucleus changes to a proton. An electron (β^{-}) and an antineutrino ($\overline{\nu}$) are emitted.
positron (β^{+})	${}^{A}_{Z}\mathrm{P} \longrightarrow {}_{Z-1}{}^{A}\mathrm{D} + \beta^{+} + \nu$	A proton in the nucleus changes into a neutron. A positron (β^{+}) and a neutrino (ν) are emitted.
electron capture (EC)	${}^{A}_{Z}\mathrm{P} + \mathrm{e}^{-} \longrightarrow {}_{Z-1}{}^{A}\mathrm{D}^{*} + \nu$	An orbital electron is absorbed by the nucleus, converts a nuclear proton into a neutron and a neutrino (ν), and, generally, leaves the nucleus in an excited state.
proton (p)	${}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A-1}_{Z-1}\mathrm{D} + p$	A nuclear proton is ejected from the nucleus.
neutron (n)	${}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A-1}_{Z}\mathrm{D} + n$	A nuclear neutron is ejected from the nucleus.
internal conversion (IC)	${}^{A}_{Z}\mathrm{P}^{*} \longrightarrow [{}^{A}_{Z}\mathrm{P}]^{+} + \mathrm{e}^{-}$	The excitation energy of a nucleus is used to eject an orbital electron (usually a K-shell electron).

The vertical energy/mass axis is on a relative scale for each daughter with zero energy being the ground state of each daughter. The energy of each excited state is written on or adjacent to the horizontal line representing the state. For an excited state with energy E_i above the ground state, the excited nucleus has an excess mass $\Delta m_i = E_i/c^2$ greater than the mass of the nucleus in its ground state. Also often given is the Q-value for the decay to the ground state. The Q-value for decay to an excited state is the Q-value to the ground state less the nuclear excitation energy.

In the decay diagram of Fig. 3.17, the parent nucleus ${}^{A}_{Z}\mathrm{X}$ can decay to four different daughters: by β^{-} decay to ${}_{Z+1}{}^{A}\mathrm{B}$, by neutron decay to ${}^{A-1}_{Z}\mathrm{X}$, by positron decay or electron capture to ${}_{Z-1}{}^{A}\mathrm{C}$, and by α decay to ${}^{A-4}_{Z-2}\mathrm{D}$. For the alpha decay, note the break in the vertical line descending from the parent to indicate the parent and daughters are on different energy/mass scales. Without such a break, the alpha decay daughter would be far (almost 4 GeV) below the other decay daughters. Each decay arrow to a ground or excited state is labeled by the type of decay, e.g., α_1, and the decay probability or *frequency*, e.g., $f(\alpha_1)$. The frequency f_i, usually expressed in percent, gives the probability of that decay mode happening *per decay of the parent*. Thus, all the decay frequencies should sum to 100%.

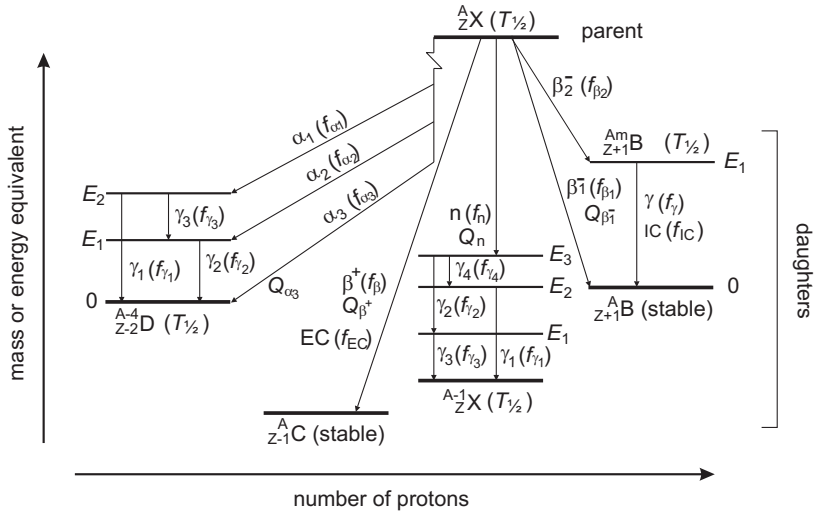

Figure 3.17. A radioactive decay diagram showing four decay modes of the hypothetical parent nuclide ${}^{A}_{Z}\mathrm{X}$ in which four different daughter nuclides are produced.

Excited states of the daughter nucleus usually decay very rapidly to lower excited states or to the ground state either by internal conversion, whereby the excitation energy is transferred to an orbital electron, or by the emission of a photon called a *gamma ray.*[12] The gamma ray energy is essentially equal to the difference between the two energy states, because the kinetic energy of the recoiling atom is negligible. Thus, the unique energies of gamma rays emitted in radioactive decay can be found readily from the energy levels in the decay diagram.

Occasionally, an excited state can persist for an appreciable time. Such excited states are called *metastable* and labeled as such with its half-life (see Section 3.7.5). For example, in Fig. 3.17, the first excited state of the daughter ${}_{Z+1}^{A}\mathrm{B}$ is denoted as metastable by ${}_{Z+1}^{Am}\mathrm{B}$. This metastable state then decays to the ground state by emission of a gamma ray or by internal conversion with the frequencies f_γ and f_{IC}, respectively.

3.7.3 Energetics of Radioactive Decay

In this section, the energies involved in the various types of radioactive decay are examined. Of particular interest are the energies of the particles emitted in the decay process.[13]

Gamma Decay

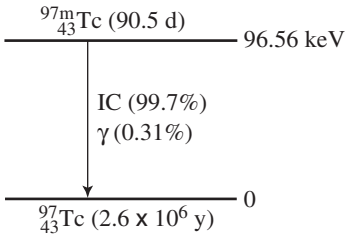

Figure 3.18. Radioactive decay diagram for the decay of ${}^{97m}\mathrm{Tc}$.

In many nuclear reactions, a nuclide is produced whose nucleus is left in an excited state. These excited nuclei usually decay very rapidly within 10^{-9} s to the ground state by emitting the excitation energy in the form of a gamma ray. However, a few excited nuclei remain in an excited state for a much longer time before they decay by gamma-ray emission. These long-lived excited nuclei are called *metastable* nuclei or *isomers.* When such an excited nuclide decays by gamma-ray emission, the decay is called an *isomeric transition.* A simple example is shown in Fig. 3.18. The first excited state of ${}^{97m}_{43}\mathrm{Tc}$ is a metastable state with a half-life of 90.5 d. It decays to the ground state with the emission of a 96.5 keV gamma photon.

[12] Any photon emitted from a nucleus is termed a *gamma* photon. Photons emitted when atomic electrons change their energy state are called *x rays.* Although x rays generally have lower energies than gamma photons, there are many exceptions.

[13] From now on, kinetic energy is given the usual symbol E instead of T used up to now.

The gamma-decay reaction of an excited isotope of element P can be written as

$$\boxed{\gamma \text{ decay:} \qquad {}^{A}_{Z}\mathrm{P}^{*} \rightarrow {}^{A}_{Z}\mathrm{P} + \gamma \ .} \tag{3.89}$$

Energy conservation for this nuclear reaction requires

$$M({}^{A}_{Z}\mathrm{P}^{*})c^2 \equiv M({}^{A}_{Z}\mathrm{P})c^2 + E^{*} = M({}^{A}_{Z}\mathrm{P})c^2 + E_P + E_\gamma \quad \text{or} \quad E^{*} = E_P + E_\gamma, \tag{3.90}$$

where E_γ is the energy of the gamma photon, E^{*} is the excitation energy (above the ground state) of the initial parent nucleus, and E_P is the recoil kinetic energy of the resulting ground-state nuclide. If the initial nuclide is at rest, the Q-value of this reaction is simply the sum of the kinetic energies of the products, which, with Eq. (3.90), yields

$$Q_\gamma = E_P + E_\gamma = E^{*}. \tag{3.91}$$

Linear momentum must also be conserved.[14] Again with the parent at rest before the decay (i.e., with zero initial linear momentum), the gamma photon and recoil nucleus must move in opposite directions and have equal magnitudes of linear momentum. Since the photon has momentum $p_\gamma = E_\gamma/c$ and the recoil nuclide has momentum $M_P v_P = \sqrt{2M_P E_P}$, conservation of momentum requires

$$E_\gamma/c = \sqrt{2M_P E_P} \qquad \text{or} \qquad E_P = \frac{E_\gamma^2}{2M_P c^2} \tag{3.92}$$

where $M_P \equiv M({}^{A}_{Z}\mathrm{P})$. Substitution of this result for E_P into Eq. (3.91) yields

$$E_\gamma = Q_\gamma \left[1 + \frac{E_\gamma}{2M_P c^2}\right]^{-1} \simeq Q_\gamma = E^{*}. \tag{3.93}$$

The approximation in this result follows from the fact that E_γ is at most 10–20 MeV, while $2M_P c^2 \geq 4000$ MeV. Thus, in gamma decay, the kinetic energy of the recoil nucleus is negligible compared to the energy of the gamma photon and $E_\gamma \simeq Q_\gamma = E^{*}$.

Alpha-Particle Decay

From the prior discussion of nuclear structure, it was noted that nucleons tend to group themselves into subunits of ${}^{4}_{2}\mathrm{He}$ nuclei, often called alpha particles. Thus, it is not surprising that, for proton-rich heavy nuclei, a possible mode of decay to a more stable state is by alpha-particle emission.

In alpha decay, the nucleus of the parent atom ${}^{A}_{Z}\mathrm{P}$ emits an alpha particle. The resulting nucleus of the daughter atom ${}^{A-4}_{Z-2}\mathrm{D}$ then has two fewer neutrons and two fewer protons. Initially, the daughter still has Z electrons, two too many, and thus is a doubly negative ion $[{}^{A-4}_{Z-2}\mathrm{D}]^{2-}$, but these extra electrons quickly break away from the atom, leaving it in a neutral state. The fast moving doubly charged alpha particle quickly loses its kinetic energy by ionizing and exciting atoms along its path of travel and acquires two orbital electrons to become a neutral ${}^{4}_{2}\mathrm{He}$ atom. Since the atomic number of the daughter is different from that of the parent, the daughter is a different chemical element. The alpha decay reaction is thus represented by

$$\boxed{\alpha \text{ decay:} \qquad {}^{A}_{Z}\mathrm{P} \longrightarrow [{}^{A-4}_{Z-2}\mathrm{D}]^{2-} + {}^{4}_{2}\alpha \longrightarrow {}^{A-4}_{Z-2}\mathrm{D} + {}^{4}_{2}\mathrm{He}.} \tag{3.94}$$

[14] Throughout this section, because of the comparatively large mass and low energy of the recoil atom, momentum of the recoil is computed using laws of classical mechanics.

Decay Energy Recall from the previous chapter, the Q-value of a nuclear reaction is defined as the decrease in the rest mass energy (or increase in kinetic energy) of the product nuclei (see Eq. (3.81)). For radioactive decay, the Q-value is sometimes called the *disintegration energy*. For alpha decay we have

$$\begin{aligned} Q_\alpha/c^2 &= M({}^A_Z\mathrm{P}) - [M([{}^{A-4}_{Z-2}\mathrm{D}]^{2-}) + m({}^4_2\alpha)] \\ &\simeq M({}^A_Z\mathrm{P}) - [M({}^{A-4}_{Z-2}\mathrm{D}) + 2m_e + m({}^4_2\alpha)] \\ &\simeq M({}^A_Z\mathrm{P}) - [M({}^{A-4}_{Z-2}\mathrm{D}) + M({}^4_2\mathrm{He})]. \end{aligned} \tag{3.95}$$

In this reduction to atomic masses, the binding energies of the two electrons in the daughter ion and in the He atom have been neglected since these are small (several eV) compared to the Q-value (several MeV). For alpha decay to occur, Q_α must be positive, or, equivalently, $M({}^A_Z\mathrm{P}) > M({}^{A-4}_{Z-2}\mathrm{D}) + M({}^4_2\mathrm{He})$.

Kinetic Energies of the Products The disintegration energy Q_α equals the kinetic energy of the decay products. How this energy is divided between the daughter atom and the α particle is determined from the conservation of momentum. The momentum of the parent nucleus was zero before the decay, and thus, from the conservation of linear momentum, the total momentum of the products must also be zero. The alpha particle and the daughter nucleus must, therefore, leave the reaction site in opposite directions with equal magnitudes of their linear momentum to ensure the vector sum of their momenta is zero.

If we assume neither product particle is relativistic,[15] conservation of energy requires

$$Q_\alpha = E_D + E_\alpha = \frac{1}{2}M_D v_D^2 + \frac{1}{2}M_\alpha v_\alpha^2, \tag{3.96}$$

and conservation of linear momentum requires

$$M_D v_D = M_\alpha v_\alpha, \tag{3.97}$$

where $M_D \equiv M({}^{A-4}_{Z-2}\mathrm{D})$ and $M_\alpha \equiv M({}^4_2\mathrm{He})$. These two equations in the two unknowns v_D and v_α can be solved to obtain the kinetic energies of the products. Solve Eq. (3.97) for v_D and substitute the result into Eq. (3.96) to obtain

$$Q_\alpha = \frac{1}{2}\frac{M_\alpha^2}{M_D}v_\alpha^2 + \frac{1}{2}M_\alpha v_\alpha^2 = \frac{1}{2}M_\alpha v_\alpha^2\left[\frac{M_\alpha}{M_D} + 1\right]. \tag{3.98}$$

Hence, we find that the kinetic energy of the alpha particle is

$$E_\alpha = Q_\alpha\left[\frac{M_D}{M_D + M_\alpha}\right] \simeq Q_\alpha\left[\frac{A_D}{A_D + A_\alpha}\right]. \tag{3.99}$$

Notice that, in alpha decay, the alpha particle is emitted with a well-defined energy. The recoiling nucleus carries off the remainder of the available kinetic energy. From Eq. (3.96) we see $E_D = Q_\alpha - E_\alpha$, so that from the above result

$$E_D = Q_\alpha\left[\frac{M_\alpha}{M_D + M_\alpha}\right] \simeq Q_\alpha\left[\frac{A_\alpha}{A_D + A_\alpha}\right]. \tag{3.100}$$

[15] Here a non-relativistic analysis is justified since the energy liberated in alpha decay is less than 10 MeV, whereas the rest mass energy of an alpha particle is about 3727 MeV.

Alpha Decay Diagrams The above calculation assumes that the alpha decay proceeds from the ground state of the parent nucleus to the ground state of the daughter nucleus. As discussed earlier, sometimes the daughter nucleus is left in an excited nuclear state (which ultimately relaxes to the ground state by the emission of one or more gamma rays). In these cases, the Q_α-value of the decay is reduced by the excitation energy of the excited state. Often a radionuclide that decays by alpha emission is observed to emit alpha particles with several discrete energies. This is an indication that the daughter nucleus is left in excited states with nuclear masses greater than the ground state mass by the mass equivalent of the excitation energy.

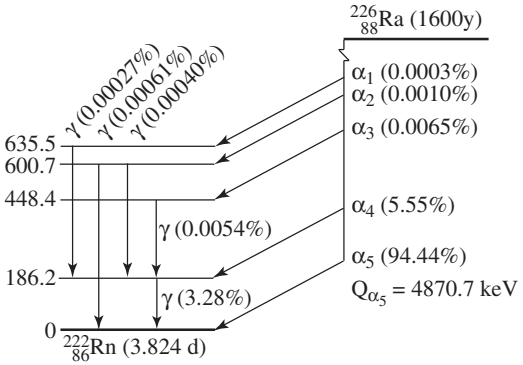

Figure 3.19. Energy levels for α decay of ^{226}Ra.

A simple case is shown in Fig. 3.19 for the decay of $^{226}_{88}$Ra. This nuclide decays to the first excited state of $^{222}_{86}$Rn 5.55% of the time and to the ground state 94.45% of the time. Two alpha particles with kinetic energies of $E_{\alpha 1} = 4.783$ MeV and $E_{\alpha 2} = 4.601$ MeV are thus observed. Also a 0.186-MeV gamma ray is observed, with an energy equal to the energy difference between the two alpha particles or the two lowest nuclear states in $^{222}_{88}$Rn.

Example 3.2: What is the initial kinetic energy of the alpha particle produced in the radioactive decay $^{226}_{88}\text{Ra} \rightarrow {}^{222}_{86}\text{Rn} + {}^{4}_{2}\text{He}$?

Solution:

The Q_α value in mass units (i.e., the mass defect) is, from Eq. (3.95),

$$\begin{aligned} Q_\alpha &= [M(^{226}_{88}\text{Ra}) - M(^{222}_{86}\text{Rn}) - M(^{4}_{2}\text{He})]c^2 \\ &= [226.025402 - 222.017571 - 4.00260325]\text{u} \times 931.5 \text{ MeV/u} \\ &= 0.005228 \text{ u} \times 931.5 \text{ MeV/u} = 4.870 \text{ MeV}. \end{aligned}$$

The kinetic energy of the alpha particle from Eq. (3.99) is

$$E_\alpha = Q_\alpha \left[\frac{A_D}{A_D + A_\alpha}\right] = 4.870 \left[\frac{222}{222+4}\right] = 4.784 \text{ MeV}.$$

The remainder of the Q_α energy is the kinetic energy of the product nucleus, $^{222}_{86}$Rn, namely, 4.870 MeV − 4.783 MeV = 0.087 MeV.

Beta-Particle Decay

Many neutron-rich radioactive nuclides decay by changing a neutron in the parent (P) nucleus into a proton and emitting an energetic electron. Many different names are applied to this decay process: electron decay, beta minus decay, negatron decay, negative electron decay, negative beta decay, or simply beta decay. The ejected electron is called a *beta particle* denoted by β^-. The daughter atom, with one more proton in the nucleus, initially lacks one orbital electron, and thus is a single charged positive ion, denoted by $[_{Z-1}{}^{A}\text{D}]^+$. However, the daughter quickly acquires an extra orbital electron from the surrounding medium. The general β^- decay reaction is thus written as

$$\beta^- \text{ decay:} \qquad {}^{A}_{Z}\text{P} \longrightarrow [_{Z+1}{}^{A}\text{D}]^+ + {}^{0}_{-1}\text{e} + \overline{\nu}_e. \tag{3.101}$$

Here $\overline{\nu}$ is an antineutrino, a chargeless particle with very little, if any, rest mass.[16] That a third product particle is involved with β^- decay is implied from the observed energy and momentum of the emitted β^- particle. If the decay products were only the daughter nucleus and the β^- particle, then, as in α decay, conservation of energy and linear momentum would require that the decay energy be shared in very definite proportions between them. However, β^- particles are observed to be emitted with a continuous distribution of energies that has a well-defined maximum energy (see Fig. 3.20). Rather than abandon the laws of conservation of energy and momentum, Pauli suggested in 1933 that at least three particles must be produced in a β^- decay. The vector sum of the linear momenta of three products can be zero without any unique division of the decay energy among them. In 1934 Fermi used Pauli's suggestion of a third neutral particle to produce a beta-decay theory which explained well the observed beta-particle energy distributions. This mysterious third particle, which Fermi named the neutrino (lit. "little neutral one"), has since been verified experimentally and today it is extensively studied by physicists trying to develop fundamental theories of our universe. The maximum energy of the β^- spectrum corresponds to a case in which the neutrino obtains zero kinetic energy, and the decay energy is divided between the daughter nucleus and the β^- particle.

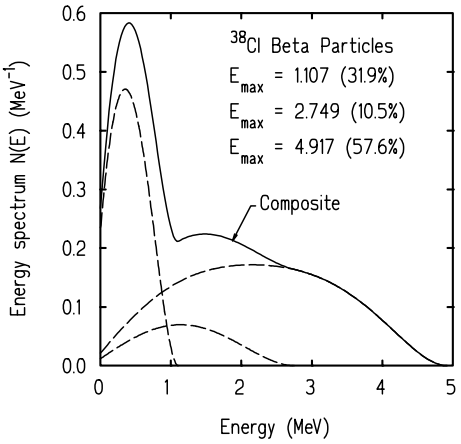

Figure 3.20. Energy spectra of principle ^{38}Cl β^- particles. From Shultis and Faw [2000].

Decay Energy The beta decay energy is readily obtained from the Q-value of the decay reaction. Specifically,

$$Q_{\beta^-}/c^2 = M(^A_Z\mathrm{P}) - [M([_{Z+1}{}^A\mathrm{D}]^+) + m_{\beta^-} + m_{\overline{\nu}_e}]$$

$$\simeq M(^A_Z\mathrm{P}) - [\{M(_{Z+1}{}^A\mathrm{D}) - m_e\} + m_{\beta^-} + m_{\overline{\nu}_e}] = M(^A_Z\mathrm{P}) - M(_{Z+1}{}^A\mathrm{D}). \tag{3.102}$$

For β^- decay to occur spontaneously, Q_{β^-} must be positive or, equivalently, the mass of the parent atom must exceed that of the daughter atom, i.e., $M(^A_Z\mathrm{P}) > M(_{Z+1}{}^A\mathrm{D})$.

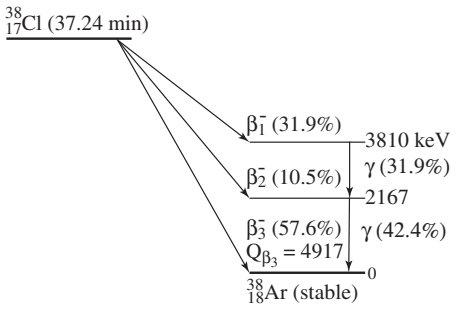

Figure 3.21. Radioactive decay diagram for the decay of ^{38}Cl. Three distinct groups of β^- particles are emitted.

Often in β^- decay, the nucleus of the daughter is left in an excited state. For example, ^{38}Cl decays both to the ground state of the daughter ^{38}Ar as well as to two excited states (see Fig. 3.21). The resulting β^- energy spectrum (Fig. 3.20) is a composite of the β^- particles emitted in the transition to each energy level of the daughter. For a decay to an energy level E^* above the ground level, the mass of the daughter atom in Eq. (3.102) $M(_{Z+1}{}^A\mathrm{D})$ must be replaced by the mass of the *excited* daughter $M(_{Z+1}{}^A\mathrm{D}^*) \simeq M(_{Z+1}{}^A\mathrm{D}) + E^*/c^2$. Thus, Q_{β^-} for β^- decay to an excited level with energy E^* above ground level in the daughter is

$$Q_{\beta^-}/c^2 = M(^A_Z\mathrm{P}) - M(_{Z+1}{}^A\mathrm{D}) - E^*/c^2. \tag{3.103}$$

[16] The mass of the emitted neutrino is essentially that of the electron neutrino ν_e. The mass of ν_e is currently a subject of great interest in the high-energy physics community. Recent experiments show that, if it has any mass, its mass is exceedingly small and is less than a few eV mass equivalent (see Table 3.4). For the energetics of radioactive beta decay, the neutrino rest mass is completely negligible and can be taken as zero.

Because the kinetic energy of the parent nucleus is zero, the Q_{β^-} decay energy must be divided among the kinetic energies of the products. The maximum kinetic energy of the β^- particle occurs when the antineutrino obtains negligible energy. In this case, since the mass of the β^- particle is much less than that of the daughter nucleus, $Q = E_D + E_{\beta^-} \simeq E_{\beta^-}$ or

$$(E_{\beta^-})_{\max} \simeq Q_{\beta^-}. \tag{3.104}$$

Positron Decay

Nuclei that have too many protons for stability often decay by changing a proton into a neutron. In this decay mechanism, an anti-electron or *positron* β^+ or ${}^{0}_{+1}\mathrm{e}$, and a neutrino ν are emitted. The daughter atom, with one less proton in the nucleus, initially has one too many orbital electrons, and thus is a negative ion, denoted by $[{}^{A}_{Z-1}\mathrm{D}]^-$. However, the daughter quickly releases the extra orbital electron to the surrounding medium and becomes a neutral atom. The β^+ decay reaction is written as

$$\boxed{\beta^+ \text{ decay:} \qquad {}^{A}_{Z}\mathrm{P} \longrightarrow [{}^{A}_{Z-1}\mathrm{D}]^- + {}^{0}_{+1}\mathrm{e} + \nu_e.} \tag{3.105}$$

The positron has the same physical properties as an electron, except that it has one unit of positive charge. The positron β^+ is the antiparticle of the electron. The neutrino ν is required (as in β^- decay) to conserve energy and linear momentum since the β^+ particle is observed to be emitted with a continuous spectrum of energies up to some maximum value $(E_{\beta^+})_{\max}$. The neutrino ν in Eq. (3.105) is the antiparticle of the antineutrino $\overline{\nu}$ produced in beta-minus decay.

Decay Energy The decay energy is readily obtained from the Q-value of the decay reaction. Specifically,

$$\begin{aligned} Q_{\beta^+}/c^2 &= M({}^{A}_{Z}\mathrm{P}) - [M([{}^{A}_{Z-1}\mathrm{D}]^-) + m({}^{0}_{+1}\mathrm{e}) + m_{\nu_e}] \\ &\simeq M({}^{A}_{Z}\mathrm{P}) - [\{M({}^{A}_{Z-1}\mathrm{D}) + m_e\} + m_{\beta^+} + m_{\nu_e}] \\ &= M({}^{A}_{Z}\mathrm{P}) - M({}^{A}_{Z-1}\mathrm{D}) - 2m_e \end{aligned} \tag{3.106}$$

where the binding energy of the electron to the daughter ion and the neutrino mass have been neglected. If the daughter nucleus is left in an excited state, the excitation energy E^* must also be included in the Q_{β^+} calculation, namely,

$$Q_{\beta^+}/c^2 = M({}^{A}_{Z}\mathrm{P}) - M({}^{A}_{Z-1}\mathrm{D}) - 2m_e - E^*/c^2. \tag{3.107}$$

Thus, for β^+ decay to occur spontaneously, Q_{β^+} must be positive, i.e., $M({}^{A}_{Z}\mathrm{P}) > M({}^{A}_{Z-1}\mathrm{D}) + 2m_e + E^*/c^2$.

The maximum energy of the emitted positron occurs when the neutrino acquires negligible kinetic energy, so that the Q_{β^+} energy is shared by the daughter atom and the positron. Because the daughter atom is so much more massive than the positron (by factors of thousands), almost all the Q_{β^+} energy is transferred as kinetic energy to the positron. Thus

$$(E_{\beta^+})_{\max} \simeq Q_{\beta^+}. \tag{3.108}$$

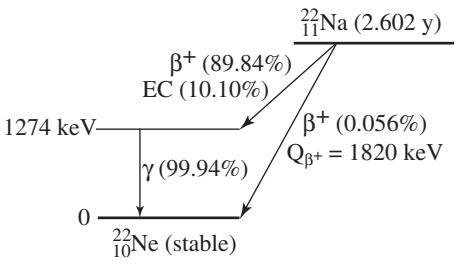

Figure 3.22. Radioactive decay diagram for positron emission from ^{22}Na.

An example of a radionuclide that decays by positron emission is ${}^{22}_{11}\mathrm{Na}$. The decay reaction is

$${}^{22}_{11}\mathrm{Na} \longrightarrow {}^{22}_{10}\mathrm{Ne} + \beta^+ + \nu_e,$$

and the level diagram for this decay is shown in Fig. 3.22. Notice that the daughter is almost always left in its first excited state. This state decays, with a mean lifetime of 3.63 ps, by emitting a 1.274-MeV gamma ray.

The emitted positron loses its kinetic energy by ionizing and exciting atomic electrons as it moves through the surrounding medium. Eventually, it captures an ambient electron, forming for a brief instant a pseudo-atom called *positronium* before they annihilate each other. Their entire rest mass energy $2m_ec^2$ is converted into photon energy (the kinetic energy at the time of annihilation usually being negligible). Before the annihilation, there is zero linear momentum, and there must be no net momentum remaining; thus, two photons traveling in opposite directions must be created, each with energy $E = m_ec^2 = 0.511$ MeV.

Electron Capture

In the quantum mechanical model of the atom, the orbital electrons have a finite (but small) probability of spending some time inside the nucleus, the innermost K-shell electrons having the greatest probability. It is possible for an orbital electron, while inside the nucleus, to be captured by a proton, which is thus transformed into a neutron. Conceptually we can visualize this transformation of the proton as $p + {}^{0}_{-1}\mathrm{e} \rightarrow n + \nu$, where the neutrino is again needed to conserve energy and momentum. The general electron capture (EC) decay reaction is written as

$$\boxed{\text{EC decay:} \qquad {}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A}_{Z-1}\mathrm{D}^{*} + \nu_e.} \tag{3.109}$$

where the daughter is generally left in an excited nuclear state with energy E^* above ground level. Unlike in most other types of radioactive decay, no charged particles are emitted. The only *nuclear* radiations emitted are gamma photons produced when the excited nucleus of the daughter relaxes to its ground state. As the outer electrons cascade down in energy to fill the inner shell vacancy, x rays and Auger electrons are also emitted.

Decay Energy The decay energy is readily obtained from the Q-value of the decay reaction. If we assume the daughter nucleus is left in its ground state

$$\begin{aligned} Q_{EC}/c^2 &= M({}^{A}_{Z}\mathrm{P}) - [M({}^{A}_{Z-1}\mathrm{D}) + m_{\nu_e}] \\ &\simeq M({}^{A}_{Z}\mathrm{P}) - M({}^{A}_{Z-1}\mathrm{D}). \end{aligned} \tag{3.110}$$

If the daughter nucleus is left in an excited state, the excitation energy E^* must also be included in the Q_{EC} calculation, namely,

$$Q_{EC}/c^2 = M({}^{A}_{Z}\mathrm{P}) - M({}^{A}_{Z-1}\mathrm{D}) - E^*/c^2. \tag{3.111}$$

Thus, for EC decay to occur spontaneously, Q_{EC} must be positive, i.e., $M({}^{A}_{Z}\mathrm{P}) > M({}^{A}_{Z-1}\mathrm{D}) + E^*/c^2$.

Notice that both β^+ and EC decay produce the same daughter nuclide. In fact, if the mass of the parent is sufficiently large compared to the daughter, both decay modes can occur for the same radionuclide. From Eq. (3.107) and Eq. (3.111), we see that if the parent's atomic mass is not at least two electron masses greater than the daughter's mass, Q_{β^+} is negative and β^+ decay cannot occur. However, Q_{EC} is positive as long as the parent's mass is even slightly greater than that of the daughter, and EC can still occur.

An example of a radionuclide that decays by electron capture is ${}^{7}_{4}\mathrm{Be}$. The decay reaction is

$${}^{7}_{4}\mathrm{Be} \longrightarrow {}^{7}_{3}\mathrm{Li} + \nu_e.$$

The level diagram for this decay is shown in Fig. 3.23. Notice that in this example, the Q_{EC} of 862 keV is less than $2m_ec^2 = 1022$ keV so that there can be no competing β^+ decay. Finally, in an EC

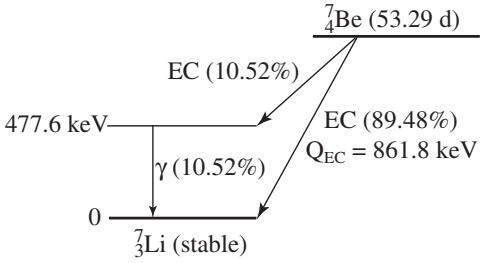

Figure 3.23. Decay of ^{7}Be by electron capture.

transition, an orbital electron (usually from an inner shell) disappears leaving an inner electron vacancy. The remaining atomic electrons cascade to lower orbital energy levels to fill the vacancy, usually emitting x rays as they become more tightly bound. The energy change in an electronic transition, instead of being emitted as an x ray, may also be transferred to an outer orbital electron ejecting it from the atom. These ejected electrons are called *Auger* electrons, named after their discoverer, and appear in any process that leaves a vacancy in an inner electron shell.

Neutron Decay

A few neutron-rich nuclides decay by emitting a neutron producing a different isotope of the same parent element. Generally, the daughter nucleus is left in an excited state which subsequently emits gamma photons as it returns to its ground state. This decay reaction is

$$\boxed{n \text{ decay:} \qquad {}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A-1}_{Z}\mathrm{P}^{*} + {}^{1}_{0}\mathrm{n}.} \tag{3.112}$$

An example of such a neutron decay reaction is $^{138}_{54}\mathrm{Xe} \rightarrow {}^{137}_{54}\mathrm{Xe} + n$. Although, neutron decay is rare, it plays a very important role in nuclear reactors. A small fraction of the radioactive atoms produced by fission reactions decay by neutron emission at times up to minutes after the fission event in which they were created. These neutrons contribute to the nuclear chain reaction and thus effectively slow it down, making it possible to control nuclear reactors.

The Q-value for such a decay is

$$Q_n/c^2 = M({}^{A}_{Z}\mathrm{P}) - [M({}^{A-1}_{Z}\mathrm{P}^{*}) + m_n] = M({}^{A}_{Z}\mathrm{P}) - M({}^{A-1}_{Z}\mathrm{D}) - m_n - E^{*}/c^2, \tag{3.113}$$

where E^* is the initial excitation energy of the daughter nucleus. Thus, for neutron decay to occur to even the ground state of the daughter, $M({}^{A}_{Z}\mathrm{P}) > M({}^{A-1}_{Z}\mathrm{D}) + m_n$.

Proton Decay

A few proton-rich radionuclides decay by emission of a proton. In such decays, the daughter atom has an extra electron (i.e., it is a singly charged negative ion). This extra electron is subsequently ejected from the atom's electron cloud to the surroundings and the daughter returns to an electrically neutral atom. The proton decay reaction is thus

$$\boxed{p \text{ decay:} \qquad {}^{A}_{Z}\mathrm{P} \longrightarrow [{}^{A-1}_{Z-1}\mathrm{D}^{*}]^{-} + {}^{1}_{1}\mathrm{p}.} \tag{3.114}$$

In this reaction P and D refer to atoms of the parent and daughter. Thus, the Q-value for this reaction is

$$\begin{aligned} Q_p/c^2 &= M({}^{A}_{Z}\mathrm{P}) - [M([{}^{A-1}_{Z-1}\mathrm{D}^{*}]^{-}) + m_p] \simeq M({}^{A}_{Z}\mathrm{P}) - [\{M({}^{A-1}_{Z-1}\mathrm{D}^{*}) + m_e\} + m_p] \\ &\simeq M({}^{A}_{Z}\mathrm{P}) - [\{M({}^{A-1}_{Z-1}\mathrm{D}) + E^{*}/c^2 + m_e\} + m_p] \simeq M({}^{A}_{Z}\mathrm{P}) - M({}^{A-1}_{Z-1}\mathrm{D}) - M({}^{1}_{1}\mathrm{H}) - E^{*}/c^2. \end{aligned} \tag{3.115}$$

Thus, for proton decay to occur and leave the daughter in the ground state ($E^* = 0$), it is necessary that $M({}^{A}_{Z}\mathrm{P}) > M({}^{A-1}_{Z-1}\mathrm{D}) - M({}^{1}_{1}\mathrm{H})$.

Internal Conversion

Often the daughter nucleus is left in an excited state, which decays (usually within about 10^{-9} s) to the ground state by the emission of one or more gamma photons. However, the excitation may also be transferred to an atomic electron (usually a K-shell electron) causing it to be ejected from the atom leaving the nucleus in the ground state but the atom singly ionized with an inner electron-shell vacancy. Symbolically,

$$\boxed{\text{IC decay:} \qquad {}^{A}_{Z}\mathrm{P}^{*} \longrightarrow [{}^{A}_{Z}\mathrm{P}]^{+} + {}^{0}_{-1}\mathrm{e}.} \tag{3.116}$$

The inner electrons are very tightly bound to the nucleus with large binding energies BE_e^K for K-shell electrons in heavy atoms. The amount of kinetic energy shared by the recoil ion and the ejected electron should take this into account. The Q value for the IC decay is calculated as follows:

$$\begin{aligned} Q_{\mathrm{IC}}/c^2 &= M({}^{A}_{Z}\mathrm{P}^{*}) - [M([{}^{A}_{Z}\mathrm{P}]^{+}) + m_e] \\ &\simeq \left\{M({}^{A}_{Z}\mathrm{P}) + E^{*}/c^2\right\} - [\left\{M({}^{A}_{Z}\mathrm{P}) - m_e + \mathrm{BE}_e^K/c^2\right\} + m_e] \\ &= [E^{*} - \mathrm{BE}_e^K]/c^2. \end{aligned} \tag{3.117}$$

This decay energy is divided between the ejected electron and the daughter ion. To conserve the zero initial linear momentum, the daughter and IC electron must divide the decay energy as

$$E_e = \left(\frac{M({}^{A}_{Z}\mathrm{P})}{M({}^{A}_{Z}\mathrm{P}) + m_e}\right)[E^{*} - \mathrm{BE}_e^K] \simeq E^{*} - \mathrm{BE}_e^K \tag{3.118}$$

and

$$E_D = \left(\frac{m_e}{M({}^{A}_{Z}\mathrm{P}) + m_e}\right)[E^{*} - \mathrm{BE}_e^K] \simeq 0. \tag{3.119}$$

Besides the monoenergetic IC electron, other radiation is also emitted in the IC process. As the outer electrons cascade down in energy to fill the inner-shell vacancy, x rays and Auger electrons are also emitted.

3.7.4 Exponential Decay

Radioactive decay is a stochastic process, i.e., one cannot predict when a particular radionuclide will decay. All that one can do is make probability statements about when it will decay. For example, as shown in this section, one can, at best, calculate the probability that it will or will not decay in a finite time interval t.

Each radionuclide species has its own characteristic *decay constant* λ which is the probability a radionuclide decays in a unit time for an infinitesimal time interval. The smaller λ, the more slowly the radionuclides decay. For stable nuclides, $\lambda = 0$. The decay constant for a radionuclide is independent of most experimental parameters such as temperature and pressure, since it depends only on the nuclear forces inside the nucleus.

Consider a sample composed of a large number of identical radionuclides with decay constant λ. With a large number of radionuclides ($N >>> 1$), one can use continuous mathematics to describe an inherently discrete process. In other words, $N(t)$ is interpreted as the *average* or *expected* number of radionuclides in the sample at time t, a continuous quantity. Then, the probability any one radionuclide decays in an interval dt is λdt, so the expected number of decays in the sample that occurs in dt at time t is $\lambda\, dt\, N(t)$. This must equal the decrease $-dN$ in the number of radionuclides in the sample, i.e., $-dN = \lambda N(t)dt$, or

$$\frac{dN(t)}{dt} = -\lambda N(t). \tag{3.120}$$

The solution of this differential equation is

$$\boxed{N(t) = N(0)e^{-\lambda t},} \tag{3.121}$$

where $N(0)$ is the number of radionuclides in the sample at $t = 0$. This exponential decay of a radioactive sample is known as the *radioactive decay law*. Such an exponential variation with time not only applies to radionuclides, but to any process governed by a constant rate of change, such as decay of excited electron states of an atoms, the rate of growth of money earning compound interest, and the growth of human populations, to name a few such processes.

3.7.5 The Half-Life

Any dynamic process governed by exponential decay has a remarkable property. The time it takes for it to decay to one-half of the initial value, $T_{1/2}$, is a constant called the *half-life*. From Eq. (3.121)

$$N(T_{1/2}) \equiv \frac{N_o}{2} = N_o e^{-\lambda T_{1/2}}. \tag{3.122}$$

Solving for $T_{1/2}$ yields

$$\boxed{T_{1/2} = \frac{\ln 2}{\lambda} \simeq \frac{0.693}{\lambda}.} \tag{3.123}$$

Notice that the half-life is independent of time t. Thus, after n half-lives, the initial number of radionuclides has decreased by a multiplicative factor of $1/2^n$, i.e.,

$$N(nT_{1/2}) = \frac{1}{2^n} N_o. \tag{3.124}$$

The number of half-lives n needed for a radioactive sample to decay to a fraction ϵ of its initial value is found from

$$\epsilon \equiv \frac{N(nT_{1/2})}{N_o} = \frac{1}{2^n}$$

which, upon solving for n, yields

$$n = -\frac{\ln \epsilon}{\ln 2} \simeq -1.44 \ln \epsilon. \tag{3.125}$$

Alternatively, the radioactive decay law of Eq. (3.121) can be expressed in terms of the half-life as

$$N(t) = N_o \left(\frac{1}{2}\right)^{t/T_{1/2}}. \tag{3.126}$$

3.7.6 Decay Probability for a Finite Time Interval

From the exponential decay law, some useful probabilities and averages can be obtained. If we have N_o identical radionuclides at $t = 0$, we expect to have $N_o e^{-\lambda t}$ atoms at a later time t. Thus, the probability $\overline{P}$ that any one of the atoms *does not* decay in a time interval t is

$$\overline{P}(t) = \frac{N(t)}{N(0)} = e^{-\lambda t}. \tag{3.127}$$

The probability P that a radionuclide *does* decay in a time interval t is

$$P(t) = 1 - \overline{P}(t) = 1 - e^{-\lambda t}. \tag{3.128}$$

As the time interval becomes very small, i.e., $t \to \Delta t \ll 1$, it is seen that

$$P(\Delta t) = 1 - e^{-\lambda \Delta t} = 1 - \left[1 - \lambda \Delta t + \frac{1}{2!}(\lambda \Delta t)^2 - + \ldots\right] \simeq \lambda \Delta t. \tag{3.129}$$

This approximation is in agreement with the earlier interpretation of the decay constant λ as being the decay probability per infinitesimal time interval.

From these results, the probability distribution function for when a radionuclide decays can be obtained. Specifically, let $p(t)dt$ be the probability a radionuclide, which exists at time $t = 0$, decays in the time interval between t and $t + dt$. Clearly,

$$\begin{aligned} p(t)dt &= \{\text{prob. it doesn't decay in } (0,t)\}\,\{\text{prob. it decays in the next } dt \text{ time interval}\} \\ &= \left\{\overline{P}(t)\right\}\{P(dt)\} = \left\{e^{-\lambda t}\right\}\{\lambda\, dt\} = \lambda e^{-\lambda t} dt. \end{aligned} \tag{3.130}$$

3.7.7 Mean Lifetime

In a radioactive sample, radionuclides decay at all times. From Eq. (3.121) it is seen that an infinite time is required for all the radioactive atoms to decay. However, as time increases, fewer and fewer atoms decay. The average lifetime of a radionuclide can be obtained by using the decay probability distribution $p(t)dt$ of Eq. (3.130). The average or mean lifetime T_{av} of a radionuclide is thus

$$T_{av} = \int_0^\infty t\, p(t)\, dt = \int_0^\infty t\lambda e^{-\lambda t} dt = \left. -te^{-\lambda t}\right|_0^\infty + \int_0^\infty e^{-\lambda t} dt = \frac{1}{\lambda}. \tag{3.131}$$

Example 3.3: What is the value of the decay constant and the mean lifetime of ^{40}K (half-life 1.29 Gy)?

Solution:

The decay constant is

$$\lambda = \frac{\ln 2}{T_{1/2}} = \frac{\ln 2}{1.29 \times 10^9 \text{ y}} = 5.37 \times 10^{-10} \text{ y}^{-1}.$$

The average lifetime is $\overline{t} = 1/\lambda = 1.86 \times 10^9$ y.

3.7.8 Activity

For detection and safety purposes, one is generally not really interested in the number of radioactive atoms in a sample; rather one is interested in the number of decays or transmutations per unit of time that occur within the sample. This decay rate, or *activity* $A(t)$, of a sample is given by[17]

$$A(t) \equiv -\frac{dN(t)}{dt} = \lambda N(t) = \lambda N_o e^{-\lambda t} = A_o e^{-\lambda t}, \tag{3.132}$$

where A_o is the activity at $t = 0$. Since the number of radionuclides in a sample decreases exponentially, the activity also decreases exponentially.

[17] Do not confuse the symbol A used here for activity with the same symbol used for the atomic mass number.

The SI unit used for activity is the becquerel (Bq) and is defined as one transformation per second. An older unit of activity, and one that is still sometimes encountered, is the curie (Ci) defined as 3.7×10^{10} Bq. One Ci is the approximate activity of one gram of $^{226}_{88}$Ra (radium). To obtain 1 Ci of tritium ($T_{1/2} = 12.6$ y, $\lambda = 1.74 \times 10^{-9}$ s^{-1}) one needs 1.06×10^{-4} g of tritium. By contrast, one Ci of ^{238}U ($\lambda = 4.88 \times 10^{-18}$ s^{-1}) is 3.00×10^{6} g.

3.7.9 Decay by Competing Processes

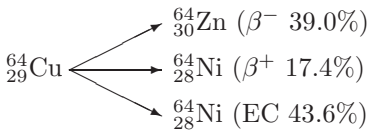

Figure 3.24. $^{62}_{29}$Cu has three radioactive decay modes.

Some radionuclides decay by more than one process. For example, $^{64}_{29}$Cu decays by β^+ emission 17.4% of the time, by β^- emission 39.0% of the time, and by electron capture 43.6% of the time, as shown in Fig. 3.24. Each decay mode is characterized by its own decay constant λ_i. For the present example of $^{64}_{29}$Cu, the decay constants for the three decay modes are $\lambda_{\beta^+} = 0.009497$ h^{-1}, $\lambda_{\beta^-} = 0.02129$ h^{-1}, and $\lambda_{\text{EC}} = 0.02380$ h^{-1}.

To find the effective decay constant when the decay process has n competing decay modes, write the differential equation that models the rate of decay. Denote the decay constant for the ith mode by λ_i. Thus, the rate of decay of the parent radionuclide is given by,

$$\frac{dN(t)}{dt} = -\lambda_1 N(t) - \lambda_2 N(t) - \cdots - \lambda_n N(t) = -\sum_{i=1}^{n} \lambda_i N(t) \equiv -\lambda N(t). \tag{3.133}$$

where λ is the overall decay constant, namely,

$$\lambda \equiv \sum_{i=1}^{n} \lambda_i. \tag{3.134}$$

The probability f_i that the nuclide will decay by the ith mode is

$$f_i = \frac{\text{decay rate by } i\text{th mode}}{\text{decay rate by all modes}} = \frac{\lambda_i}{\lambda}. \tag{3.135}$$

3.7.10 Decay Dynamics

The transient behavior of the number of atoms of a particular radionuclide in a sample depends on the nuclide's rates of production and decay, the initial values of it and its parents, and the rate at which it escapes from the sample. In this section, several common decay transients are discussed.

Decay with Production

In many cases the decay of radionuclides is accompanied by the creation of new ones, either from the decay of a parent or from production by nuclear reactions such as cosmic ray interactions in the atmosphere or from neutron interactions in a nuclear reactor. If $Q(t)$ is the rate at which the radionuclide of interest is being created, the rate of change of the number of radionuclides is

$$\frac{dN(t)}{dt} = -\text{rate of decay} + \text{rate of production} \tag{3.136}$$

or

$$\frac{dN(t)}{dt} = -\lambda N(t) + Q(t). \tag{3.137}$$

The most general solution of this differential equation is

$$\boxed{N(t) = N_o e^{-\lambda t} + \int_0^t dt'\, Q(t') e^{-\lambda(t-t')}} \tag{3.138}$$

where again N_o is the number of radionuclides at $t = 0$.

For the special case that $Q(t) = Q_o$ (a constant production rate), the integral in Eq. (3.138) can be evaluated analytically to give

$$N(t) = N_o e^{-\lambda t} + \frac{Q_o}{\lambda}[1 - e^{-\lambda t}]. \tag{3.139}$$

As $t \to \infty$ it is seen that $N(t) \to N_e = Q_o/\lambda$, where N_e is the equilibrium value. This constant equilibrium value N_e can be obtained more directly from Eq. (3.137). Upon setting the left-hand side of Eq. (3.137) to zero (the equilibrium condition), it is seen that $0 = -\lambda N_e + Q_o$, or $N_e = Q_o/\lambda$.

Three Component Decay Chains

Often a radionuclide decays to another radionuclide which in turn decays to yet another. The chain continues until a stable nuclide is reached. For simplicity, first consider a three-component chain. Such three component chains are quite common and an example is

$$^{90}_{38}\mathrm{Sr} \overset{T_{1/2}=29.1\mathrm{y}}{\longrightarrow} {}^{90}_{39}\mathrm{Y} \overset{T_{1/2}=64\mathrm{h}}{\longrightarrow} {}^{90}_{40}\mathrm{Zn}(\text{ stable}),$$

in which both radionuclides decay by β^- emission. Such three-member decay chains can be written schematically as

$$\mathrm{X}_1 \xrightarrow{\lambda_1} \mathrm{X}_2 \xrightarrow{\lambda_2} \mathrm{X}_3(\text{ stable}).$$

At $t = 0$ the number of atoms of each type in the sample under consideration is denoted by $N_i(0)$, $i = 1, 2, 3$. The differential decay equations for each species are (assuming no loss from or production in the sample)

$$\frac{dN_1(t)}{dt} = -\lambda_1 N_1(t). \tag{3.140}$$

$$\frac{dN_2(t)}{dt} = -\lambda_2 N_2(t) + \lambda_1 N_1(t). \tag{3.141}$$

$$\frac{dN_3(t)}{dt} = \lambda_2 N_2(t). \tag{3.142}$$

The solution of Eq. (3.140) is just the exponential decay law of Eq. (3.121), i.e.,

$$N_1(t) = N_1(0) e^{-\lambda_1 t}. \tag{3.143}$$

The number of first daughter atoms $N_2(t)$ is obtained from Eq. (3.138) with the production term $Q(t) = \lambda_1 N_1(t)$. The result is

$$N_2(t) = N_2(0) e^{-\lambda_2 t} + \frac{\lambda_1 N_1(0)}{\lambda_2 - \lambda_1}[e^{-\lambda_1 t} - e^{-\lambda_2 t}]. \tag{3.144}$$

The number of second daughter (granddaughter) atoms is obtained by integrating Eq. (3.142). Thus,

$$\begin{aligned} N_3(t) &= N_3(0) + \lambda_2 \int_0^t dt'\, N_2(t') \\ &= N_3(0) + \lambda_2 N_2(0) \int_0^t dt'\, e^{-\lambda_2 t'} + \frac{N_1(0)\lambda_1\lambda_2}{\lambda_2 - \lambda_1} \int_0^t dt' \, [e^{-\lambda_1 t'} - e^{-\lambda_2 t'}] \\ &= N_3(0) + N_2(0)[1 - e^{-\lambda_2 t}] + \frac{N_1(0)}{\lambda_2 - \lambda_1}[\lambda_2(1 - e^{-\lambda_1 t}) - \lambda_1(1 - e^{-\lambda_2 t})]. \end{aligned} \tag{3.145}$$

General Decay Chain

The general decay chain can be visualized as

$$\mathrm{X}_1 \xrightarrow{\lambda_1} \mathrm{X}_2 \xrightarrow{\lambda_2} \mathrm{X}_3 \xrightarrow{\lambda_3} \cdots \mathrm{X}_i \xrightarrow{\lambda_i} \cdots \xrightarrow{\lambda_{n-1}} \mathrm{X}_n \text{ (stable)}$$

The decay and buildup equations for each member of the decay chain are

$$\begin{aligned} \frac{dN_1(t)}{dt} &= -\lambda_1 N_1(t) \\ \frac{dN_2(t)}{dt} &= \lambda_1 N_1(t) - \lambda_2 N_2(t) \\ \frac{dN_3(t)}{dt} &= \lambda_2 N_2(t) - \lambda_3 N_3(t) \\ &\vdots \quad \vdots \\ \frac{dN_{n-1}(t)}{dt} &= \lambda_{n-2} N_{n-2}(t) - \lambda_{n-1} N_{n-1}(t) \\ \frac{dN_n(t)}{dt} &= \lambda_{n-1} N_{n-1}(t). \end{aligned} \tag{3.146}$$

For the case when only radionuclides of the parent X_1 are initially present, the initial conditions are $N_1(0) \neq 0$ and $N_i(0) = 0, i > 1$. The solution of these so-called Bateman equations with these initial conditions is [Faw and Shultis 1999]

$$A_j(t) = \lambda_j N_j(t) = N_1(0)(C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} + \cdots + C_j e^{-\lambda_j t}) = N_1(0) \sum_{m=1}^{j} C_m e^{-\lambda_m t}. \tag{3.147}$$

The coefficients C_m are

$$C_m = \frac{\prod_{i=1}^{j} \lambda_i}{\prod_{\substack{i=1 \\ i \neq m}}^{j} (\lambda_i - \lambda_m)} = \frac{\lambda_1 \lambda_2 \lambda_3 \cdots \lambda_j}{(\lambda_1 - \lambda_m)(\lambda_2 - \lambda_m) \cdots (\lambda_j - \lambda_m)}, \tag{3.148}$$

where the $i = m$ term is excluded from the denominator.

PROBLEMS

1. In 1911, Robert A. Millikan determined the singular charge held by an electron. In the experiment, parallel metal plates were fashioned as depicted in Fig. 1.14 with a voltage applied. Millikan would discharge an atomized cloud of oil droplets into the chamber. Free electrons would attach to oil droplets, and an appropriate adjustment of the voltage would allow the electric force on the oil droplet to equal the gravitational force, thereby suspending such an oil droplet motionless in the chamber. Calculate the change in voltage needed to suspend an oil droplet onto which three electrons have attached. The electron charge is 1.602×10^{-19} C.

2. For slowly moving particles, that is, $v \ll c$, show that Eq. (3.8) yields the usual classical result,

$$T = mc^2 - m_o c^2 \simeq \frac{1}{2} m_o v^2. \tag{3.149}$$

3. An accelerator increases the kinetic energy of electrons uniformly to 10 GeV over a 3000 m path. That means that at 30 m, 300 m, and 3000 m, the kinetic energy is 10^8, 10^9, and 10^{10} eV, respectively. At each of these distances, compute the velocity, relative to light (v/c), and the mass in atomic mass units.

4. Muons are subatomic particles that have the negative charge of an electron but are 206.77 times more massive. They are produced high in the atmosphere by cosmic rays colliding with nuclei of oxygen or nitrogen, and muons are the dominant cosmic-ray contribution to background radiation at the earth's surface. A muon, however, rapidly decays into an energetic electron, existing, from its point of view, for only 2.20 μs, on the average. Cosmic-ray generated muons typically have speeds of about $0.998c$ and thus should travel only a few hundred meters in air before decaying. Yet muons travel through several kilometers of air to reach the earth's surface. Using the results of special relativity, explain how this is possible. HINT: consider the atmospheric travel distance as it appears to a muon, and the muon lifetime as it appears to an observer on the earth's surface.

5. A 1-MeV gamma ray loses 200 keV in a Compton scatter. Calculate the scattering angle.

6. At what energy (in MeV) can a photon lose at most one-half of its energy in Compton scattering?

7. What is the de Broglie wavelength of a water molecule moving at a speed of 2400 m/s? What is the wavelength of a 3-g bullet moving at 400 m/s?

8. If a neutron is confined somewhere inside a nucleus of characteristic dimension $\Delta x \simeq 10^{-14}$ m, what is the uncertainty in its momentum Δp? For a neutron with momentum equal to Δp, what is its total energy and its kinetic energy in MeV? Verify that classical expressions for momentum and kinetic energy may be used.

9. Repeat the previous problem for an electron trapped in the nucleus. HINT: relativistic expressions for momentum and kinetic energy must be used.

10. Estimate the wavelengths of the first three spectral lines in the Lyman spectral series for hydrogen. What energies (eV) do photons with these wavelengths have?

11. Consider an electron in the first Bohr orbit of a hydrogen atom. (a) What is the radius (in meters) of this orbit? (b) What is the total energy (in eV) of the electron in this orbit? (c) How much energy is required to ionize a hydrogen atom when the electron is in the ground state?

12. What photon energy (eV) is required to excite the hydrogen electron in the innermost (ground state) Bohr orbit to the first excited orbit?

13. What is the de Broglie wavelength of the electron in the first Bohr orbit? Compare this wavelength to the circumference of the first Bohr orbit. What does this comparison reveal about the standing wave in the first Bohr orbit?

14. Calculate the limiting (smallest) wavelength of the Lyman, Balmer, and Paschen series for the Bohr model of the hydrogen atom.

15. What is the net energy released (in MeV) for each of the following fusion reactions? (a) ${}_1^2\mathrm{H} + {}_1^2\mathrm{H} \longrightarrow {}_2^3\mathrm{He} + {}_0^1\mathrm{n}$ and (b) ${}_1^2\mathrm{H} + {}_1^3\mathrm{H} \longrightarrow {}_2^4\mathrm{He} + {}_0^1\mathrm{n}$.

Data: $M({}_1^2\mathrm{H}) = 2.0141018$ u; $M({}_1^3\mathrm{H}) = 3.0160493$ u;
$M({}_2^3\mathrm{He}) = 3.0160293$ u; $M({}_2^4\mathrm{He}) = 4.0026032$ u; $m_n = 1.0086649$ u, .

16. Calculate the Q-values for the following two beta radioactive decays.
(a) ${}_{11}^{22}\mathrm{Na} \longrightarrow {}_{10}^{22}\mathrm{Ne} + {}_{+1}^{0}\mathrm{e} + \nu$ and (b) $M{}_{17}^{38}\mathrm{Cl} \longrightarrow {}_{18}^{38}\mathrm{Ar} + {}_{-1}^{0}\mathrm{e} + \overline{\nu}$.

Data: $M({}_{11}^{22}\mathrm{Na}) = 21.9944368$ u; $M({}_{10}^{22}\mathrm{Ne}) = 21.9913855$ u;
$M({}_{17}^{38}\mathrm{Cl}) = 37.9680106$ u; $M({}_{18}^{38}\mathrm{Ar}) = 37.9637322$ u; $m_e = 5.485799 \times 10^{-4}$ u. .

17. The radioisotope ${}^{224}\mathrm{Ra}$ decays by α emission primarily to the ground state of ${}^{220}\mathrm{Rn}$ (94% probability) and to the first excited state 0.241 MeV above the ground state (5.5% probability). What are the energies of the two associated α particles?

Data: $M({}_{88}^{224}\mathrm{Ra}) = 224.0202020$ u; $M({}_{86}^{220}\mathrm{Rn}) = 220.0113841$ u;
$M({}_2^4\mathrm{He}) = 4.0026032$ u;

18. The activity of a radioisotope is found to decrease by 30% in one week. What are the values of its (a) decay constant, (b) half-life, and (c) mean life?

19. How many atoms are there in a 1.20 MBq source of (a) ${}^{24}\mathrm{Na}$ and (b) ${}^{238}\mathrm{U}$?

20. The isotope ${}^{132}\mathrm{I}$ decays by β^- emission to ${}^{132}\mathrm{Xe}$ with a half-life of 2.3 h. (a) How long will it take for 7/8 of the original number of ${}^{132}\mathrm{I}$ nuclides to decay? (b) How long will it take for a sample of ${}^{132}\mathrm{I}$ to lose 95% of its activity?

21. How many grams of ${}^{32}\mathrm{P}$ are there in a 5 mCi source?

22. The average mass of potassium in the human body is about 140 g. From the abundance and half-life of ${}^{40}\mathrm{K}$ (see Table 5.1), estimate the average activity (Bq) of ${}^{40}\mathrm{K}$ in the body.

23. A 6.2 mg sample of ${}^{90}\mathrm{Sr}$ (half-life 29.12 y) is in secular equilibrium with its daughter ${}^{90}\mathrm{Y}$ (half-life 64.0 h). (a) How many Bq of ${}^{90}\mathrm{Sr}$ are present? (b) How many Bq of ${}^{90}\mathrm{Y}$ are present? (c) What is the mass of ${}^{90}\mathrm{Y}$ present? (d) What will the activity of ${}^{90}\mathrm{Y}$ be after 100 y?

24. Consider a sample in which A is a radioactive parent that decays to a radioactive daughter B. If the initial activity of B at $t = 0$ is zero, show that the maximum activity of B is reached at time

$$t_{max} = A_0 \frac{\ln\left(\dfrac{\lambda_B}{\lambda_A}\right)}{\lambda_B - \lambda_A}. \tag{3.150}$$

25. Using a chart of nuclides, start with ^{241}Am and list the daughter products and methods of decay for each daughter product to the end of the chain (stable isotope).

Chapter 4

Radiation Interactions in Matter

Every great discovery I ever made, I gambled that the truth was there, and then I acted in faith until I could prove its existence.

Arthur H. Compton

4.1 Introduction

It is important that any professional working with or designing radiation detectors and instrumentation be familiar with fundamental interactions of radiation with matter. It is through these interactions that observable phenomena can be manipulated to yield information about the radiation type, intensity, and energy, as well as other possible uses, such as expected results and characteristic signatures. For radiation to be detected, it must first interact with neutral atoms in the detector and produce ionization and/or excitation in the detector material. Ionizing radiation is generally subdivided into two classes: *directly ionizing* radiation whose interactions produce ionization and excitation in a medium, and *indirectly ionizing* radiation that cannot ionize atoms but that can cause interactions whose charged products, known as *secondary* radiation, are directly ionizing. Fast moving charged particles, such as alpha particles, beta particles and fission fragments, can directly ionize and excite matter. Neutral particles, such as neutron and photons, cannot interact Coulombically with the electrons of the matter through which they pass; rather they cause interactions that transfer some of their incident kinetic energy to charged secondary particles.

In this chapter, how these two types of ionizing radiation interact with matter is discussed. Particular emphasis is given to quantifying the rate at which the radiation interacts with the medium and how the kinetic energy of the radiation is transfered to the medium.

4.2 Indirectly Ionizing Radiation

First considered is indirectly ionizing radiation whose particles carry no charge. Of primary concern are the interactions of photons and neutrons, although the general principles discussed here also apply to other neutral particles such as neutrinos and neutral mesons. Later in the chapter the interaction of directly ionizing radiation is considered.

4.2.1 Attenuation of Neutral Particle Beams

The interaction of a photon or neutrons with constituents of matter is dominated by short-range forces. Consequently, unlike charged particles, neutral particles move in straight lines through a medium, punctuated by occasional "point" interactions, in which the neutral particle may be absorbed or scattered or cause some

other type of reaction. The interactions are stochastic in nature, i.e., the travel distance between interactions with the medium can be predicted only in some average or expected sense.

The interaction of a given type of neutral radiation with matter may be classified according to the type of interaction and the matter with which the interaction takes place. The interaction may take place with an electron, and in many cases the electron behaves as though it were free. Similarly, the interaction may take place with an atomic nucleus, which in many cases behaves as though it were not bound in a molecule or crystal lattice. However, in some cases, particularly for radiation particles of comparatively low energy, molecular or lattice binding must be taken into account.

The interaction may be a scattering of the incident radiation accompanied by a change in its energy. A scattering interaction may be elastic or inelastic. Consider, for example, the interaction of a gamma photon with an electron in what is called Compton scattering. In the sense that the interaction is with the entire atom within which the electron is bound, the interaction must be considered as inelastic, since some of the incident photon's energy must compensate for the binding energy of the electron in the atom. However, in most practical cases, electron binding energies are orders of magnitude lower than gamma-photon energies, and the interaction may be treated as a purely elastic scattering of the photon by a free electron. Neutron scattering by an atomic nucleus may be elastic, in which case the incident neutron's kinetic energy is shared by that of the scattered neutron and that of the recoil nucleus, or it may be inelastic, in which case, some of the incident neutron's kinetic energy is transformed to internal energy of the nucleus and thence to a gamma ray emitted from the excited nucleus. It is important to note that, for both elastic and inelastic scattering, unique relationships between energy exchanges and angles of scattering arise from conservation of energy and linear momentum.

Other types of interactions are absorptive in nature. The identity of the incident particle is lost, and total relativistic momentum and energy are conserved, some of the energy appearing as nuclear excitation energy, some as translational, vibrational, and rotational energy. The ultimate result may be the emission of particulate radiation, as occurs in the photoelectric effect and in neutron radiative capture.

The discussion in this section of how a beam of radiation is attenuated as it passes through matter applies equally to both neutrons and photons. In later sections, descriptions specific to each type of neutral radiation and the particular radiation-medium interactions involved are given. The concept of the interaction coefficient is first introduced to describe how readily radiation particles interact with matter, and then use it to quantify the attenuation of a beam of neutral particles passing through some material.

4.2.2 The Linear Interaction Coefficient

The interaction of radiation with matter is always statistical in nature, and, therefore, must be described in probabilistic terms. Consider a particle traversing a homogeneous material and let $P_i(\Delta x)$ denote the probability that this particle, while traveling a distance Δx in the material, causes a reaction of type i (e.g., it is scattered). It is found empirically that the probability per unit distance traveled, $P_i(\Delta x)/\Delta x$, approaches a constant as Δx becomes very small, i.e.,

$$\mu_i \equiv \lim_{\Delta x \to 0} \frac{P_i(\Delta x)}{\Delta x}. \tag{4.1}$$

The quantity μ_i is a property of the material for a given incident particle and interaction. In the limit of small path lengths, μ_i is seen to be the probability, per unit differential path length of travel, that a particle undergoes an ith type of interaction.

That μ_i is constant for a given material and for a given type of interaction implies that the probability of interaction, per unit differential path length, is independent of the path length traveled prior to the interaction. In this book, when the interaction coefficient is referred to as the *probability per unit path length* of an interaction, it is understood that this is true only in the limit of very small path lengths.

The constant μ_i is called the *linear coefficient* for reaction i. For each type of reaction, there is a corresponding linear coefficient. For, example, μ_a is the *linear absorption coefficient*, μ_s the *linear scattering coefficient*, and so on. Although this nomenclature is widely used to describe photon interactions, μ_i is often referred to as the *macroscopic cross section* for reactions of type i, and is usually given the symbol Σ_i when describing neutron interactions. In this section, the photon jargon is used, although the present discussion applies equally to neutrons.

The probability, per unit path length, that a neutral particle undergoes some sort of reaction, μ_t, is the sum of the probabilities, per unit path length of travel, for each type of possible reaction, i.e.,

$$\mu_t(E) = \sum_i \mu_i(E). \tag{4.2}$$

Because these coefficients generally depend on the particle's kinetic energy E, this dependence has been shown explicitly. The total interaction probability per unit path length, μ_t, is fundamental in describing how indirectly ionizing radiation interacts with matter and is usually called the *linear attenuation coefficient*. It is perhaps more appropriate to use the words *total linear interaction coefficient* since many interactions do not "attenuate" the particle in the sense of an absorption interaction.

4.2.3 Attenuation of Uncollided Radiation

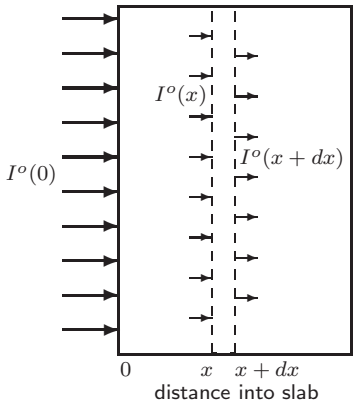

Figure 4.1. Uniform illumination of a slab by radiation.

Consider a plane parallel beam of neutral particles of intensity I_o particles $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ normally incident on the surface of a thick slab (see Fig. 4.1). As the particles pass into the slab, some interact with the slab material. Of interest in many situations, is the intensity $I^o(x)$ of *uncollided* particles at depth x into the slab. At some distance x into the slab, some uncollided particles undergo interactions for the first time as they cross the next Δx of distance, thereby reducing the *uncollided* beam intensity at x, $I^o(x)$, to some smaller value $I^o(x+\Delta x)$ at $x+\Delta x$. The probability an uncollided particle interacts as it crosses Δx is

$$P(\Delta x) = \frac{I^o(x) - I^o(x+\Delta x)}{I^o(x)}.$$

In the limit as $\Delta x \to 0$, Eq. (4.1) yields

$$\mu_t = \lim_{\Delta x \to 0} \frac{P(\Delta x)}{\Delta x} = \lim_{\Delta x \to 0} \frac{I^o(x) - I^o(x+\Delta x)}{\Delta x} \frac{1}{I^o(x)} \equiv -\frac{dI^o(x)}{dx} \frac{1}{I^o(x)}$$

or

$$\frac{dI^o(x)}{dx} = -\mu_t I^o(x). \tag{4.3}$$

The solution for the uncollided intensity is

$$\boxed{I^o(x) = I^o(0)e^{-\mu_t x}.} \tag{4.4}$$

Uncollided, indirectly ionizing radiation is thus exponentially attenuated as it passes through a medium.

From this result, the interaction probability $P(x)$ that a particle interacts somewhere along a path of length x is

$$P(x) = 1 - \frac{I^o(x)}{I^o(0)} = 1 - e^{-\mu_t x}. \tag{4.5}$$

The probability $\overline{P}(x)$ that a particle does *not* interact while traveling a distance x is

$$\overline{P}(x) = 1 - P(x) = e^{-\mu_t x}. \tag{4.6}$$

As $x \to dx$, it is found that $P(dx) \to \mu_t dx$, which is in agreement with the definition of μ_t.

4.2.4 Average Travel Distance Before an Interaction

From the above results, the probability distribution for how far a neutral particle travels before interacting can be derived. Let $p(x)dx$ be the probability that a particle interacts for the first time between x and $x + dx$. Then

$$p(x)dx = \{\text{prob. particle travels a distance } x \text{ without interaction}\} \times \{\text{prob. it interacts in the next } dx\}$$

$$= \left\{\overline{P}(x)\right\}\{P(dx)\} = \left\{e^{-\mu_t x}\right\}\{\mu_t dx\} = \mu_t e^{-\mu_t x} dx. \tag{4.7}$$

Note that $\int_0^\infty p(x)\,dx = 1$, as is required for a proper probability distribution function.

This probability distribution can be used to find the average distance $\overline{x}$ traveled by a neutral particle to the site of its first interaction, namely, the average distance such a particle travels before it interacts. The average of x is

$$\overline{x} = \int_0^\infty x\,p(x)\,dx = \mu_t \int_0^\infty x\,e^{-\mu_t x}\,dx = \frac{1}{\mu_t}. \tag{4.8}$$

This average travel distance before an interaction, $1/\mu_t$, is called the *mean-free-path length*.

The total linear attenuation coefficient μ_t can be interpreted, equivalently, as (1) the probability, per unit differential path length of travel, that a particle interacts, or (2) the inverse of the average distance traveled before interacting with the medium. Note the analogy to radioactive decay, where the decay constant λ is the inverse of the mean lifetime of a radionuclide.

4.2.5 Half-Thickness

To estimate how incident radiation interacts in a detector medium, a convenient concept is that of the *half-thickness*, $x_{1/2}$, namely, the thickness of a medium required for half of the incident radiation to undergo an interaction. For the uncollided beam intensity to be reduced to one-half of its initial value, $x_{1/2}$ must be such that

$$\frac{1}{2} = \frac{I^o(x_{1/2})}{I^o(0)} = e^{-\mu_t x_{1/2}}$$

from which one finds

$$x_{1/2} = \frac{\ln 2}{\mu_t}. \tag{4.9}$$

Again, note the similarity to the half-life of radioactive decay.

4.2.6 Microscopic Cross Sections

The linear coefficient $\mu_i(E)$ depends on the type and energy E of the incident particle, the type of interaction i, and the composition and density of the interacting medium. One of the more important quantities that determines μ is the density of target atoms or electrons in the material. It seems reasonable to expect that μ_i should be proportional to the "target" atom density N in the material, that is,

$$\boxed{\mu_i = \sigma_i\,N = \sigma_i \frac{\rho N_a}{A},} \tag{4.10}$$

where σ_i is a constant of proportionality independent of N. Here ρ is the mass density of the medium, N_a is Avogadro's number (mol^{-1}), and A is the atomic weight of the medium.

The proportionality constant σ_i is called the *microscopic cross section* for reaction i, and is seen to have dimensions of area. It is often interpreted as being the effective cross-sectional area presented by the target atom to the incident particle for a given interaction. Indeed, in many cases σ_i has dimensions comparable to those expected from the physical size of the nucleus. However, this simplistic interpretation of the microscopic cross section, although conceptually easy to grasp, leads to philosophical difficulties when it is observed that σ_i generally varies with the energy of the incident particle and, for a crystalline material, the particle direction. The view that σ is the interaction probability per unit differential path length, normalized to one target atom per unit volume, avoids such conceptual difficulties while emphasizing the statistical nature of the interaction process. Cross sections are usually expressed in units of cm^2. A widely used special unit is the *barn*, equal to 10^{-24} cm^2.

Data on cross sections and linear interaction coefficients, especially for photons, are frequently expressed as the ratio of μ_i to the density ρ, called the *mass interaction coefficient* for reaction i. Upon division of Eq. (4.10) by ρ, one obtains

$$\frac{\mu_i}{\rho} = \frac{\sigma_i N}{\rho} = \frac{N_a}{A}\sigma_i. \tag{4.11}$$

From this result, it is seen that μ_i/ρ is an intrinsic property of the interacting medium—independent of its density. This method of data presentation is used much more for photons than for neutrons, in part because, for a wide variety of materials and a wide range of photon energies, μ_i/ρ is only weakly dependent on the nature of the interacting medium.

For compounds or homogeneous mixtures, the linear and mass interaction coefficients for interactions of type i are, respectively,

$$\mu_i = \sum_j \mu_i^j = \sum_j N^j \sigma_i^j \tag{4.12}$$

and

$$\frac{\mu_i}{\rho} = \sum_j w_j \left(\frac{\mu_i}{\rho}\right)^j, \tag{4.13}$$

in which the superscript j refers to the jth component of the material, the subscript i to the type of interaction, and w_j is the weight fraction of component j. In Eq. (4.12), the atomic density N^j and the linear interaction coefficient μ_i^j are values for the jth material *after* mixing.

4.2.7 Calculation of Radiation Interaction Rates

To quantify the number of interactions caused by neutral particles as they pass through matter, one often needs to estimate the number of a specific type of interaction that occurs, in a unit time and in a unit volume, at some point in the matter. This density of reactions per unit time is called the *reaction rate density*, denoted by F_i. This quantity depends on (1) the amount or strength of the radiation at the point of interest, and (2) the readiness with which the radiation can cause the interaction of interest.

Flux Density

At any given location $\mathbf{r}$, the radiation field is generally a function of time t (e.g., a detector can pass by a radiation source) and of the radiation particles' energy E (e.g., radiation sources often emit photons or neutrons with many energies). To quantify the "strength" of a radiation field one could use the particle density $n(\mathbf{r}, E, t)$ where $n(\mathbf{r}, E, t)dV\,dE$ is the expected number of particles in differential volume element

dV about $\mathbf{r}$ with energies in dE about E at time t. Alternatively, one could use the flux density, often just called the flux, which is defined as

$$\phi(\mathbf{r}, E, t) \equiv v(E)\, n(\mathbf{r}, E, t), \tag{4.14}$$

where $v(E)$ is the speed of a radiation particle with kinetic energy E.[1]

Because $v(E)$ is the distance a radiation particle of energy E travels in a unit time, the flux $\phi(\mathbf{r}, E, t)dV\, dE$ has the interpretation of being the distance traveled in a unit time by particles in dV and $\mathbf{r}$ that have energies in dE and E.

Reaction-Rate Density

With the concepts of flux and interaction coefficient, the rate at which radiation interacts with a medium can be quantified. Specifically, let $\widehat{F}_i(\mathbf{r}, E, t)dE$ be the expected number of ith type interactions per unit time that occurs in a unit volume at $\mathbf{r}$ caused by radiation particles with energies in dE about E. Thus,

$$\begin{aligned}\widehat{F}_i(\mathbf{r}) &= \{\text{total path-length traveled by the particles in one cm}^3 \text{ in one second}\}/ \\ &\qquad \{\text{average distance particles must travel for an } i\text{th type interaction}\} \\ &= \{\phi(\mathbf{r}, E, t)dE\}/\{1/\mu_i(\mathbf{r}, E, t)\}\end{aligned}$$

or

$$\boxed{\widehat{F}_i(\mathbf{r}, E, t)dE = \mu_i(\mathbf{r}, E, t)\, \phi(\mathbf{r}, E, t)dE.} \tag{4.15}$$

This simple expression for reaction-rate densities is a key equation for many nuclear calculations.

From the interaction rate density, all sorts of useful information can be calculated about the effects of the radiation. For example, the total number of scattering interactions that occur in some detector volume V between times t_1 and t_2 by radiation particle of all energies is

$$\text{Number of scatters in } (t_1, t_2) = \int_{t_1}^{t_2} dt \iiint_V dV \int_0^{E_{\max}} dE\, \mu_s(\mathbf{r}, E, t)\phi(\mathbf{r}, E, t). \tag{4.16}$$

Finally, to obtain the reaction rate density per *unit mass*, simply replace μ in the above expression by (μ/ρ), where ρ is the mass density of the interacting medium.

Radiation Fluence

In most interaction rate calculations, the interaction properties of the medium do not change appreciably in time. For this usual situation, the example of Eq. (4.16) reduces to

$$\text{Number of fissions in } (t_1, t_2) = \iiint_V dV \int_0^{E_{\max}} dE\, \Sigma_f(\mathbf{r}, E)\, \Phi(\mathbf{r}, E), \tag{4.17}$$

where the *fluence* of radiation between t_1 and t_2 is the time-integrated flux density, namely

$$\boxed{\Phi(\mathbf{r}, E) \equiv \int_{t_1}^{t_2} dt\, \phi(\mathbf{r}, E, t).} \tag{4.18}$$

[1] Photons, of course, always travel with the speed of light so $v(E) = c$. However, neutrons of different energies have different speeds.

For a steady-state radiation field, the fluence is simply $\Phi(\mathbf{r}, E) = (t_2 - t_1)\phi(\mathbf{r}, E)$.

Often the time interval over which the flux density is integrated to obtain the fluence is implicitly assumed to be over all prior time. Thus, the fluence at time t is

$$\Phi(\mathbf{r}, E, t) \equiv \int_{-\infty}^{t} dt'\, \phi(\mathbf{r}, E, t'). \tag{4.19}$$

The rate of change of the fluence with time, or the fluence rate, is simply the flux density. The fluence is thus used to quantify the cumulative effect of radiation interactions, while the flux density is used to quantify the rate of interactions.

4.3 Scattering Interactions

Scattered radiation is of great concern in interpreting the results of radiation detectors. First scattering transfers a spectrum of energies to the scattering medium as a result of the many different scattering angles that can occur. Likewise scattering of radiation from material near a detector cause radiation with a great variety of energies to reach a detector.

4.3.1 Differential Scattering Coefficients

The scattering coefficient μ_s is generally a function of the energy of the incident radiation. However, to describe the many features of a scattering interaction, μ_s may depend on other variables, leading to so-called *differential scattering coefficients*. Such coefficients may be a function of (1) the energy of the particle after scattering, (2) the energy of the recoil atom or electron, (3) the angles of deflection of the scattered radiation and recoil atom or electron,[2] and (4) the angles of emission of secondary particles.

For example, the doubly differential scattering interaction coefficient is defined in such a way that $d^2\mu_s(E, E', \theta_s)/dE'\, d\Omega_s$ is the probability per unit path length for an interaction in which the incident particle of energy E emerges from the interaction with energy between E' and $E' + dE'$ and with scattering angle θ_s, measured with respect to the incident direction, within the differential solid angle $d\Omega_s$.[3] In this form, μ has units such as $\text{cm}^{-1}\ \text{MeV}^{-1}\ \text{sr}^{-1}$. Alternatively, the interaction coefficient could be expressed in terms of energy T_r and angles θ_r for recoil electrons or atoms, or other secondary radiations. Thus, one has an equivalent doubly differential scattering interaction coefficient $d^2\mu_s(E, T_r, \theta_r)/dT_r\, d\Omega_r = d^2\mu_s(E, E', \theta_s)/dE'\, d\Omega_s$. This later description is most useful for radiation detection, because it is the energy of recoil secondary radiation that is of interest, i.e., the energy deposited in the detector.

Often it is also of interest to deal only with, say, the energy dependence or the angular distribution of scattered radiation. In this case, one or the other of the following forms of *singly differential* scattering coefficient may be used:

$$\frac{d\mu_s(E, T_r)}{dT_r} \equiv \int_{4\pi} d\Omega_r\, \frac{d^2\mu_s(E, T_r, \theta_r)}{dT_r\, d\Omega_r} \tag{4.20}$$

or

$$\frac{d\mu_s(E, \theta_r)}{d\Omega_r} \equiv \int_0^{\infty} dT_r\, \frac{d^2\mu_s(E, T_r, \theta_r)}{dT_r\, d\Omega_r}. \tag{4.21}$$

Here $d\mu_s(E, T_r)/dT_r$ is the probability, per unit path length of travel, that scattering produces a recoil particle with energy dT_r about T_r, without regard to scattering angle. Likewise, $d\mu_s(E, \theta_r)/\, d\Omega_r$ is the probability

[2] This dependence is true for isotropic media, which is assumed to be the case unless otherwise noted specifically. For crystalline and other anisotropic media, μ_s generally depends on the incident radiation direction $\mathbf{\Omega}$ and the exit radiation direction $\mathbf{\Omega}'$.

[3] In many references the differential coefficient $d^2\mu_s(E, E', \theta_s)/dE'\, d\Omega_s$ is simply written as $\mu_s(E, E', \theta_s)$.

for scattering into direction range $d\Omega_r$, without regard to the energy of the exit radiation. Finally,

$$\mu_s(E) \equiv \int_0^\infty dT_r \, \frac{d\mu_s(E, T_r)}{dT_r} \equiv \int_{4\pi} d\Omega_r \, \frac{d\mu_s(E, \theta_r)}{d\Omega_r}, \tag{4.22}$$

which is just the total linear interaction coefficient for the scattering of incident radiation of energy E, without regard to the recoil particle's energy or angle of recoil. Associated with the differential scattering coefficients are the differential microscopic scattering cross sections as a generalization of Eq. (4.10). For example

$$\frac{d^2\mu_s(E, E', \theta_s)}{dE' \, d\Omega_s} = N \frac{d^2\sigma_s(E, E', \theta_s)}{dE' \, d\Omega_s} = \frac{\rho N_a}{A} \frac{d^2\sigma_s(E, E', \theta_s)}{dE' \, d\Omega_s}. \tag{4.23}$$

4.3.2 Conservation Laws for Scattering Reactions

Conservation of Momentum

Consider the nuclear reaction illustrated in Fig. 4.2. Reactants are a stationary target of rest mass M and an incident particle of rest mass m, kinetic energy E, and momentum $\mathbf{p}$. Products are one particle of rest mass m', kinetic energy E', and momentum $\mathbf{p}'$, and a second particle of rest mass M', kinetic energy T, and momentum $\mathbf{p}_r$. Energies E, E', and T are kinetic energies in the laboratory system, except for photons for which the adjective *kinetic* is not used.

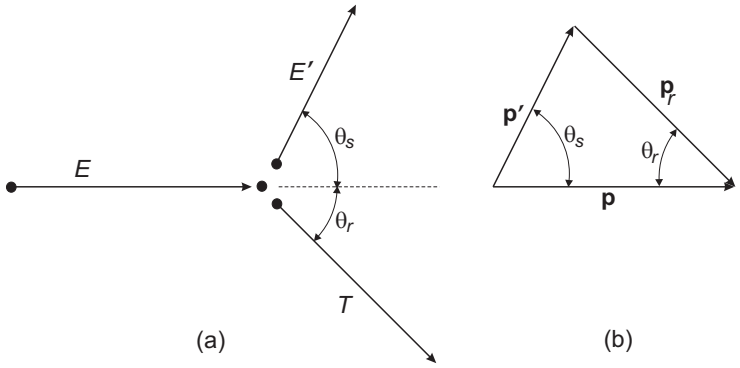

Figure 4.2. Nuclear reaction with one reactant initially stationary and with products emerging at angles θ_s and θ_r in the laboratory system. (a) Energies and scattering angles. (b) Conservation of linear momentum.

Energy and momentum of the incident particle are related by the equation

$$E = \sqrt{p^2c^2 + m^2c^4} - mc^2, \tag{4.24}$$

in which scalar p is the magnitude of the momentum $\mathbf{p}$ and c is the speed of light in vacuum, 2.9979×10^8 m/s. Similar equations relate E' and $\mathbf{p}'$, and T and $\mathbf{p}_r$. Conservation of linear momentum is depicted in the vector diagram Fig. 4.2(b), in which the initial momentum vector $\mathbf{p}$ must equal the sum of the product momentum vectors $\mathbf{p}'$ and $\mathbf{p}_r$. From the law of cosines,

$$(p')^2 = p^2 + p_r^2 - 2pp_r \cos\theta_r \tag{4.25}$$

and

$$p_r^2 = p^2 + (p')^2 - 2pp' \cos\theta_s. \tag{4.26}$$

It is also clear from the figure that from the law of sines,

$$p'/\sin\theta_r = p_r/\sin\theta_s. \tag{4.27}$$

Conservation of Energy

The fact that total energy, the sum of kinetic and rest-mass energy, is conserved in the nuclear reaction is expressed by the equation

$$E = E' + T - Q, \tag{4.28}$$

in which Q is the Q *value* of the reaction. If it is assumed that the reactants are initially in the ground state, i.e., $m = m_o$ and $M = M_o$, the Q value is given by

$$Q = \Delta M_o c^2 - W \equiv (m_o + M_o - m'_o - M'_o)c^2 - \sum E_{ex}, \tag{4.29}$$

in which $\Delta M_o c^2$ is energy equivalent of the changes in the ground-state rest masses of the reactants, and W is the sum of the nuclear excitation energies E_{ex} of the reaction products.

Application of the Conservation Laws

If an incident particle is a photon, the rest mass is zero and, from Eq. (4.24), $p = E/c$. If the incident particle is a neutron, classical mechanics may be assumed to apply for energies less than about 15 MeV, and $p = \sqrt{2mE}$. If the incident particle is an electron, then relativistic conservation laws generally should be applied and the following equations are useful. The ratio of the particle speed to the speed of light in vacuum is identified as $\beta = v/c$, and, with $\epsilon \equiv E/mc^2$, then obtains the results

$$\beta^2 = \frac{\epsilon(\epsilon+2)}{(\epsilon+1)^2}, \quad \frac{\beta^2}{1-\beta^2} = \epsilon(\epsilon+2) \tag{4.30}$$

and

$$p^2c^2 = E(E + 2mc^2) = \frac{\beta^2 m^2 c^4}{1-\beta^2}. \tag{4.31}$$

Equations (4.24) through (4.31) provide the framework for treatment of the kinematics of a large class of nuclear reactions. They are drawn upon throughout this book. The topics now to be addressed are scattering reactions, for which $m' = m$ and $M' = M$. Most reactions addressed are elastic scattering, for which the Q value is zero. The exception is inelastic scattering of a neutron by an atomic nucleus. That reaction is *endothermic*, and the Q value is negative and equal in magnitude to the excitation energy of the final state of the nucleus with respect to its ground state.

4.3.3 Scattering of Photons by Free Electrons

This scattering process is known as the *Compton effect*, to recognize its 1923 discovery by A.H. Compton. Since the photon has zero rest mass, $p = E/c$ and $p' = E'/c$. Because the electron is free, the scattering is elastic and $E = E' + T$. Thus, Eqs. (4.25) and (4.26) reduce to

$$E' = \frac{E}{1 + (E/m_e c^2)(1-\cos\theta_s)}, \quad 0 \le \theta_s \le \pi, \tag{4.32}$$

and

$$T = \frac{2m_e c^2 E^2 \cos^2\theta_r}{(E + m_e c^2)^2 - E^2\cos^2\theta_r}, \quad 0 \le \theta_r \le \pi/2. \tag{4.33}$$

Here $m_e c^2$ is the rest-mass energy of the electron, 0.51099892 MeV or 8.1871×10^{-14} J. These equations are very much simplified if expressed in terms of the dimensionless variables[4] $\Lambda = m_e c^2/E$ and $\tau = T/m_e c^2$, namely,

$$\Lambda' = 1 + \Lambda - \cos\theta_s, \tag{4.34}$$

and

$$\tau = \frac{2\cos^2\theta_r}{(1+\Lambda)^2 - \cos^2\theta_r}. \tag{4.35}$$

Note that $\Lambda \leq \Lambda' \leq \Lambda + 2$. Note too that the maximum energy transfer to initial kinetic energy of a recoil electron is given by

$$\left[\frac{T}{E}\right]_{\max} = \frac{2}{\Lambda + 2}, \tag{4.36}$$

which approaches unity for incident photons of very high energy. Similarly,

$$\frac{E'}{E} = \frac{\Lambda}{\Lambda + 1 - \cos\theta_s} \tag{4.37}$$

and

$$\left[\frac{E'}{E}\right]_{\min} = \frac{\Lambda}{\Lambda + 2}, \tag{4.38}$$

which approaches unity for incident photons of very low energy. A relationship between scattering angles is given by

$$\cot\theta_r = (1 + \Lambda^{-1})\tan(\theta_s/2)\,. \tag{4.39}$$

4.3.4 Scattering of Neutrons by Atomic Nuclei

The scattering interaction is the most probable interaction of fast neutrons and is the mechanism relied upon to slow these neutrons to thermal energies, at which they can be absorbed through (n, γ) reactions. There are two distinct types of scattering processes, both of importance in fast neutron attenuation. In *capture scattering* the incident neutron is absorbed by the scattering nucleus to form a compound nucleus which subsequently decays by the emission of a neutron. If the residual nucleus is left in the ground state, the scattering is called *elastic*. If the residual nucleus is left in an excited state, the scattering is called *inelastic*. The other type of scattering is referred to as *potential scattering*. In this process, which is always elastic, the incident neutron is scattered by the nucleus as a whole—analogous to the diffraction of the incident neutron wave by the entire nuclear potential. Capture-scattering cross sections generally exhibit resonance behavior, while potential scattering cross sections usually vary slowly with energy.

In all scattering processes the total energy and momentum must be conserved. Except for thermal neutron scattering, for which the thermal motion of the target atoms may be comparable to the neutron speed, one can properly neglect the initial kinetic energy of the scattering nucleus in the laboratory coordinate system. Furthermore, these scattering interactions may be treated by classical mechanics, so that energy and momentum are related by $p^2 = 2mE$. The ratio M/m of the mass of the target nucleus to the mass of

[4] In this book, the dimensionless variable Λ is called the *reduced* wavelength. Clearly it does not have units of length. Usually in most texts the symbol for reduced wavelength is λ, but because λ is already used as the decay constant, and later is used as actual wavelength, to avoid confusion the symbol Λ is used as a substitute. It might better be called the *wave number*. It may be construed more properly as the ratio of the actual wavelength hc/E to the *Compton wavelength* $\Lambda_c = hc/m_e c^2 = 2.4263 \times 10^{-12}$ m, in which h is Planck's constant, 6.6261×10^{-34} J s. More correctly, then, Λ is the wavelength in units of the Compton wavelength.

the neutron is so nearly equal to the atomic mass A of the target nucleus that in this book, the difference is neglected. In the general case of inelastic scattering, Eqs. (4.24) to (4.26) reduce to (see Problem 16)

$$\omega_s(E,E') = \frac{1}{2}\left[(A+1)\sqrt{\frac{E'}{E}} - (A-1)\sqrt{\frac{E}{E'}} - \frac{QA}{\sqrt{EE'}}\right], \tag{4.40}$$

in which $\omega_s \equiv \cos\theta_s$, $-1 \le \omega_s \le +1$. It follows that

$$\sqrt{E'} = \frac{1}{(A+1)}\left[\omega_s\sqrt{E} \pm \sqrt{E(\omega_s^2 + A^2 - 1) + A(A+1)Q}\right] \tag{4.41}$$

and

$$T = \frac{AE}{(1+A)^2}\left[\Delta + 2\cos^2\theta_r \pm \sqrt{(\Delta + 2\cos^2\theta_r)^2 - \Delta^2}\right], \tag{4.42}$$

in which

$$\Delta = \frac{Q(1+A)}{AE} \tag{4.43}$$

and $0 \le \theta_r \le \pi/2$.

Because $\sqrt{E'}$ physically must be non-negative, only the plus sign in Eqs. (4.41) and (4.42) gives meaningful results for elastic scattering ($Q = 0$) and for most inelastic scattering. However, when a neutron with energy only slightly greater than $|Q|$ is inelastically scattered, both signs may lead to physically realistic results. This so-called "double value" region is discussed below.

4.3.5 Threshold Energies for Neutron Inelastic Scattering

From Eq. (4.41), it is clear that for E' to be real it is necessary that

$$E \ge -\frac{A(A+1)Q}{\omega_s^2 + A^2 - 1}. \tag{4.44}$$

The least value of E allowing inelastic scatter, the threshold energy E_t, corresponds to $\omega_s = 1$, namely,

$$E_t = -\frac{A+1}{A}Q. \tag{4.45}$$

The energies of the first and second excited nuclear states tend to decrease as the atomic weight A increases. Consequently, the threshold for inelastic scattering tends to decrease as the atomic mass of the scatterer increases. The level spacings of the light elements and the magic number[5] nuclides are relatively large and hence inelastic scattering is generally less significant for such nuclides. Moreover, the odd-even and even-odd nuclides tend to have smaller thresholds than the even-even nuclides.

It is also clear from Eq. (4.41) that for values of E just greater than E_t, the scattered neutron can appear in the forward direction, $\omega_s > 0$, with either of two distinct positive energies. The largest value of E for which this is possible—the cutoff energy E_c—is the largest value of E for which $\omega_s\sqrt{E} - \sqrt{E(\omega_s^2 + A^2 - 1) + A(A+1)Q} \ge 0$, namely,

$$E_c = -\frac{AQ}{A-1}. \tag{4.46}$$

For E between E_t and E_c, there is a maximum scattering angle, or minimum ω_s, permitting real values of E', namely, $\omega_{s,min} = \sqrt{1 - A^2 - QA(A+1)/E}$. Discussion of the implications of dual values of E' may be found in the works of Evans [1955] and Amaldi [1959].

[5] A magic number nucleus is one in which the number of neutrons or protons equals 2, 8, 20, 50, 82, or 126. When the nucleus is magic, a particularly stable configuration of the nucleons in the nucleus is achieved analogous to closed electron shells in atomic physics.

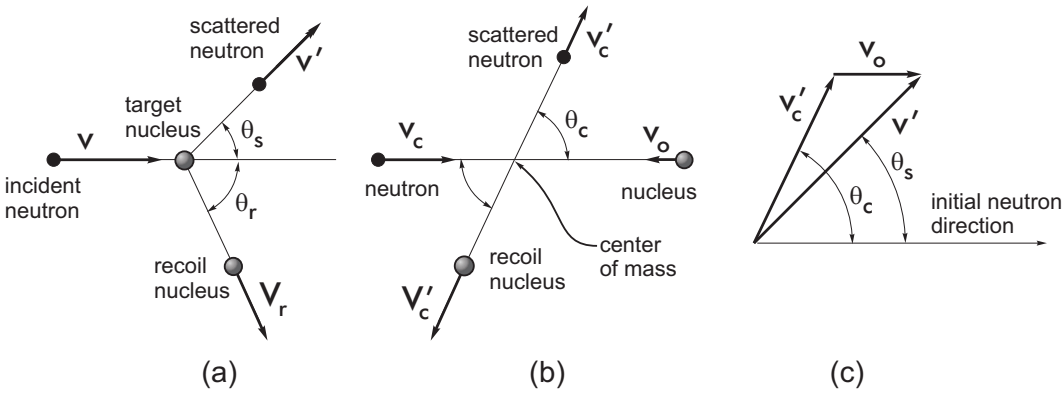

Figure 4.3. Conversion between laboratory and center-of-mass coordinate systems. (a) Velocities in the laboratory system. (b) Velocities in the center-of-mass system. (c) Relationship between scattering angles in the two systems.

4.3.6 Neutron Scattering in the Center-of-Mass System

Particle kinematics may be described and understood completely in the laboratory coordinate system used implicitly to this point. It may therefore seem a needless complication to introduce a different coordinate system—the center-of-mass system. Nevertheless, there are certain aspects of particle kinematics that are greatly simplified when described in the new system. This is especially true for angular characteristics of scattering cross sections and angular distributions of neutrons after scattering. Such distributions are more easily and more precisely described in the center-of-mass system. For example, the angular distribution of neutrons scattered from hydrogen atoms or, indeed, the angular distribution of billiard balls after elastic collision is very anisotropic in the laboratory system but completely isotropic in the center-of-mass system.

Consider the scattering reaction illustrated in Fig. 4.3(a). The target nucleus is initially at rest. Prior to scatter, the center of mass is moving to the right with velocity $\mathbf{v}_o$ defined in such a way that the total linear momentum $m\mathbf{v}$ is equal to $(m+M)\mathbf{v}_o$. In the center-of-mass system, Fig. 4.3(b), the center of mass is stationary. Prior to scatter, the target atom is moving to the left with velocity $\mathbf{v}_o$ and the incident neutron is moving to the right with velocity $\mathbf{v}_c = \mathbf{v} - \mathbf{v}_o$. The total momentum before and after scattering is zero. Thus, products of the scattering must move in opposite directions, the neutron with velocity $\mathbf{v}'_c$ and the recoil nucleus with velocity $\mathbf{V}'_c$. Figure 4.3(c) illustrates the relationship between the scattering angles in the two systems and, as addressed in Problem 18, reveals that in terms of their cosines, where from Fig. 4.3, $\omega_s = \cos\theta_s$, $\omega_r = \cos\theta_r$, and $\omega_c = \cos\theta_c$,

$$\omega_s = \frac{\gamma + \omega_c}{\sqrt{1 + 2\gamma\omega_c + \gamma^2}} \tag{4.47}$$

and[6]

$$\omega_c = -\gamma(1-\omega_s^2) \pm \omega_s\sqrt{1-\gamma^2(1-\omega_s^2)}, \tag{4.48}$$

[6]For elastic scattering, only the positive sign in Eq. (4.48) applies, with one exception. For $A = 1$, $\omega_s \geq 0$, and $\omega_c = -1 + 2\omega_s^2$. For inelastic scattering, the positive sign applies except in the region of dual values of E', and then $\omega_s > 0$ and ω_c is dual valued.

in which (see Problem 20)

$$\gamma \equiv \frac{v_o}{v_c'} = \left[A^2 + \frac{A(A+1)Q}{E}\right]^{-1/2}. \tag{4.49}$$

Energies after scattering are given by (see Problem 21)

$$E' = \frac{1}{2}E(1+\alpha) + \frac{1}{2}(1-\alpha)E\omega_c\sqrt{1+\Delta} + \frac{QA}{A+1} \tag{4.50}$$

and

$$T = E - E' + Q = \frac{1}{2}E(1-\alpha)\left[1 - \omega_c\sqrt{1+\Delta}\right] + \frac{Q}{A+1}, \tag{4.51}$$

in which

$$\alpha \equiv \left[\frac{A-1}{A+1}\right]^2. \tag{4.52}$$

Note that E'/E always lies between the limits

$$\frac{E'_{\min}}{E} = \left[\frac{A\sqrt{1+\Delta}-1}{1+A}\right]^2 \text{ and } \quad \frac{E'_{\max}}{E} = \left[\frac{A\sqrt{1+\Delta}+1}{1+A}\right]^2. \tag{4.53}$$

4.3.7 Limiting Cases in Classical Mechanics of Elastic Scattering

By setting $Q = 0$ and $E' = E - T$ in Eqs. (4.41) and (4.50) and using Eq. (4.27), one finds that

$$\frac{T}{E} = \frac{2A}{(1+A)^2}(1-\omega_c) = \frac{4A}{(1+A)^2}\omega_r^2, \tag{4.54}$$

where $A \equiv M/m$. Thus,

$$\omega_r = \sqrt{\frac{1-\omega_c}{2}} = \sin\left(\frac{\theta_c}{2}\right). \tag{4.55}$$

By substituting $\omega_c = 1 - 2\omega_r^2$ from this equation into Eq. (4.47), one finds that for the classical mechanics of elastic scattering,

$$\omega_s = \frac{1 - [2A\omega_r^2/(A+1)]}{\sqrt{1 - [4A\omega_r^2/(A+1)^2]}}. \tag{4.56}$$

Listed as follows are limiting values of scattering parameters for three cases.

Case 1: $m = M$. This case describes neutron-proton scattering and the scattering by stationary free electrons of low-energy electrons or positrons. All scattering angles are possible in the center-of-mass system, but in the laboratory system, θ_s and θ_r are limited to the range 0 to $\pi/2$.

θ_c	θ_s	θ_r	E'/E	T/E
0	0	$\pi/2$	1	0
$\pi/2$	$\pi/4$	$\pi/4$	1/2	1/2
π	$\pi/2$	0	0	1

Case 2: $m < M$. This case describes electron scattering by nuclei and neutron scattering from heavier nuclei. Scattering is possible for values of θ_s and θ_c between 0 and π but for θ_r only between 0 and $\pi/2$. As A increases, θ_s approaches θ_c.

θ_c	θ_s	θ_r	E'/E	T/E
0	0	$\pi/2$	1	0
$\pi/2$	$\tan^{-1}A$	$\pi/4$	$(1+\alpha)/2$	$(1-\alpha)/2$
π	π	0	α	$1-\alpha$

Case 3: $m > M$. This case approximately describes scattering of heavy charged particles by electrons. Scattering is possible for $0 \leq \sin\theta_s \leq M/m$. As $M/m \to 0$, $\theta_s \to 0$.

4.3.8 Relativistic Elastic Scattering of Electrons and Heavy Charged Particles

The basic working equation follows directly from the conservation laws, Eqs. (4.24) through (4.29), namely,

$$T = \frac{2Mc^2\,p^2c^2\,\omega_r^2}{\left[Mc^2 + \sqrt{p^2c^2 + m^2c^4}\right]^2 - p^2c^2\,\omega_r^2}. \tag{4.57}$$

The maximum energy is transferred to the recoil target when $\omega_r = 1$. In terms of $\beta \equiv v/c$, and in terms of Eqs. (4.30) and (4.31),

$$T_{\max} = \frac{\beta^2}{1-\beta^2}\left[\frac{2Mm^2c^2}{m^2 + M^2 + [2mM/\sqrt{1-\beta^2}]}\right]. \tag{4.58}$$

Electron-Electron Scattering

Here $M = m = m_e$. The scattered and recoil electrons are indistinguishable, so the convention is adopted that the one with the lesser energy is identified as the recoil:

$$T = \frac{\beta^2}{1-\beta^2}\left[\frac{2m_ec^2\;\omega_r^2}{\left(1 + [1/\sqrt{1-\beta^2}]\right)^2 - \beta^2\omega_r^2/(1-\beta^2)}\right] \tag{4.59}$$

and

$$T_{\max} = \frac{\beta^2}{1-\beta^2}\left[\frac{m_ec^2}{1 + [1/\sqrt{1-\beta^2}]}\right] = E. \tag{4.60}$$

4.4 Cross Sections for Photon Interactions

For details of the mechanisms of photon interactions, the reader is referred to the standard reference works of Heitler [1954] and Evans [1955]. For comprehensive data tabulations, the reader is referred to ANSI [1991], Biggs and Lighthill [1972], Cullen [1994], Cullen et al. [1989], Hubbell [1969, 1982], Hubbell and Seltzer [1995], Hubbell et al. [1975, 1979], Plechaty et al. [1975], Seltzer [1993], and Trubey et al. [1989]. Photon energies between 10 eV and 10 MeV are important in the design and analysis of photon radiation detectors. For this energy range, only the photoelectric effect, pair production, and Compton scattering mechanisms of interaction are significant. Of these three, the photoelectric effect predominates at the lower photon energies. Pair production is important only for higher-energy photons. Compton scattering predominates at intermediate energies. In rare instances one may need to account also for coherent scattering.

4.4.1 Thomson Cross Section for Incoherent Scattering

Incoherent scattering refers to the interaction of a photon with an individual electron, as distinguished from the coherent interaction of a photon with all electrons of an atom. It is assumed in the discussion that follows that the incident radiation is not polarized.

In the limit of zero photon energy, scattering of the photon by a free electron may be treated by the classical theory of radiation. The electron in the electromagnetic field of the incident radiation vibrates with the same frequency as that of the incident radiation, thereby giving rise to the emission of secondary electromagnetic radiation of the same frequency. Named for discoverer of the electron, J.J. Thomson (1856–1940) [see Thomson 1897], the total cross section *per electron* for such scattering is

$$\sigma_T = \frac{8}{3}\pi r_e^2, \tag{4.61}$$

in which r_e is the *classical electron radius*. The value of r_e is given by

$$r_e = \frac{q_e^2}{4\pi\epsilon_o m_e c^2}, \tag{4.62}$$

where q_e is the electronic charge, 1.6022×10^{-19} C, and ϵ_o is the permittivity of free space, 8.8542×10^{-14} F cm^{-1}. Thus, $r_e = 2.8179 \times 10^{-13}$ cm and $\sigma_T = 6.6525 \times 10^{-25}$ cm^2.

For unpolarized incident radiation, the Thomson *electronic* cross section per steradian for scattering at angle θ_s, as in Fig. 4.2, is

$$\frac{d\sigma_T(\theta_s)}{d\Omega_s} = \frac{1}{2}r_e^2(1 + \cos^2\theta_s). \tag{4.63}$$

Knowledge of the Thomson cross section is important for two reasons. It is the low-energy limit for the incoherent (Compton) scattering cross section. It is also, as is evident from Eq. (4.82), the basis for computing Rayleigh-scattering cross sections for interactions of photons coherently with atomic electrons.

4.4.2 Klein-Nishina Cross Section for Incoherent Scattering

The atomic Compton cross section for incoherent scattering may be approximated as the atomic number times the electronic cross section for scattering by a free electron (i.e., the total Klein-Nishina cross section σ_{KN}), namely

$$\sigma_c = Z\,\sigma_{KN}. \tag{4.64}$$

The differential scattering cross section *per electron* $\mathrm{d}\sigma_{KN}(\Lambda, \theta_s)/d\Omega_s$ was calculated by Klein and Nishina [1929] and by Tamm [1930]. This differential scattering cross section for unpolarized photons is[7]

$$\frac{d\sigma_{KN}(\Lambda, \theta_s)}{d\Omega_s} = \frac{1}{2}r_e^2\frac{\Lambda^2}{(1 + \Lambda - \cos\theta_s)^2}\left(\frac{\Lambda}{1 + \Lambda - \cos\theta_s} + \frac{1 + \Lambda - \cos\theta_s}{\Lambda} - \sin^2\theta_s\right). \tag{4.65}$$

A convenient alternative form is

$$\frac{d\sigma_{KN}(E, \theta_s)}{d\Omega_s} = \frac{1}{2}r_e^2\zeta[1 + \zeta^2 - \zeta(1 - \cos^2\theta_s)], \tag{4.66}$$

in which $\zeta \equiv E'/E = \Lambda/\Lambda'$ is given by Eq. (4.37). This cross section is illustrated in Fig. 4.4. Note that as Λ approaches infinity, that is, E approaches zero, ζ approaches unity and Eq. (4.66) reduces to the Thomson formula, Eq. (4.63).

[7] Although both polarized and unpolarized cases were derived, the unpolarized case is generally of more interest for radiation detection.

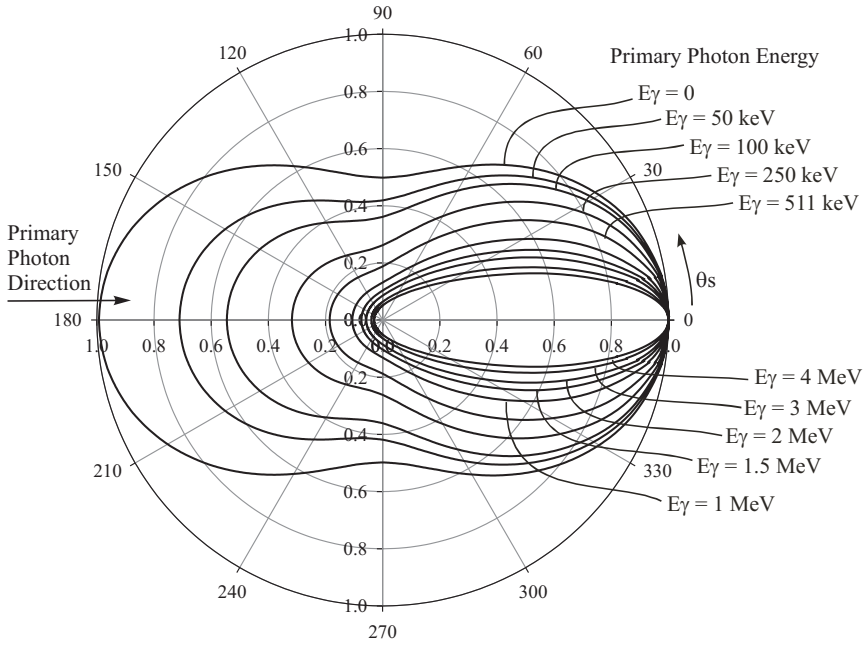

Figure 4.4. Shown is the function $d\sigma_{KN}/d\Omega_s$ divided by r_e^2 as a function of scattering angle θ. Notice that the number of photons scattered into a unit differential solid angle increases in the forward direction as the primary photon energy increases.

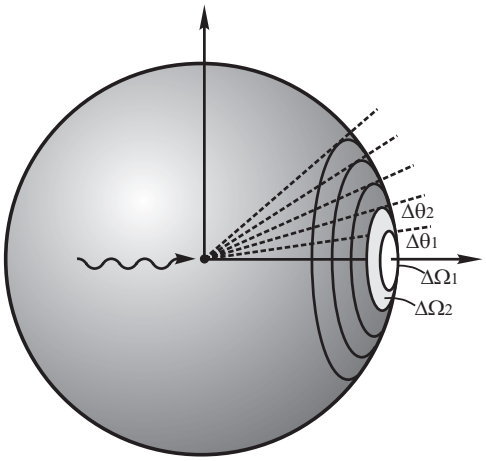

Figure 4.5. For equal $\Delta\theta_i$, the solid angle $\Delta\Omega_i$ increases as θ increases from 0 to $\pi/2$.

One must be wary in interpreting Fig. 4.4. At first glance an observer might mistakenly think that high energy photons are primarily scattered directly forward. Although the term $d\sigma_{KN}/d\Omega_s$ increases with decreasing angle θ as energy increases (as shown in Fig. 4.4), the total differential solid angle defined by $d\Omega_s$ *decreases* as θ decreases (see Fig. 4.5). This change in solid angle with angle θ is defined by

$$\frac{d\Omega_s}{d\theta_s} = 2\pi \sin\theta_s, \tag{4.67}$$

which clearly increases as θ_s approaches 90^o. Further, when $\theta_s = 0$, $d\Omega_s/d\theta_s = 0$. Hence, the density of photons scattering into $d\Omega_s$ increases with decreasing θ, but the total probability of photons scattering into the differential solid angle, $d\Omega_s$, is proportional to the product of the differential solid angle and the density of photons scattered into a unit solid angle about angle θ, namely the differential scattering cross section.

The distribution of photons scattered per unit polar angle θ_s is quite different than $d\sigma_{KN}/d\Omega_s$. Multiplying Eq. (4.66) by Eq. (4.67) yields the probability of scattering a photon of initial energy E through angle θ_s, namely

$$\frac{d\sigma_{KN}(E,\theta_s)}{d\theta_s} = \frac{d\sigma_{KN}(E,\theta_s)}{d\Omega_s}\frac{d\Omega_s}{d\theta_s} = \pi r_e^2 \zeta[1+\zeta^2-\zeta(1-\cos^2\theta_s)]\sin\theta_s. \tag{4.68}$$

This cross section is plotted in Fig. 4.6. Notice that there is still a preference for forward scattering with increasing photon energy; however, the highest cross section is no longer at $\theta_s = 0^o$, and it changes as a function of E. Notice also, quite unlike Fig. 4.4, which shows the density of photons scattering into $d\Omega_s$, that the highest differential cross section in Fig. 4.6 for low energy photon (Thomson) scattering is at scattering angles of 55^o and 125^o.

A related quantity is the *energy scattering* differential cross section,

$$\frac{d\sigma_{KNe}(E,\theta_s)}{d\Omega_s} \equiv \frac{E'}{E}\frac{d\sigma_{KN}(E,\theta_s)}{d\Omega_s} = \frac{Z}{2} r_e^2 \zeta^2 [1 + \zeta^2 - \zeta(1 - \cos^2\theta_s)]. \quad (4.69)$$

The total Compton cross section *per atom*, based on the free-electron approximation, is obtained from Eq. (4.65) by integration over all directions.

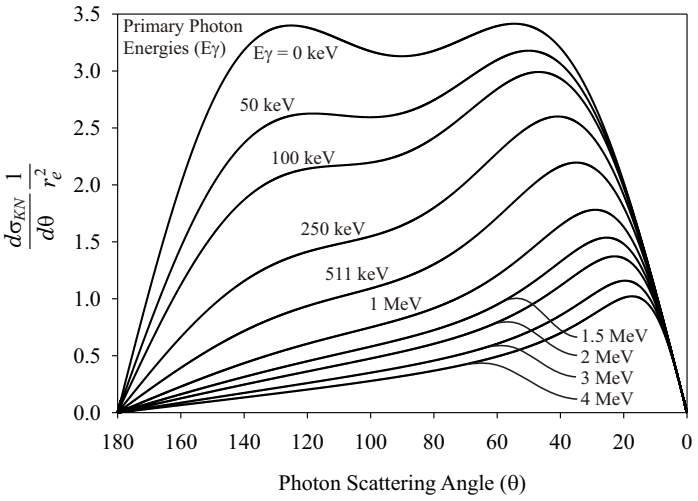

Figure 4.6. Shown is $d\sigma_{KN}/d\theta_s$ divided by r_e^2 as a function of scattering angle θ_s. Notice that the number of photons scattered into angle θ_s increases towards the forward direction (approaching $\theta_s = 0$) as the primary photon energy increases; however, $d\sigma_{KN}/d\theta_s$ approaches zero as θ_s goes to zero for all photon energies.

$$\sigma_C(\Lambda) = Z\sigma_{KN}(\Lambda) = 2\pi Z \int_{-1}^{+1} d(\cos\theta_s)\, \frac{d\sigma_{KN}(\Lambda,\theta_s)}{d\Omega_s}$$
$$= \pi Z r_e^2 \Lambda \left[(1 - 2\Lambda - 2\Lambda^2)\ln\left(1 + \frac{2}{\Lambda}\right) + \frac{2(1 + 9\Lambda + 8\Lambda^2 + 2\Lambda^3)}{(\Lambda + 2)^2}\right]. \quad (4.70)$$

Other Differential Compton Cross Sections

The cross section, per unit wavelength, for scattering of a photon into wavelength Λ' without regard to angle is, from Eq. (4.69),[8]

$$\frac{d\sigma_C(\Lambda,\Lambda')}{d\Lambda'} = Z\frac{d\sigma_{KN}(\Lambda,\Lambda')}{d\Lambda'} = Z\pi\, r_e^2 \left(\frac{\Lambda}{\Lambda'}\right)^2 \left[\left(\frac{\Lambda}{\Lambda'}\right) + \left(\frac{\Lambda'}{\Lambda}\right) + (\Lambda' - \Lambda)(\Lambda' - \Lambda - 2)\right]. \quad (4.71)$$

A related quantity is the cross section, per unit recoil electron energy, for creating a recoil electron with energy T. Here it is convenient to use the ratio $\tau \equiv T/m_e c^2$. Because $1/\Lambda - 1/\Lambda' = \tau$, $d\Lambda'/d\tau = \Lambda^2(1-\Lambda\tau)^{-2}$. Thus, $\sigma_{KN}(\Lambda,\tau) = \sigma_{KN}(\Lambda,\Lambda')d\Lambda'/d\tau$, or

$$\frac{d\sigma_C(\Lambda,\tau)}{d\tau} = \pi Z\, r_e^2 \Lambda^2 \left[(1 - \Lambda\tau) + (1 - \Lambda\tau)^{-1} + \frac{(\Lambda^2\tau)(\Lambda^2\tau + 2\Lambda\tau - 2)}{(1 - \Lambda\tau)^2}\right]. \quad (4.72)$$

Energy Spectrum of Recoil Electrons

Unlike shielding analyses in which the more penetrating scattered photon is of primary interest, for energy spectroscopy detectors it is the energy spectrum of the recoil secondary electron produced in Compton

[8] Note that $\sigma(\Lambda,\theta_s) = -\sigma(\Lambda,\Lambda') \times d\Lambda'/d\Omega_s$ and that $d\Lambda'/d\Omega_s = (1/2\pi)\, d\Lambda'/d\omega_s = -1/2\pi$.

scattering that is of primary interest. The energy of the secondary electron is simply $T = E - E'$ or from Eq. (4.37), in terms of dimensionless quantities,

$$\tau = \frac{1}{\Lambda} - \frac{1}{\Lambda'} = \frac{1 - \cos\theta_s}{\Lambda(1 + \Lambda - \cos\theta_s)}. \tag{4.73}$$

Because $\Lambda = m_e c^2/E$ and $\tau = T/m_e c^2$, this relation reduces to

$$T = \frac{E(1 - \cos\theta_s)}{m_e c^2/E + (1 - \cos\theta_s)}. \tag{4.74}$$

The Compton recoil electron energy function described in Eq. (4.73) is plotted in Fig. 4.7, which clearly shows that the majority of energy is lost to the Compton recoil electrons for angles θ_s greater than 90^o. This result means that, although more photons are generally scattered in the forward direction, as shown in Fig. 4.6, the energy transferred to the Compton recoil electrons is distributed over a wider range of energies. Conversely, fewer photons are scattered from 90^o–180^o; however, the energy transferred to the Compton recoil electrons is distributed over a smaller range of energies as T approaches the maximum energy defined by Eq. (4.36).

Also of importance is the probability the recoil electron has a particular value. Let $g(\Lambda, T)$ be the probability that the recoil electron has an energy, per unit energy about T. This probability density function can be computed as

$$g(\Lambda, T) = g(\Lambda, \tau)\frac{d\tau}{dT} = \frac{1}{m_e c^2}\frac{d\sigma_C(\Lambda, \tau)/d\tau}{\sigma_C(\Lambda)}. \tag{4.75}$$

This expression is readily evaluated from Eqs. (4.70) and (4.72) and is shown in Fig. 4.8.

Compton Energy-Absorption and Energy-Scattering Cross Sections

The mean fraction of the photon energy transferred to the recoil electron is designated as f_C and the Compton energy-absorption cross section[9] per electron is defined as

$$\sigma_{Ca}(\Lambda) \equiv f_C\ \sigma_C(\Lambda). \tag{4.76}$$

The factor f_C is the weighted average of $T/E = \Lambda\tau$, namely,

$$f_C = \frac{1}{\sigma_C(\Lambda)}\int_0^{2/[\Lambda(\Lambda+2)]} d\tau\ \Lambda\tau\,\sigma_C(\Lambda, \tau). \tag{4.77}$$

The energy-scattering cross section is the product of the total cross section and the mean fraction of the photon energy retained by the scattered photon:

$$\sigma_{Ce}(\Lambda) = (1 - f_C)\,\sigma_C(\Lambda). \tag{4.78}$$

It is evident from the definition of f_C that the factor $(1 - f_C)$ can be evaluated as the mean value of $E'/E = \Lambda/\Lambda'$, namely,

$$1 - f_C = \frac{1}{\sigma_C(\Lambda)}\int_\Lambda^{\Lambda+2} d\Lambda'\frac{\Lambda}{\Lambda'}\ \sigma_C(\Lambda, \Lambda'). \tag{4.79}$$

[9]The Compton energy absorption cross section thus defined is not a true cross section for photon absorption since, in the interaction, a scattered photon always results. Rather, it is an effective energy absorption cross section with respect to the incident photon energy such that the product $E(\mu_{Ca}/\rho)\phi$ is the rate per unit mass at which energy is transferred to initial kinetic energy of Compton recoil electrons.

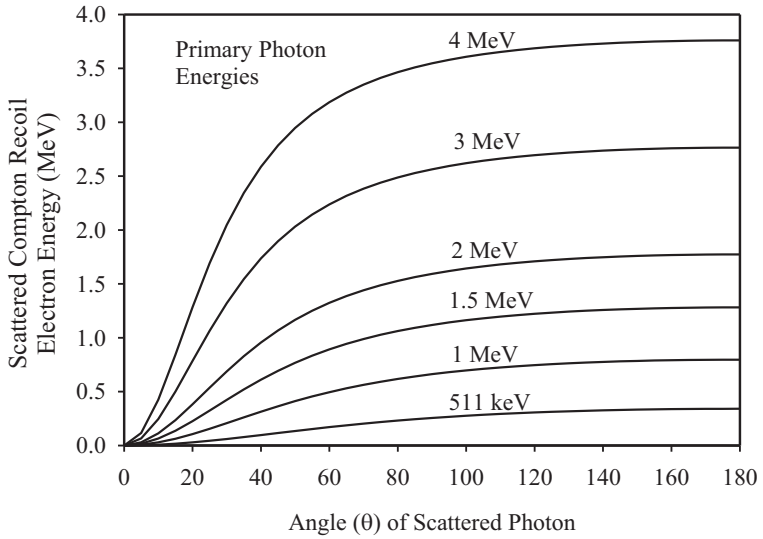

Figure 4.7. The Compton recoil electron energy as a function of primary photon energy and scattered photon angle θ_s. Notice that the change in Compton electron energy is small for photon scattering angles above 90^o.

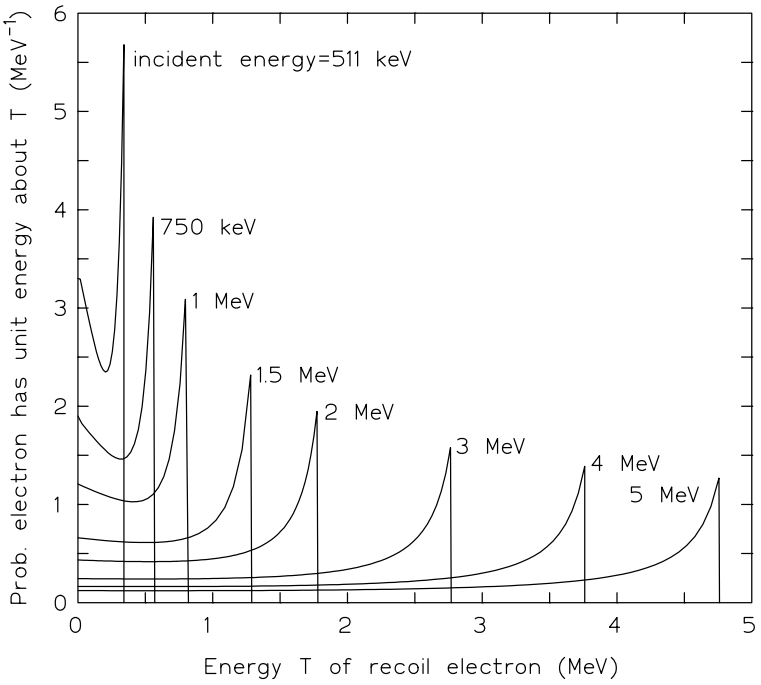

Figure 4.8. The Compton recoil electron spectrum as a function of Compton electron energy.

4.4.3 Incoherent Scattering Cross Sections for Bound Electrons

The equations for scattering from free electrons break down when the kinetic energy of the recoil electron would be comparable to its binding energy in the atom. Thus, binding effects might be thought to be an important consideration for the attenuation of low-energy photons in media of high atomic number. For example, the binding energy of K-shell electrons in lead is 88 keV. However, under these same circumstances, cross sections for the photoelectric interaction of photons greatly exceed incoherent scattering cross sections. Radiation attenuation in this energy region is dominated by photoelectric interactions, and in most attenuation calculations, the neglect of electron binding effects on incoherent scattering causes negligible error. Corrections for electron binding and related data are available in the literature [e.g., Storm and Israel 1967; Biggs and Lighthill 1972; Plechaty et al. 1975; Hubbell 1982; Trubey et al. 1989]. The total atomic cross section for incoherent scattering by bound electrons is given by

$$\sigma_{incoh}(\Lambda) = 2\pi \int_{-1}^{+1} d(\cos\theta_s)\, S(x, Z) \frac{d\sigma_{KN}(\Lambda, \theta_s)}{d\Omega_s}, \tag{4.80}$$

in which $S(x, Z)$ is the *incoherent scattering function* [Hubbell et al. 1975] and x is the *momentum-transfer parameter*, given approximately by

$$x = \frac{E}{hc} \sin(\theta_s/2). \tag{4.81}$$

Figure 4.9 shows the relative importance, in lead, of electron binding effects by comparing photoelectric cross sections with those for incoherent scattering from both free and bound electrons. As is apparent, $S(x, Z)$ is very small for low-energy photons and approaches Z as photon energy increases.

4.4.4 Coherent (Rayleigh) Scattering

In competition with the incoherent scattering of photons by individual electrons is coherent scattering by the electrons of an atom collectively. Since the recoil momentum in the Rayleigh interaction is taken up by the atom as a whole, the energy loss of the gamma photon is slight and the scattering angle small. For example, for 1-MeV photons scattering coherently from iron atoms, 75% of the photons are scattered within a cone of less than 4° half-angle [Hubbell 1969]. As is apparent from Fig. 4.9, coherent scattering cross sections may greatly exceed incoherent scattering cross sections, especially for low-energy photons and high-Z materials. However, because of the minimal effect on photon energy and direction, and because the coherent scattering cross section is so much less than the cross section for the photoelectric effect, it is common practice to ignore Rayleigh scattering in the design of many photon detectors, especially when electron binding effects mentioned in the preceding section are ignored. Named for the 4th Lord Rayleigh, R.J. Strutt (1875–1947), the scattering cross section per atom is

$$\frac{d\sigma_R(E, \theta_s)}{d\Omega_s} = \frac{1}{2} r_e^2 (1 + \cos^2\theta_s)[F(x, Z)]^2, \tag{4.82}$$

in which $F(x, Z)$ is the *atomic form factor*, and the momentum-transfer parameter x is given by Eq. (4.81). Form factors are tabulated by Hubbell and Overbø [1979]. As E approaches zero, $F(x, Z)$ approaches Z and σ_R varies as Z^2. Effects of coherent scattering are addressed in detail by Trubey and Harima [1987] and data are available in an ANSI standard [1991].

4.4.5 Photoelectric Effect

In the photoelectric effect, a photon interacts with an entire atom, resulting in the emission of a photoelectron, usually from the K shell of the atom. Although the difference between the photon energy E and the electron

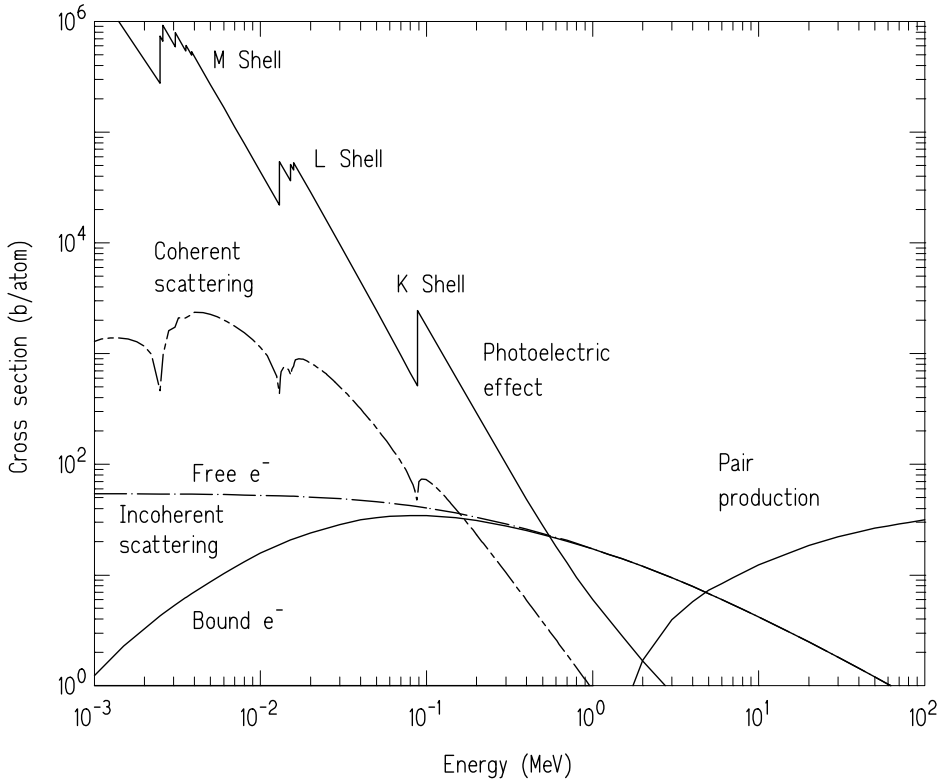

Figure 4.9. Comparison of scattering, photoelectric-effect, and pair-production cross sections for photon interactions in lead.

binding energy E_b is distributed between the electron and the recoil atom, virtually all of that energy is carried as kinetic energy of the photoelectron because of the comparatively small electron mass. Thus, $T = E - E_b$.

K-shell binding energies E_k vary from 13.6 eV for hydrogen to 7.11 keV for iron, 88 keV for lead, and 116 keV for uranium. As the photon energy drops below E_k, the cross section drops discontinuously. As E decreases further, the cross section increases until the first L edge is reached, at which energy the cross section drops again, then rises once more, and so on for the remaining edges. These "edges" for lead are readily apparent in Fig. 4.9. The cross section varies as E^{-n}, where $n \simeq 3$ for energies less than about 150 keV and $n \simeq 1$ for energies greater than about 5 MeV. The atomic cross section varies as Z^m, where m varies from about 4 at $E = 100$ keV to 4.6 at $E = 3$ MeV. As a very crude approximation in the energy region for which the photoelectric effect is dominant,

$$\sigma_{ph}(E) \propto \frac{Z^4}{E^3}. \tag{4.83}$$

Although it is true that for light nuclei, K-shell electrons are responsible for almost all photoelectric interactions, such interactions are normally much less important than incoherent scattering. As a general rule, about 80% of photoelectric interactions with heavy nuclei result in ejection of a K-shell electron. Consequently, the approximation is often made for heavy nuclei that the total photoelectric cross section is 1.25 times the cross section for K-shell electrons.

As the vacancy left by the photoelectron is filled by an electron from an outer shell, either fluorescence x rays or Auger electrons[10] may be emitted. The probability of x-ray emission is given by the *fluorescent yield*. For the K shell, fluorescent yields vary from 0.005 for $Z = 8$ to 0.965 for $Z = 90$. Although x rays of various energies may be emitted, the approximation is often made that only one x ray or Auger electron is emitted, with energy equal to the binding energy of the photoelectron.

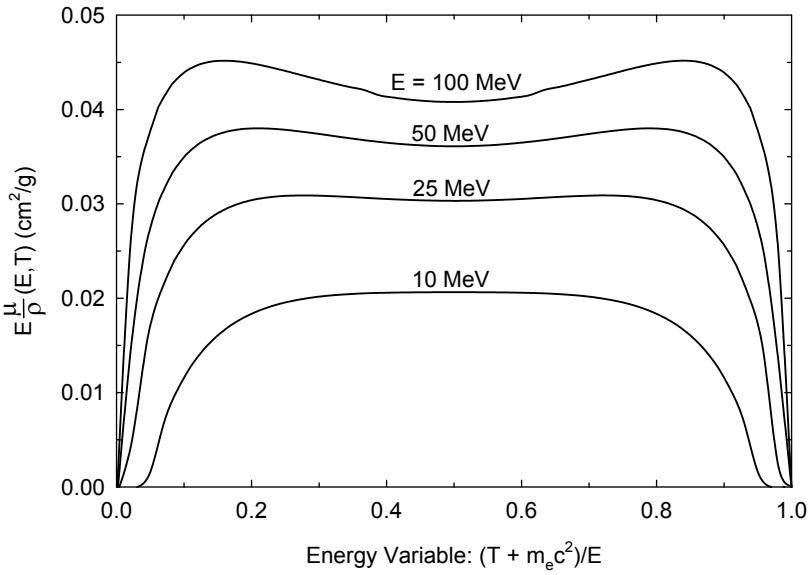

Figure 4.10. Differential pair-production cross section in iron, in the form of the mass interaction coefficient. The function $\mu(E, T)\, dT$ is the probability per unit distance of travel that a photon of energy E experiences a pair-production interaction in which a product electron has kinetic energy between T and $T + dT$. Data derived using the PEGS4 Code [Nelson, Hirayama, and Rogers 1985].

4.4.6 Pair Production

In this process, the incident photon is completely absorbed and in its place appears a positron-electron pair. The phenomenon is induced by the strong electric field in the vicinity of the nucleus and has a photon threshold energy of $2m_e c^2$ ($= 1.02$ MeV). In the nuclear pair production process, the nucleus acquires indeterminate momentum but negligible kinetic energy. Thus,

$$T_+ + T_- = E - 2m_e c^2, \tag{4.84}$$

in which T_+ and T_- are the kinetic energies of the positron and electron, respectively. To a first approximation, the total atomic pair production cross section varies as Z^2. The cross section increases with photon energy, approaching a constant value at high energy. As illustrated in Fig. 4.10, the resulting electron and

[10] If an electron in an outer shell, say Y, makes a transition to a vacancy in an inner shell, say X, an x ray may be emitted with energy equal to the difference in binding energy between the two shells. Alternatively, an electron in some other shell, say Y′, which may be the same as Y, may be emitted with energy equal to the binding energy of the electron in shell X less the sum of the binding energies of electrons in shells Y and Y′. This electron is called an *Auger electron*. If an electron makes a transition from one subshell to a vacancy in another subshell of the same shell, the small difference in binding energies may be transferred to an outer-shell electron, in this case called a *Coster-Kronig electron*.

positron are widely distributed in energy. Both have directions not far from the original direction of the photon but separated by π radians in azimuth about the photon direction. As an approximation, the angles ϑ with respect to the photon direction are $m_e c^2/E$ radians.

Far less likely than nuclear pair production, a photon of sufficient energy can interact in the electric field of an orbital electron producing an electron-positron pair and a recoil orbital electron. This electron pair production is referred to as *triplet production* and is, except for the lightest nuclei, a small fraction of the total pair production events (see Fig. 4.11). It can be shown that because of the constraints of conservation of energy and momentum the threshold photon energy for triplet production is $4m_e c^2 \simeq 2.044$ MeV, twice that for pair production. The photon energy less the energy equivalent of four electron masses is shared as kinetic energy among the positron and the two electrons, namely

$$T_{e^+} + T_{1e^-} + T_{2e^-} = E - 4m_e c^2. \qquad (4.85)$$

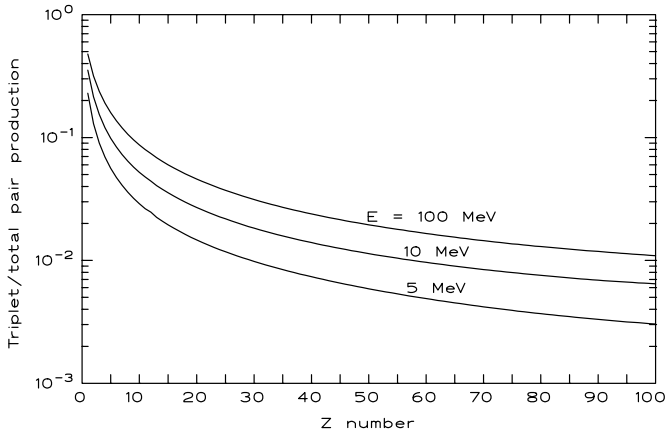

Figure 4.11. Ratio of the triplet to total pair production cross sections as a function of the Z-number of the nuclide for three incident photon energies.

The fate of the positron produced in pair production is annihilation with an ambient electron, generally after slowing to practically zero kinetic energy. This annihilation process results in the creation of two photons moving in opposite directions (to conserve the near zero linear momentum of the slowed electron and positron), each with energy $m_e c^2$.

4.4.7 Photon Interactions—Minor Effects

Discussed above are the photon interaction mechanisms that are important for radiation detection. Photons can interact with matter in several other ways, but are relatively unimportant for most detector designs.

In 1933 Max Delbrück predicted that high energy photons could be scattered in the Coulombic field near a nucleus as a result of the polarization in the vacuum produced by this field. In this process the incident photon is most often scattered coherently by a virtual electron-positron pair in the field, resulting in little change in direction or loss of energy. This predicted scattering mechanism was finally confirmed experimentally only 20 years later.

Another photon scattering mechanism is that of *nuclear resonance scattering*. In this process an incident photon can be absorbed by a nucleus placing the nucleus in an excited nuclear state. Because these states have very short lifetimes (typically ps), the energy of the incident photon must, consequently, almost exactly match the nuclear energy level (recall the uncertainty principle $\Delta t \Delta E \leq h/(2\pi)$). The excited nuclear state decays, almost always by electric dipole transitions, to lower nuclear states emitting a cascade of gamma rays isotropically, analogous to the fluorescence x-ray cascades produced by the photoelectric effect.

Another very minor scattering process is that of nuclear Rayleigh scattering in which the nucleons scatter an incident photon coherently just as in Rayleigh scattering from all the orbital electrons. However, this is an extremely minor phenomenon, again with little change in direction or energy loss. These minor scattering mechanisms are reviewed by Kane et al. [1986].

At higher energies (5-50 MeV), photons can cause (γ, n) reactions and at even higher energies they can result in meson production. Such phenomena are of importance only in the design of detectors for high energy physics research.

4.4.8 Photon Attenuation Coefficients

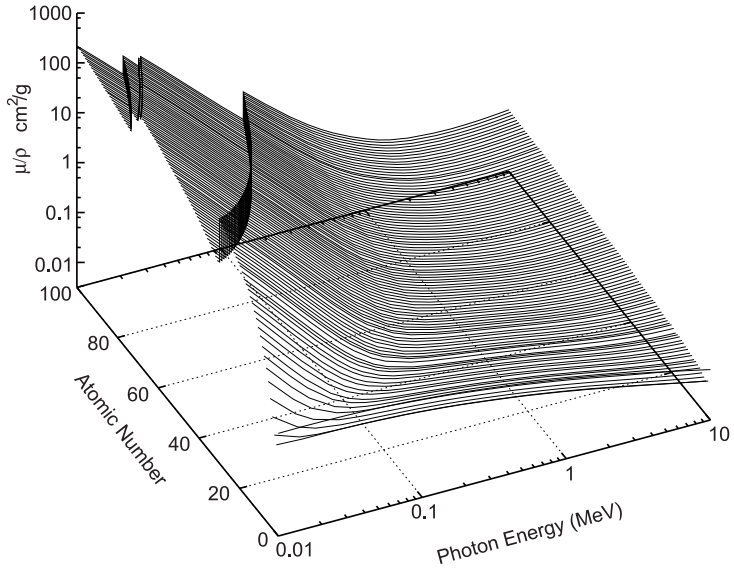

Figure 4.12. Mass attenuation coefficients as a function of photon energy for all the elements. Notice the smooth variation of μ/ρ with energy and the atomic number Z, except for the discontinuities at the edge energies.

The photon linear attenuation coefficient μ is, in the limit of small path lengths, the probability per unit distance of travel that a gamma photon undergoes any significant interaction. Thus, for a specified medium,

$$\mu(E) = N\left[\sigma_c(E) + \sigma_{ph}(E) + \sigma_{pp}(E)\right], \tag{4.86}$$

in which $N = \rho N_a/A$ is the atom density. Note that Rayleigh scattering and other minor effects are specifically excluded from this definition.[11] More common in data presentation is the mass interaction coefficient

$$\frac{\mu}{\rho} = \frac{N_a}{A}\left[\sigma_c(E) + \sigma_{ph}(E) + \sigma_{pp}(E)\right] = \frac{\mu_c}{\rho} + \frac{\mu_{ph}}{\rho} + \frac{\mu_{pp}}{\rho}, \tag{4.87}$$

in which N_a is Avogadro's number. It is important to note that the mass interaction coefficients are independent of the mass density ρ of the material, and it is for this reason that μ/ρ rather than μ values are usually tabulated. The variation of μ/ρ with energy for all the elements is shown in Fig. 4.12.

4.5 Neutron Interactions

The interaction processes of neutrons with matter are fundamentally different from those for the interactions of photons. Whereas photons interact, more often, with the atomic electrons, neutrons interact essentially only with the atomic nucleus. Although neutron-electron interactions do occur, this type of interaction is highly improbable and therefore negligible when compared to the neutron-nucleus interactions. The cross sections that describe the various neutron interactions are also very unlike those for photons. Neutron cross sections not only can vary rapidly with the incident neutron energy, but also can vary erratically from one element to another and even between isotopes of the same element. The description of the interaction of a neutron with a nucleus involves complex interactions between all the nucleons in the nucleus and the incident neutron, and consequently fundamental theories which can be used to predict neutron cross-section variations in any accurate way are still lacking. As a result, all cross-section data are empirical in nature, with little guidance available for interpolation between different energies or isotopes.

Over the years, many compilations of neutron cross sections have been generated, and the more extensive, such as the Evaluated Nuclear Data Files (ENDF) [Kinsey 1979; Rose and Dunford 1991], contain so much information that digital computers are used almost exclusively to process these cross-section libraries to extract cross sections or data for a particular neutron interaction. Even with the large amount of cross-section information available for neutrons, there are still energy regions and special interactions for which

[11] When referring to data tables in other publications, the reader should be aware that occasionally Rayleigh scattering and incoherent scattering are included.

the cross sections are poorly known. For example, cross sections for interactions which produce energetic secondary photons or charged particles are of concern in radiation detection and often still are not known with an accuracy sufficient to perform satisfactory analyses of neutron detectors that rely on such interactions.

4.5.1 Classification of Types of Interactions

There are many possible neutron-nuclear interactions, only some of which are of concern in radiation-protection calculations. Ultra-high-energy interactions can produce many and varied secondary particles; however, the energies required for such reactions are usually well above the neutron energies commonly encountered, and therefore such interactions can be neglected here. Similarly, for low-energy neutrons many complex neutron interactions are possible—Bragg scattering from crystal planes, phonon excitation in a crystal, coherent scattering from molecules, and so on—none of which is of particular importance in the design of many neutron detectors. The neutron reactions of principal importance are those that produce various secondary radiations that, in turn, deposit energy in the active medium of a radiation detector.

The total cross section, which is the sum of cross sections for all possible interactions, gives a measure of the probability that a neutron of a certain energy interacts in some manner with the medium through which the neutrons are traveling. The components of the total cross section for absorption and scattering interactions are usually of primary concern. Nonetheless, when the total cross section is large, the probability of some type of interaction is great and thus the total cross section, which is the most easily measured and the most widely reported, gives at least an indication of the neutron energy regions over which one must investigate the neutron interactions in greater detail.

The total cross sections, although they vary from nuclide to nuclide and with the incident neutron energy, have certain common features. For the sake of classification, the nuclides are usually divided into three broad categories: light nuclei, with mass number $\lesssim 25$; intermediate nuclei; and heavy nuclei, with mass number $\gtrsim 150$. Example total cross sections for each category are shown in Figs. 4.13 through 4.15.

For light nuclei and some magic number nuclei the cross section at low energies (< 1 keV) often varies as

$$\sigma_t = \sigma_1 + \frac{\sigma_2}{\sqrt{E}}, \tag{4.88}$$

where E is the neutron energy, σ_1 and σ_2 are constants, and the two terms on the right-hand side represent the elastic scattering and the radiative capture (or absorption) reactions, respectively. For solids at energies less than about 0.01 eV, there may be *Bragg cutoffs* representing energies below which coherent scattering from the various crystalline planes of the material is no longer possible. These cutoffs are not shown in Figs. 4.13 through 4.15. At energies greater than about 0.1 eV, the cross sections are usually slowly varying and "smooth" up to the MeV energy range, at which energies fairly wide (keV to MeV) resonances appear.

Of all the nuclides, only hydrogen and its isotope deuterium exhibit no resonances. For both isotopes, the cross sections above 1 eV are almost constant up to the MeV region, above which they decrease with increasing energy.

For heavy nuclei, as illustrated in Fig. 4.15, the total cross section, unless masked by a low-energy resonance, exhibits a $1/\sqrt{E}$ behavior at low energies and usually a Bragg cutoff (not shown). The resonances appear at much lower energies than for the light nuclei (usually in the eV region) and have very narrow widths (1 eV or less) with large peak values. Above a few keV the resonances are so close together and so narrow that they cannot be resolved and the cross sections appear to be smooth except for a few broad resonances. Finally, the intermediate nuclei, as would be expected, are of intermediate character between the light and heavy nuclei, with resonances in the region from 100 eV to several keV. The resonances are not as high or as narrow as for the heavy nuclei.

Because neutrons are invariably born with high energies (100 keV – 10 MeV), neutron radiation fields almost always contain a spectrum of neutrons ranging from thermal energies to high energy. As neutrons

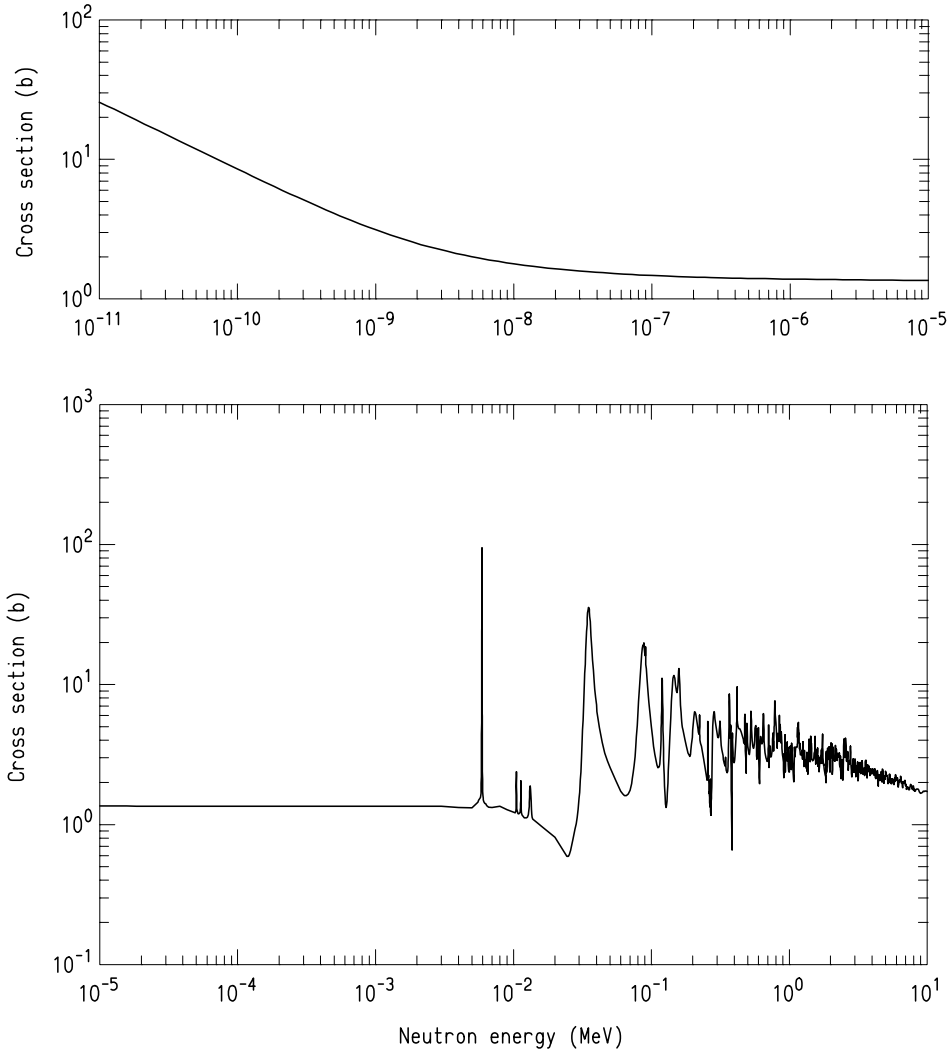

Figure 4.13. Total neutron cross section for aluminum computed using NJOY-processed ENDF/B (version V) data.

scatter they lose energy and, unless they are absorbing while they slow down, they eventually come into thermal equilibrium with the ambient medium. Detector materials that have large thermal absorption cross sections for producing charged reaction products are typically used to detect thermal neutrons. Three commonly used isotopes are ^{3}He, ^{10}B, and ^{6}Li, all having large thermal $\sigma_{(n,p)}$, $\sigma_{(n,\alpha)}$, and $\sigma_{(n,t)}$ cross sections, respectively. These cross sections are shown in Fig. 4.16. Another charged-particle producing reaction that is useful for detecting thermal neutrons is the fission reaction.

Alternatively, one could use (n,γ) absorption reactions and use a photon detector. If the result of such a reaction produces a radioactive isotope, then detectors for the radiation emitted by the isotope's decay can be used to infer the presence of neutrons. However, the absorption cross sections at all energies, except

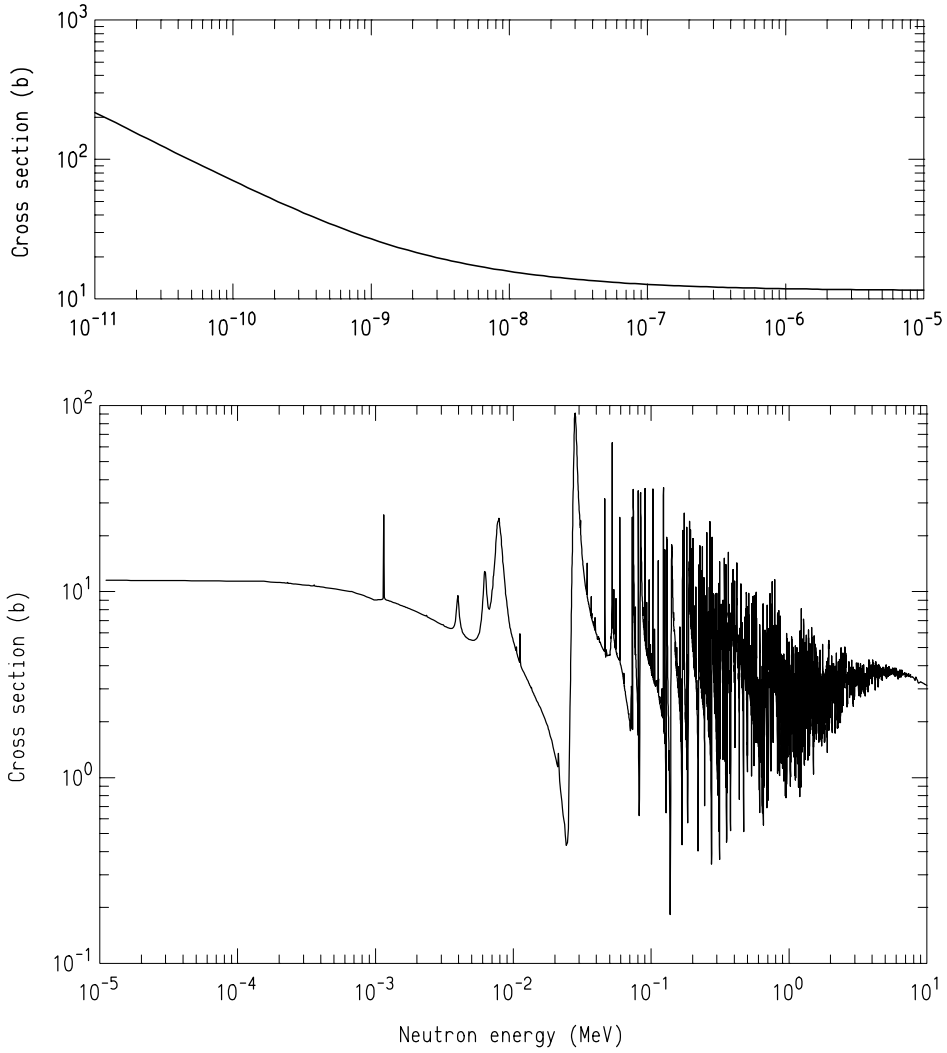

Figure 4.14. Total neutron cross section for iron computed using NJOY-processed ENDF/B (version V) data.

thermal energies, for all nuclides are usually small compared to other reactions. Over the fission-neutron energy spectrum, the (n, γ) reaction cross sections seldom exceed 200 mb for the heavy elements, and for the lighter elements this cross section is considerably smaller. Only for thermal neutrons and a few isolated absorption resonances in the keV region for heavy elements is the (n, γ) reaction important.

In the high energy region, by far the most important neutron interaction is the scattering process. Generally, elastic scattering is more important, although, when the neutron energy somewhat exceeds the energy level of the first excited state of the scattering nucleus, inelastic scattering becomes possible. The recoil energy of the scattering nucleus can be measured and used to infer the energy distribution of incident neutrons. Also in the MeV region the (n, α) reaction cross sections for Be, N, and O are appreciable fractions

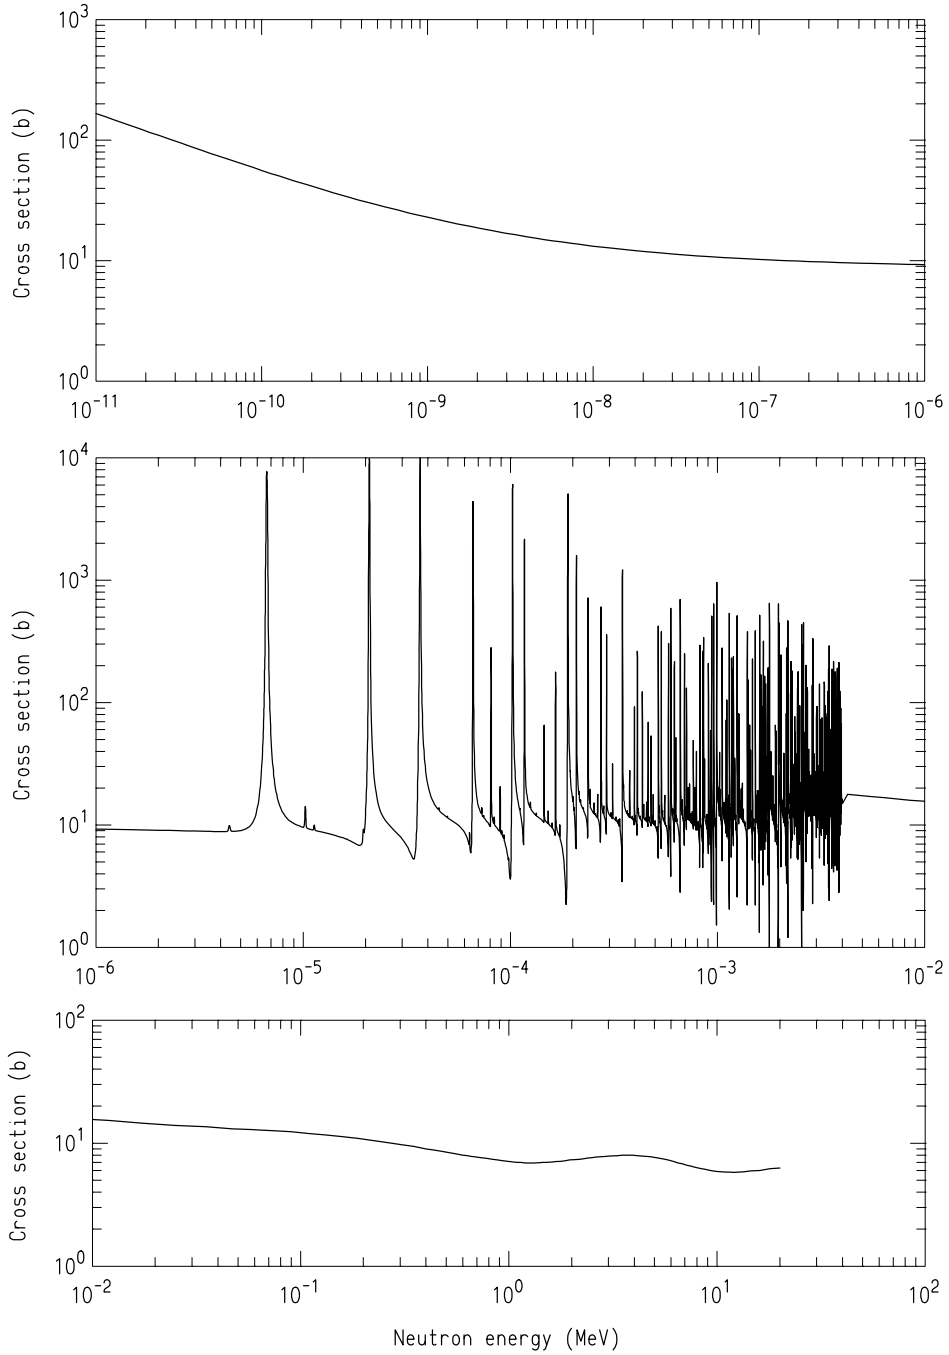

Figure 4.15. Total neutron cross section for uranium computed using NJOY-processed ENDF/B (version V) data. Above 4 keV the resonances are no longer resolved and only the average cross-section behavior is shown.

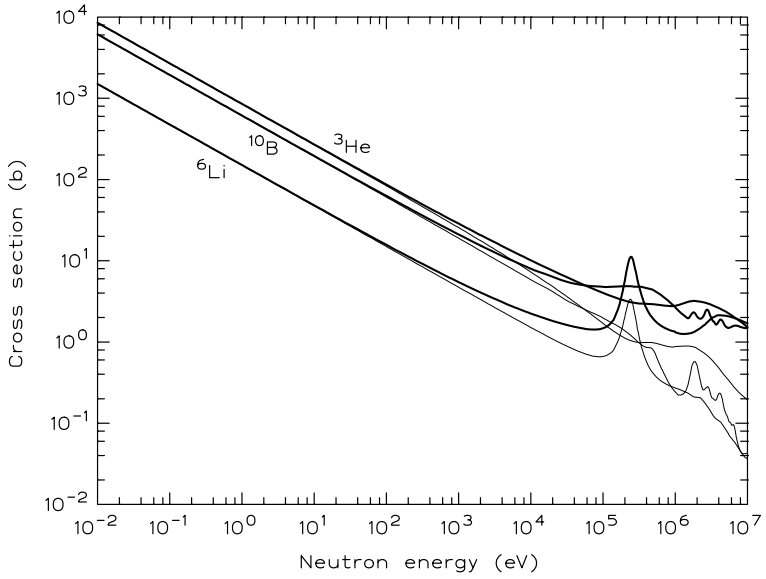

Figure 4.16. Total neutron cross sections for ^{3}He, ^{10}B, and ^{6}Li (heavy lines) and the (n,p), (n,α), and (n,t) cross sections (light lines), respectively.

of the total cross sections and may exceed the inelastic scattering contributions. This situation is probably true for most light elements, although only partial data are available. For heavy and intermediate nuclei the charged-particle emission interactions are at most a few percent of the total inelastic interaction cross section and hence are usually ignored.

4.5.2 Thermal Neutron Interactions

As neutrons slow through scattering, their speeds become comparable to those of the ambient atoms in thermal motion. In this case it is important to account for the motion of *both* the neutrons and the interacting nuclei. In the following treatment, it is assumed that neutrons interact with only a single atom at a time (unlike, for example, Bragg scattering) so that interactions can be described by microscopic cross sections.

Let $n(\mathbf{v})d\mathbf{v}$ and $N(\mathbf{V})d\mathbf{V}$ be the number density at some point of interest of, respectively, the neutrons with laboratory velocities in $d\mathbf{v}$ about $\mathbf{v}$ and the atoms with laboratory velocities in $d\mathbf{V}$ about $\mathbf{V}$. Neutrons and nuclei thus approach each other with a relative velocity $\mathbf{v}_r = \mathbf{v} - \mathbf{V}$. Now consider a coordinate system in which the atomic nuclei are at rest, so that the neutrons approach the nuclei with the relative velocity $\mathbf{v}_r$. Thus, from the nuclei's perspective, the neutrons appear as a beam with intensity $dI = n(\mathbf{v})v_r\, d\mathbf{v}$, where $v_r = |\mathbf{v}_r|$. These neutrons cause interactions of type i at a rate of

$$dF_i = n(\mathbf{v})N(\mathbf{V})\sigma_i(v_r)v_r\, d\mathbf{v}\, d\mathbf{V} \tag{4.89}$$

interactions $\mathrm{cm}^{-3}\mathrm{s}^{-1}$. The total interaction rate density for neutrons and nuclei of all speeds is thus [Lamarsh 1966]

$$F_i = \iint n(\mathbf{v})N(\mathbf{V})\sigma_i(v_r)v_r\, d\mathbf{v}\, d\mathbf{V}, \tag{4.90}$$

where the integration is over the six components of $\mathbf{v}$ and $\mathbf{V}$. Below several special cases are considered. More general cases are considered by Meghreblian and Holmes [1960].

$1/v$ Absorption

Consider now the case of thermal neutron absorption (capture or fission). In the thermal energy range $\sigma_a(v)$ varies as $1/v$, so that

$$\sigma_a(v_r) = \frac{v_{ro}}{v_r}\sigma_a(v_{vo}), \tag{4.91}$$

where v_{ro} is an arbitrary reference speed. Substitution of this result into Eq. (4.90) gives

$$F_a = v_{ro}\sigma_a(v_{ro}) \iint n(\mathbf{v})N(\mathbf{V})\, d\mathbf{v}\, d\mathbf{V} = N\sigma_a(v_{ro})nv_{ro}, \tag{4.92}$$

where N and n are, respectively, the atomic and neutron number densities. This astounding result shows that the absorption *rate* of a $1/v$ absorber is a constant that is independent of the velocity distributions of either the neutrons or atoms! Here F_a depends only on a single arbitrary relative speed v_{ro} between the neutron and nucleus. McGregor and Shultis [2011] show the benefit of this result for neutron detector calibrations. One could also view all the nuclei at rest and treat v_{ro} as an arbitrary *laboratory* speed of the neutron. Thus, the absorption rate density can be calculated as

$$F_a = \Sigma_a(E_o)\phi_o \tag{4.93}$$

where $\phi_o = nv_o$ with v_o an arbitrary laboratory speed and E_o is the corresponding energy. Typically, v_o is taken as 2200 m/s so that $E_o = 0.0253$ eV, the most probable energy of a Maxwellian distribution at $T_o = 293.61$ K. Here $\phi_o = nv_o$ is the "2200-m/s flux", the flux that would result if all thermal neutrons were to travel at 2200 m/s.

Non-$1/v$ Absorption

The absorption cross section of some nuclei, particularly those heavy nuclei with resonances just above the thermal region, deviates significantly from the ideal $1/v$ behavior. However, for such heavy nuclei the center-of-mass and laboratory coordinate systems are nearly the same, so that v_r in Eq. (4.90) equals the laboratory speed v of the neutrons. Equation (4.90) becomes

$$F_a = \iint n(\mathbf{v})N(\mathbf{V})\sigma(v)v\, d\mathbf{v}\, d\mathbf{V} = N\int n(\mathbf{v})\sigma(v)v\, d\mathbf{v}. \tag{4.94}$$

Because $n(\mathbf{v})\, d\mathbf{v} = n(E)\, dE$ where E is the laboratory neutron energy, Eq. (4.94) transforms to

$$F_a = N\int n(E)\sigma_a(E)v(E)\, dE = \int \Sigma_a(E)\phi(E)\, dE, \tag{4.95}$$

where the integration is over all thermal energies.

In many instances the energy dependence of thermal neutrons is well approximated by a Maxwellian distribution with an effective neutron temperature T, i.e., by

$$\phi_M(E,T) = \frac{2\pi n}{(\pi kT)^{3/2}}\sqrt{\frac{2}{m_n}}E\exp[-E/kT], \tag{4.96}$$

where n is the neutron density, m_n is the neutron mass, k is Boltzmann's constant ($k = 8.617\,343 \times 10^{-5}$ eV K^{-1}).

In this case Eq. (4.95) can be numerically evaluated to give

$$F_a = g_a(T)\Sigma_a(E_o)\phi_o = \overline{\Sigma}_a\phi_t, \tag{4.97}$$

where the total thermal flux

$$\phi_t = \int_0^{\sim 5kT} \phi(E)\, dE \simeq \int_0^{\infty} \phi_M(E,T)\, dE, \tag{4.98}$$

and the thermal-averaged macroscopic absorption cross section is

$$\overline{\Sigma}_a = \frac{\sqrt{\pi}}{2} g_a(T) \left(\frac{T_o}{T}\right)^{1/2} \Sigma_a(E_o). \tag{4.99}$$

In this result, the Westcott non-$1/v$ factor $g_a(T)$ accounts for deviations from the $1/v$ behavior of absorption cross sections in the thermal energy region.[12] If $\sigma_a(E) \simeq 1/\sqrt{E}$, then $g_a(T) = 1$. Finally, the relation between the thermal flux ϕ_t and the fictitious 2200-m/s flux is obtained from Eqs. (4.97) and (4.99) as

$$\phi_t = \frac{2}{\sqrt{\pi}} \left(\frac{T}{T_o}\right)^{1/2} \phi_o. \tag{4.100}$$

The result for the absorption rate density of Eq. (4.95) is also obtained for light nuclei with non-$1/v$ behavior and for which the center-of-mass and laboratory systems are not equal, *provided* both the neutrons and atoms have Maxwellian distributions of energy with the same temperature [Lamarsh 1966].

Scattering Interaction Rate

Scattering cross sections at thermal energies (always elastic) are usually nearly constant, i.e., $\Sigma_s(E) \simeq \Sigma_s(E_o)$. The scattering interaction rate density is given by

$$F_s = \int \Sigma_s(E)\phi(E)\, dE. \tag{4.101}$$

If $\Sigma_s(E) = \Sigma_s(E_o)$, then clearly $F_s = \Sigma_s(E_o)\phi_t$. Sometimes $\Sigma(E)$ is not quite constant. In this case, Eq. (4.101) is integrated numerically after assuming a Maxwellian for $\phi(E)$ to give, in analogy to Eq. (4.97),

$$F_s = g_s(T)\Sigma_s(E_o)\phi_o = \overline{\Sigma}_s \phi_t, \tag{4.102}$$

where the thermal averaged scattering cross section is

$$\overline{\Sigma}_s = \frac{\sqrt{\pi}}{2} g_s(T) \left(\frac{T_o}{T}\right)^{1/2} \Sigma_s(E_o). \tag{4.103}$$

For the case $\Sigma_s(E) = \Sigma_s(E_o)$, $g_s(T) = 2/\sqrt{\pi} \simeq 1.1283$, a result seen in most of the scattering cross sections listed in Appendix B, Table B.1.

4.5.3 Neutron Differential Scattering Cross Sections

The differential scattering cross section $\sigma_s(E,\theta)$ is sometimes reported in cross-section libraries in terms of ω_c, the cosine of the scattering angle in the center-of-mass coordinate system. This is done because, in the center-of-mass system, scattering of low- and intermediate-energy neutrons is nearly isotropic, that is,

$$\frac{d\sigma_s(E,\omega_c)}{d\Omega_c} \simeq \frac{\sigma_s(E)}{4\pi}. \tag{4.104}$$

[12] Westcott used a more general form to account also for epithermal neutron absorption. See Westcott [1955].

In fact, for hydrogen, the scattering in the center-of-mass system is isotropic for energies up to about 30 MeV. Generally, the heavier the nuclide, the lower is the energy above which elastic scattering becomes anisotropic. The differential scattering cross section is thus well represented by a low-order Legendre polynomial expansion in the form

$$\frac{d\sigma_s(E,\omega_c)}{d\Omega_c} \simeq \frac{\sigma_s(E)}{4\pi}\sum_{n=0}^{N}(2n+1)f_n(E)P_n(\omega_c). \tag{4.105}$$

Cross-section data may be tabulated in terms of the expansion coefficients $f_n(E)$. Because of the way that Eq. (4.105) is formulated, f_0 is always equal to 1. The order of the expansion seldom exceeds $N = 8$. Few data are available on the angular distributions of inelastically scattering neutrons. When only one or two levels are involved, the scattering may be anisotropic; however, it has generally been found that it is a good approximation to assume that the inelastically scattered neutrons are emitted isotropically in the center-of-mass system. This is particularly true when multiple levels are involved in the inelastic process. The potential scattering of fast neutrons is never isotropic but is highly peaked in the forward directions. In fact, the angular distribution can exhibit several maxima as the scattering angle varies.

The relation between the laboratory and center-of-mass scattering angular distributions may be obtained from a formal change of independent variable or from recognition that the probability of scattering into corresponding differential solid angles $d\Omega_s = 2\pi\, d\omega_s$ and $d\Omega_c = 2\pi\, d\omega_c$ must be the same, that is,[13]

$$\frac{d\sigma_s(E,\omega_s)}{d\Omega_s}\, d\omega_s = \frac{d\sigma_s(E,\omega_c)}{d\Omega_c}\, d\omega_c. \tag{4.106}$$

Transformations between the two systems make use of Eqs. (4.47) and (4.48) as well as the interrelationship

$$\frac{d\omega_c^{\pm}}{d\omega_s} = \pm\frac{(1+2\gamma\omega_c^{\pm}+\gamma^2)^{3/2}}{1+\gamma\omega_c^{\pm}} = 2\gamma\omega_s \pm \frac{1-\gamma^2(1-2\omega_s^2)}{[1-\gamma^2(1-\omega_s^2)]^{1/2}}. \tag{4.107}$$

For elastic scattering and for inelastic scattering with single values of E', only the positive sign in this equation applies, and there is only a single value of ω_c. However, for inelastic scattering with dual values of E', there are two values of ω_c, as indicated in Eq. (4.48). The positive signs in Eqs. (4.48) and (4.107) are associated with ω_c^+, and the negative signs with ω_c^-.

4.5.4 Average Energy Transfer in Neutron Scattering

Here it is necessary to be very careful in distinguishing between the kinetic energy lost by the neutron and the kinetic energy gained by the recoil atom, for the two are not the same when the scattering is inelastic. Knowledge of the energy lost by the neutron is important in the examination of neutron moderation. Knowledge of the energy gained by the recoil atom is important in dosimetry. The mean *fraction* of the energy E lost is described as $1-\langle E'\rangle/E$, and the mean fraction of E transferred to the recoil atom as $\langle T\rangle/E$. The two are related by $\langle T\rangle = \langle E - E'\rangle + Q$.

The mean fraction of energy transferred $\langle E'\rangle/E$ may be determined based on $[d\sigma_s(E,E')/dE']\,dE'/\sigma_s(E)$ being the probability that a neutron of energy E leaves a scattering interaction with energy between E' and $E' + dE'$. Thus,

$$\frac{\langle E'\rangle}{E} = \frac{1}{\sigma_s(E)}\int_{E'_{\min}}^{E'_{\max}} dE'\ \frac{E'}{E}\frac{d\sigma_s(E,E')}{dE'}, \tag{4.108}$$

[13] It should be noted that following standard usage, $\sigma_s(E,\omega_c)$ and $\sigma_s(E,\omega_s)$ are different functions even though they carry the same symbol, σ_s.

Table 4.1. Average fraction $1 - \langle E' \rangle / E$ of neutron energy lost in center-of-mass scattering interactions. Note that $\Delta = Q(A+1)/AE$ and that $\langle T' \rangle / E = 1 - \langle E' \rangle / E + Q/E$.

	Isotropic scatter	Anisotropic scatter
Elastic scatter	$\frac{1-\alpha}{2}$	$\frac{1-\alpha}{2}[1 - f_1(E)]$
Inelastic scatter	$\frac{1-\alpha}{2}\left[1 - \frac{A}{2}\Delta\right]$	$\frac{1-\alpha}{2}\left[1 - \frac{A}{2}\Delta - f_1(E)\sqrt{1+\Delta}\right]$

in which the limits are given in Eqs. (4.53). Scattering into a particular range of energies requires scattering within an associated range of directions, that is, $[d\sigma_s(E, E')/dE']\, dE' = 2\pi[d\sigma_s(E, \omega_c)/d\Omega_c]\, d\omega_c$. Thus, from Eq. (4.50), with $\Delta = Q(1 + A)/AE$,

$$\frac{d\sigma_s(E, E')}{dE'} = \frac{4\pi}{(1-\alpha)E\sqrt{1+\Delta}} \frac{d\sigma_s(E, \omega_c)}{d\Omega_c}. \tag{4.109}$$

The determination of $\langle E' \rangle / E$ may be accomplished more simply by using the angular distribution of the cross section directly, that is,

$$\frac{\langle E' \rangle}{E} = \frac{2\pi}{\sigma_s(E)} \int_{-1}^{+1} d\omega_c \, \frac{E'}{E} \frac{d\sigma_s(E, \omega_c)}{d\Omega_c}, \tag{4.110}$$

where the ratio E'/E is given in Eq. (4.50), and by using the Legendre expansion of Eq. (4.105) for $d\sigma_s(E, \omega_c)/d\Omega_c$.

Evaluation of energy transfer for several cases of neutron scattering is summarized in Table 4.1. In this table f_1 is the first order Legendre expansion coefficient of Eq. (4.105). Notice that as A increases, α approaches unity, and the average energy loss in elastic scattering approaches zero. Only by inelastic scattering can appreciable energy losses be realized. Although for hydrogen the average energy loss is one-half of the initial energy, the total scattering cross section $\sigma_s(E)$ declines with increasing energy in the MeV energy region and hydrogen scattering events become relatively improbable. For this reason inelastic scattering by heavy nuclides plays a crucial role in the slowing of fast neutrons.

The energy of the recoil nucleus from a scattering event caused by a fast neutron is quickly dissipated in solids or liquids, and hence for all practical purposes the recoil energy can be assumed to be deposited locally. For example, a 5-MeV proton travels at most 0.5 mm in aluminum. Heavier recoiling nuclei are stopped in much shorter distances. Only for the case of neutron scattering in a gas does one have to be concerned with the travel of the recoil atoms and then only if very detailed calculations are required. The energy distribution of the recoil nuclei is usually of great interest in radiation detection and dosimetry.

4.5.5 Radiative Capture of Neutrons

When a neutron is absorbed by a nucleus any kinetic energy of the neutron plus its binding energy in the resulting compound nucleus (usually 7 to 9 MeV) leaves the compound nucleus in a highly excited state. The excited nucleus usually decays within 1 ps of the capture, often through several intermediate states, thereby emitting one or more energetic gamma photons. These *capture gamma photons* from (n, γ) reactions can be used to identify the isotope that absorbed the neutron.

The cross section for radiative capture is very small for high energy neutrons, typically no more than a few hundred millibarns for neutrons with energies between 20 keV and 10 MeV. For many nuclides, the (n, γ) capture cross section is poorly known in the keV and MeV energy region. Only for certain important nuclides such as fissionable isotopes is the cross section known with a good degree of certainty. Of more importance are the (n, γ) reactions caused by thermal neutrons which have been slowed by scattering and come into equilibrium with the thermal motion of atoms in the shield. The (n, γ) cross section for thermal neutrons may be quite large—up to thousands of barns for nuclides such as cadmium that have capture resonances near the thermal energy region—and for most isotopes it comprises almost the total absorption cross section. In a material at room temperature, the thermal neutrons have an average energy of 0.025 eV, corresponding to a speed of 2200 m s^{-1}. In Appendix B, thermal neutron cross sections, as well as yields and energies of the capture photons, are given for common elements.

4.5.6 Neutron-Induced Fission

When a neutron is absorbed by a heavy nucleus, the resulting compound nucleus is produced in a very excited state. The "nuclear fluid" of such an excited nucleus undergoes large oscillations and deformations in shape. The compound nucleus may, during one of its oscillations in shape, deform into an elongated or dumbbell configuration in which the two ends Coulombically repel each other and the nuclear forces, being very short ranged, are no longer able to hold the two ends together. The two ends then separate (*scission*) within about 10^{-20} s into two nuclear pieces, repelling each other with such tremendous Coulombic force that many of the orbital electrons are left behind. Two highly charged *fission fragments* are thus created.[14] The fission fragments are produced in such highly excited nuclear states that neutrons can "boil" off them. Anywhere from 0 to about 8 *prompt* neutrons evaporate from the primary fission fragments within about 10^{-17} s of the scission. After prompt neutron emission, the fission fragments are still in excited states, but with excitation energies insufficient to cause further neutron emission. They quickly decay to lower energy levels only by the emission of *prompt* gamma rays within about 2×10^{-14} s after the prompt-neutron emission.

The highly charged fission fragments pass through the surrounding medium producing millions of ionizations and excitations of the ambient atoms. As the fission fragments slow, they gradually acquire electrons reducing their ionization charge, until, by the time they are stopped after about 10^{-12} s, they become electrically neutral atoms. After prompt neutron and gamma ray emission, the fission fragments are then termed *fission products*. The fission products are generally radioactive and, thus, start decay chains whose members radioactively decay, usually by isobaric β^- decay, until a stable end-nuclide is reached. Occasionally, short-lived fission products decay by neutron emission producing *delayed neutrons* seconds to minutes after the fission event. The half-lives of the many possible fission product daughters range from fractions of a second to many thousands of years.

Sometimes very heavy radionuclides, e.g., ^{238}U and ^{252}Cf, are already sufficiently unstable that the addition of a neutron is not needed to excite the nucleus to produce oscillations that lead to fission. Such nuclides are said to *spontaneously* fission.

4.6 Charged-Particle Interactions

Knowledge of the ranges of ionizing charged particles and the rates at which energy is dissipated along their paths is of crucial importance in the design of radiation detectors and in radiation dosimetry. A charged particle is slowed as a result of both Coulombic interactions with (atomic) electrons and radiation losses (bremsstrahlung). Energetic charged particles cause thousands of ionizations and excitations of the atoms along their path before they are slowed and become part of the ambient medium.

[14] Sometimes three fission fragments are formed in *ternary* fission with the third being a small nucleus. Alpha particles are created in about 0.2% of the fissions, and nuclei of ^{2}H, ^{3}H, and others up to about ^{10}B are formed much less frequently.

The *stopping power*, often denoted as $-dE/dx$, is the expected energy loss per unit distance of travel by the charged particle along its trajectory. As used in this book, the term is synonymous with linear energy transfer (LET), denoted as $L(E)$. During deceleration, the stopping power generally increases until the energy of the particle is so low that charge neutralization or quantum effects bring about a reduction in the rate of energy loss.

Unlike photons and neutrons, charged particles have a finite range in matter, i.e., there is a distance beyond which none can travel. The distance the particle travels before being stopped is called the *range*. However, this definition is not very precise because, for stochastic reasons, not every particle starting with the same energy travels the same distance before stopping. Also the distance used to define the range can be either along the particle's trajectory or a straight-line (crow-flight) distance from the source of the charged particles. The resulting slightly different definitions of range are described more fully later in this section. A charged particle range is often reported as a *mass thickness range* defined as R/ρ, with units such as g cm^{-2}, in order to mostly remove the density dependence of the range on the density ρ of stopping medium. The paths traveled by light particles, like electrons and positrons, are quite different from those of heavy charged particles such as protons and alpha particles, and are considered separately in the following sections.

Heavy charged particles (HCPs) are ions with masses greater than or equal to that of a proton. With kinetic energies much less than their rest-mass energies, HCPs lose energy almost entirely from Coulombic interactions with atomic electrons. A multitude of such interactions take place—so many that the slowing down is virtually continuous along a straight-line path. These interactions, taken individually, may range from ionization processes producing energetic recoil electrons called *delta rays* to weak atomic or molecular excitation, which may not result in ionization at all. The LET resulting from Coulombic interactions, L_{coll}, is called the *collisional LET* or *collisional stopping power*. Only for heavy charged particles of very low energy do collisions with atomic nuclei of the stopping medium become important and can result in large angular deflections from their usual straight-line trajectories.

Another energy-loss mechanism, which is especially important for electrons, is radiative energy loss through bremsstrahlung production and is characterized by the *radiative LET* or *radiative stopping power* L_{rad}. Also, a careful treatment of electron slowing down requires consideration of delta-ray production and the concomitant deflection of the incident electron from its original direction. As a result the trajectory of slowing electrons is tortuous exhibiting many large angle deflections.

The total stopping power is defined as

$$L = -\frac{dE}{dx} = -\left.\frac{dE}{dx}\right|_{coll} - \left.\frac{dE}{dx}\right|_{rad}, \tag{4.111}$$

which is the sum of the collisional and radiative energy losses. The *mass stopping power* is defined as

$$\frac{L}{\rho} = -\frac{dE}{dx}\frac{1}{\rho}, \tag{4.112}$$

where ρ is the mass density of the stopping material, and has units such as MeV cm^2 g^{-1}. Also, the *specific ionization* is defined as

$$\frac{L}{w} = -\frac{dE}{dx}\frac{1}{w}, \tag{4.113}$$

where w is the average energy required to liberate an electron from its host atom, usually described as the production of electron-ion pairs (gases) or electron-hole pairs (solids).

4.6.1 Collisional Energy Loss

Collisional energy loss results from momentum transfer caused by the Coulombic force between the incident particle with speed v and charge number z and the target, of mass M, which is an atomic nucleus with

charge number Z equal to the atomic number, or an electron of charge number $Z = 1$. The kinematics of individual interactions were described earlier in this chapter with notation as illustrated in Fig. 4.2. The LET may be computed on the basis of a differential interaction cross section $d\sigma(E,T)/dT$ defined so that $[d\sigma(E,T)/dT]\,dT$ is the cross section for interaction of an incident particle of energy E, resulting in a target recoil with energy between T and $T + dT$. A differential linear interaction coefficient $d\mu(E,T)/dT$ is the product of $d\sigma(E,T)/dT$ and the density N of targets, atomic nuclei, or atomic electrons, as appropriate. The product $T\,[d\mu(E,T)/dT]\,dT$ is the total energy loss per unit differential distance of travel of the primary particle associated with individual losses between T and $T + dT$. Thus, the LET $L(E)$ is given, in principle, by

$$L(E) = \int_0^{T_{\max}} T \frac{d\mu(E,T)}{dT}\, dT. \tag{4.114}$$

The total LET is the sum of the collisional and radiative LETs, $L_{coll}(E) + L_{rad}(E)$ based on integrals over $d\mu_{coll}(E,T)/dT$ and $d\mu_{rad}(E,T)/dT$.

Rutherford Cross Section

The fundamental formula for collisional loss, named for Ernest Rutherford (1871–1937), is based on classical mechanics and was originally derived for scattering of alpha particles by atomic nuclei. Its derivation may be found in most textbooks on atomic and nuclear physics. A rigorous derivation, based on conservation of angular momentum as well as kinetic energy and linear momentum, may be found in Evans [1955]. The differential cross section may be written as

$$\frac{\sigma_{ruth}(E,T)}{dT} = \frac{2\pi z^2 Z^2 q_e^4}{(4\pi\epsilon_o)^2 M v^2 T^2} = \frac{2\pi z^2 Z^2 q_e^4}{(4\pi\epsilon_o)^2 M c^2} \frac{1}{\beta^2 T^2}, \tag{4.115}$$

in which q_e is the unit electronic charge. Note that if targets are atomic electrons, their density is $N_e = \rho(Z/A)N_a$, where Z is the medium atomic number. Then $M = m_e$ and the target charge number is unity. In terms of dimensionless variables $\epsilon = E/m_e c^2$ and $\tau = T/m_e c^2$, and with $d\mu(\epsilon,\tau)/d\tau = m_e c^2 d\mu(E,T)/dT$, the linear coefficient for interactions with atomic electrons is given by

$$\frac{d\mu_{ruth}(\epsilon,\tau)}{d\tau} = \frac{2\pi N_e z^2 r_e^2}{\beta^2} \left[\frac{1}{\tau^2}\right], \tag{4.116}$$

in which r_e is the classical electron radius, given in Eq. (4.62). Equation (4.115) commonly appears in the cgs system of units, within which the factor $4\pi\epsilon_o$ does not appear and $r_e = q_e^2/m_e c^2$. Bhabha [1938] showed that for heavy charged incident particles and electron targets, the Rutherford cross section must be modified to

$$\frac{d\mu_{coll}(\epsilon,\tau)}{d\tau} = \frac{2\pi N_e z^2 r_e^2}{\beta^2} \left[\frac{1}{\tau^2} - \frac{\beta^2}{\tau\tau_{\max}}\right], \tag{4.117}$$

where $\tau_{\max} \equiv T_{\max}/m_e c^2$, with $T_{\max}$ being the maximum energy transferred to the recoil particle (see Section 4.3.8). This equation applies to alpha particles or other particles with spin 0. An additional correction term, important only for highly relativistic conditions, is required for protons or particles with spin 1/2.

Møller and Bhabha Cross Sections

The relativistic collisional energy loss in electron-electron interactions was addressed by Møller [1932], who found that

$$\frac{d\mu_{coll}(\epsilon,\tau)}{d\tau} = \frac{2\pi\, N_e\, r_e^2}{\beta^2} \left[\frac{1}{\tau^2} + \frac{1}{(\epsilon-\tau)^2} + \frac{1}{(\epsilon+1)^2} - \frac{2\epsilon+1}{\tau(\epsilon-\tau)(\epsilon+1)^2}\right]. \tag{4.118}$$

This interaction coefficient is illustrated in Fig. 4.17. A similar expression for positron energy losses was derived by Bhabha [1936].

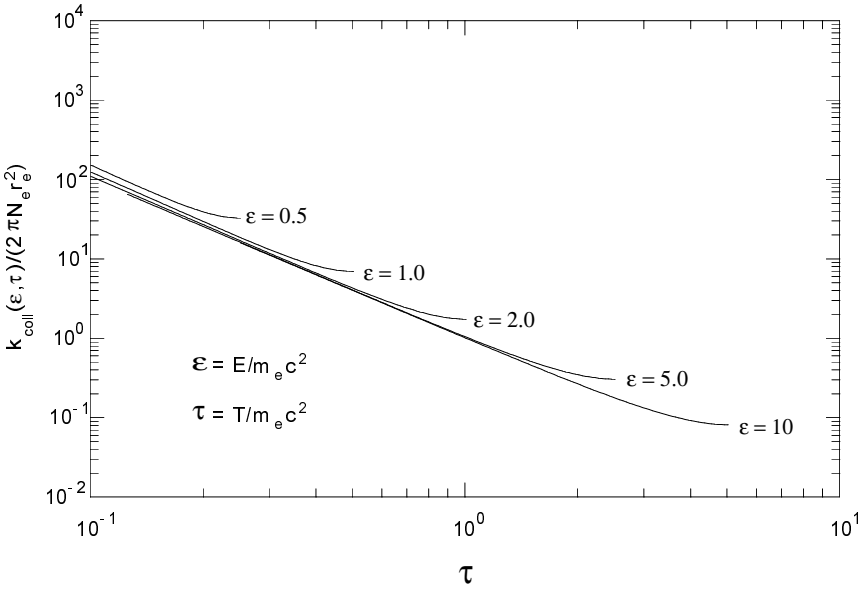

Figure 4.17. Møller cross section for electron-electron interactions.

Collisional LET

Both the classical and the relativistic approaches fail when Eq. (4.116) or (4.118) is substituted into Eq. (4.114). The integral $\int d\tau\, \tau^{-2}$ is infinite for a lower limit of zero. However, the zero limit is not realistic physically. A quantum mechanical approach is necessary because energy losses less than some finite value are prohibited due to quantized states of atomic electrons in the stopping medium. Bethe [1930, 1932] showed that the collisional LET can be written in the form

$$L_{coll}(\epsilon) = 2\pi z^2 N_e m_e c^2 r_e^2 \frac{1}{\beta^2} \int_0^{\tau_{\max}} d\tau\, \tau\, [\tau^{-2} + \cdots] \simeq \frac{\rho Z z^2 \mathcal{C}}{A\beta^2} f(\tau_{max}, \bar{I}), \tag{4.119}$$

in which $\mathcal{C} = 4\pi N_a r_e^2 m_e c^2 = 0.30705$ cm^2 MeV mol^{-1}. In the function f, $\bar{I} \equiv I/m_e c^2$ is a dimensionless *mean excitation energy* and is determined empirically for the stopping medium. Note that when the target is an electron

$$\tau_{\max} = \begin{cases} \epsilon/2 & \text{for electron collisions,} \\ \epsilon & \text{for positron collisions,} \\ 2\beta^2/(1-\beta^2) & \text{for non-relativistic heavy particles.} \end{cases} \tag{4.120}$$

Selected values of I are given in Table 4.2. For $Z \geq 13$, I for elemental substances, in units of eV, is given approximately by the empirical formula [Barkas and Berger 1964]

$$I = 9.76Z + 58.8Z^{-0.19}. \tag{4.121}$$

Janni [1982] gives the following formula, valid within 10% for $Z > 34$:

$$I = 10.3Z - 8.17Z^{1/3}. \tag{4.122}$$

Table 4.2. Selected values of the mean excitation energy for compounds and atomic constituents of compounds in the condensed state.

Material	Form	I (eV)	Material	Form	I (eV)
H	saturated bond	19.0	H_2	gas	19.2
H	unsaturated bond	16.0	N_2	gas	82.0
C	saturated bond	81.1	O_2	gas	95.0
C	unsaturated bond	79.8	CO_2	gas	85.0
C	highly chlorinated	69.0	Air	dry	85.7
N	amines, nitrates, etc.	105.7	Water	gas	71.6
N	in rings	81.9	Water	liquid	75.0
O	–O–	104.6	Tissue	ICRU muscle	74.7
O	=O	94.4	Bone	ICRU compact	91.9

Source: ICRU [1984].

For atomic constituents of compounds, I should be increased by a factor of 1.13 [ICRU 1984]. For mixtures of elements identified by the index j, the average values of Z/A and I are given by the empirical formulas

$$\langle Z/A\rangle = \sum_j w_j \left(\frac{Z_j}{A_j}\right) \tag{4.123}$$

and

$$\ln I = \langle Z/A\rangle^{-1} \sum_j w_j \left(\frac{Z_j}{A_j}\right) \ln I_j. \tag{4.124}$$

in which w_j is the weight fraction of the jth constituent.

4.6.2 Radiative Energy Loss

Classical electromagnetic theory requires that the rate at which electromagnetic energy is radiated from an accelerating charged particle be proportional to the square of the acceleration. In the electric field of a nucleus with atomic number Z, the force on a charged particle with z elemental charges is proportional to the product Zz. The resulting acceleration of the charged particle is proportional to this force and inversely proportional to the particle's mass m. Thus, the rate of radiative energy loss by the charged particle would be expected to be proportional to $(Zz/m)^2$. This inverse-square dependence on particle mass explains why bremsstrahlung from protons or heavier charged particles is negligible in most circumstances compared to that from electrons or positrons. The dependence on the square of Z also explains why, except for the lightest elements, bremsstrahlung in the field of the nucleus far exceeds bremsstrahlung in the fields of atomic electrons.

One may define a differential interaction coefficient for radiative energy loss in such a way that $\mu_{rad}(E, E')\,dE'$ is the probability per unit differential distance of travel that deceleration of an electron of energy E results in emission of a photon with energy between E' and $E' + dE'$. However, it is not possible to write a simple expression for $\mu_{rad}(E, E')$ or for the associated microscopic cross section $\sigma_{rad}(E, E')$. The interaction coefficient for radiative energy loss by an electron is illustrated in Fig. 4.18, which is based on calculations performed by the PEGS4 computer program [Nelson et al. 1985].

For a relativistic heavy charged particle of rest mass M, with $E \gg Mc^2$, it can be shown that the ratio of radiative to ionization losses is approximately [Evans 1955]

$$\frac{(-dE/ds)_{rad}}{(-dE/ds)_{coll}} \simeq \frac{EZ}{700}\left(\frac{m_e}{M}\right)^2, \tag{4.125}$$

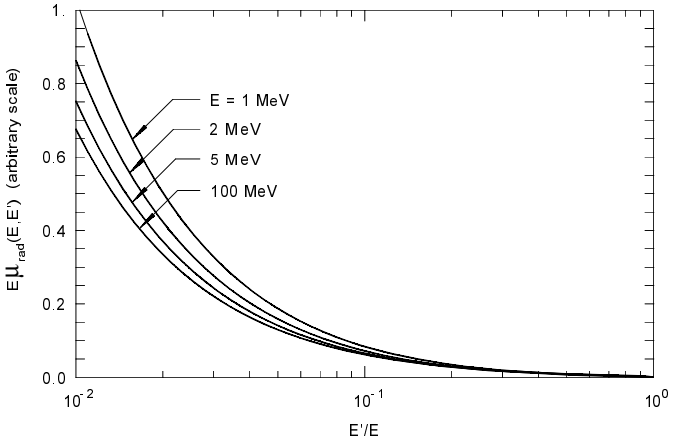

Figure 4.18. Energy spectrum of bremsstrahlung photons released in lead by radiative energy losses of electrons with initial energy E.

where E is in MeV. From this result it is seen that bremsstrahlung is more important for high-energy particles of small mass incident on high-Z material. In most dosimetry situations, only electrons ($m_e/M = 1$) are of importance for their associated bremsstrahlung. All other charged particles are far too massive to produce significant amounts of bremsstrahlung. Bremsstrahlung from electrons is of particular radiological interest for devices that accelerate electrons, such as betatrons and x-ray tubes, or for situations involving radionuclides that emit only beta particles.

4.6.3 Estimating Charged-Particle Ranges

Charged particles as they travel through some medium lose energy through Coulombic interactions with ambient electrons (and, infrequently, with atomic nuclei) and by bremsstrahlung production. As a consequence, they eventually come to rest (discounting thermal motion) after a finite distance of travel. The distance a charged particle travels before coming to rest is called its *range*. However, there are several measures used for the range of a charged particle.

The Continuous Slowing Down Range

It is common to neglect energy-loss fluctuations and assume that particles lose energy continuously along their tracks, with a mean energy loss per unit path length given by the total stopping power. Under this approximation [ICRU 1984], the *continuous slowing down range* R_{CSDA} of a charged particle with initial kinetic energy E_o is given by [ICRU 1984]

$$R_{\mathrm{CSDA}} = \int_0^R ds = \int_0^{E_o} \frac{dE}{(-dE/ds)_{tot}}. \tag{4.126}$$

where $(-dE/ds)_{tot} = (-dE/ds)_{coll} + (-dE/ds)_{rad}$, the total stopping power. This range is the expected length of a particle's trajectory before it comes to rest.

Evaluation of the integral is complicated by difficulties in formulating both the radiative stopping power and the collisional stopping power for low-energy particles, particularly electrons, and it is common to assume that the reciprocal of the stopping power is zero at zero energy and increases linearly to the known value at the least energy. It should be noted that this range cannot be measured experimentally since, to do so, would require a three-dimensional visualization of a particle's track and an evaluation of the length of this track.

Ranges for Penetration Depths

For a charged particle of a specific type traveling in a given medium, there is some average distance the particle travels between where it starts with energy E_0 and where it comes to rest and becomes part of the ambient medium. The *mean forward* or *projected* range R_p is the expected or average maximum depth of penetration in the initial direction of the charged particle. This range can be measured experimentally by finding the distance from a monodirectional source along the emission direction at which the intensity of charged particles is reduced by 50%.

Because charged particles, especially electrons and positrons, can be backscattered as they slow down, another range, which is sometimes encountered, is the average penetration distance R_{end} to where the particle comes to rest, i.e., to where the particle trajectory ends. As in the definition of R_p, this range is defined along a straight line in the initial particle direction. For HCPs $R_p \leq R_{end}$ but for electrons R_{end} can be substantially smaller than R_m.

There are other ranges that are sometimes encountered for heavy charged particles. One is the *maximum* range R_{max} that is the crow-flight distance, in the initial particle direction, between the particle source to a point beyond which no particle reaches. Yet another straight-line range is the *extrapolated* range R_e that is based on a linear extrapolation of the distance versus intensity plot from R_p to zero intensity. These two ranges are discussed in more detail later in this section.

The CSDA and projected ranges are non-stochastic quantities and for heavy charged particles are nearly equal. For electrons, however, R_{CSDA} can be significantly greater than R_p and R_{end}. This difference is quantified by the *detour* factor, discussed next.

Detour Factor

The difference between R_{CSDA} and R_p is due to the deviation of a charged particle's trajectory from an ideal straight-line trajectory, a result of the multiple scattering events that occur along the trajectory. This deviation is very pronounced for electrons and positrons but much less so for heavy charged particles. The detour factor is defined as R_p/R_{CSDA} [Andreo et al. 2017]. It should be noted that this definition is subtly different for protons and alpha particles as defined by the ICRU [1993] who, instead of R_p used R_{end}, the depth of penetration to the termination point. Examples of the detour factor for electrons, protons and alpha particles are shown in Fig. 4.19 where it is seen that electrons have smaller detour factors than the heavy charged particles. This difference is a consequence of the much more tortuous path an electron travels while traversing matter compared to the path taken by a heavy charged particle.

4.6.4 Electron Energy Loss and Range

Before modern-day computers, analytical expressions were used to approximate the energy loss of electrons through matter. One widely used expression for relativistic electrons, based on the electron scattering results of Møller [1932], was derived by Bethe for electron stopping power in a substance with electron density N_e [Bethe and Ashkin 1953]

$$L = \frac{2\pi N_e q_e^4}{mv^2}\left\{ \ln\left[\frac{mv^2 E}{2I^2(1-\beta)}\right] - \left(2\sqrt{1-\beta^2} - 1 + \beta^2\right)\ln 2 \right.$$
$$\left. +1 - \beta^2 + \frac{1}{8}(1-\sqrt{1-\beta^2})^2 \right\}. \tag{4.127}$$

where E is the incident particle energy and I is the average excitation potential. Although generally convenient for a wide variety of materials, Eq. (4.127) becomes inaccurate at low electron velocities. More recently, computer codes with corrections to the Bethe equation render improved results. For *electrons and positrons*, integration of the Møller [1932] or Bhabha [1938] cross section, with $z = 1$, leads to the Rohrlich and Carlson

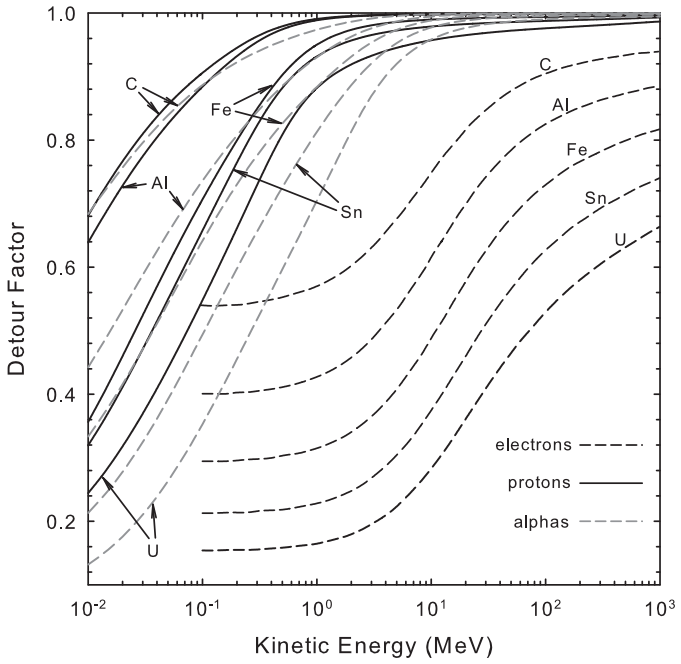

Figure 4.19. Detour factors R_p/R_{CSDA} for electrons (heavy dashed lines), protons (solid lines) and alpha particles (light dashed lines). The data for protons and alpha particles were obtained with the STAR codes [Berger 1992] and for electrons from Andreo et al. [2017].

[1954] formula used by Seltzer and Berger [1985; 1986] in their compilations of stopping powers [ICRU 1984]

$$L_{coll}(E) = \frac{\rho Z \mathcal{C}}{2A\beta^2}\left[2\ln(\epsilon/\bar{I}) + \ln(1+\epsilon/2) + F^{\pm}(\epsilon) - \delta\right]. \tag{4.128}$$

The factor F^- for electrons is given by

$$F^-(\epsilon) = (1-\beta^2)\left[1 + \epsilon^2/8 - (1+2\epsilon)\ln 2\right]. \tag{4.129}$$

The factor F^+ for positrons is given by

$$F^+(\epsilon) = 2\ln 2 - (\beta^2/12)\left[23 + 14/(\epsilon+2) + 10/(\epsilon+2)^2 + 4/(\epsilon+2)^3\right]. \tag{4.130}$$

In Eq. (4.128), the *density-effect correction term* δ accounts for polarization of atoms in the stopping medium caused by passage of the electron, the result of which is a reduction of the electric field acting on the moving electron and thus a reduction in the stopping power. Evaluation of δ is quite involved. Procedures are described by the ICRU [1984]. In liquid water, for example, the density effect causes a 1.2% reduction in L_{coll} at $E = 1$ MeV, 3.9% at 2 MeV, and 11.5% at 10 MeV. Selected values of mean excitation energies are given in Table 4.2. Stopping powers are illustrated in Fig. 4.20.

Restricted Electron Stopping Power The rate at which energy is deposited locally along the track of an electron is of great importance in certain radiation detector analyses. This requires establishing a cutoff energy, say E_{cut}, below which an energy loss is considered to be local. A value of E_{cut} on the order of 200

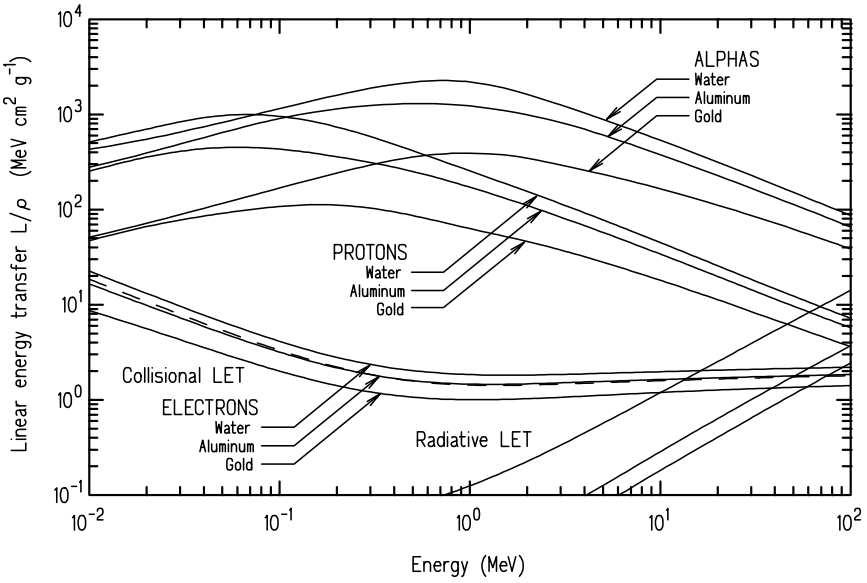

Figure 4.20. Linear energy transfer L/ρ in mass units (MeV cm^2/g) for alpha particles, protons and electrons. The dashed line for aluminum is the collisional LET for positrons. Data is from the STAR series of codes [Berger 1992].

eV is often chosen. The restricted stopping power $L_{coll}(E, E_{cut})$ is defined in analogy with Eq. (4.119), but with $\tau_{\max}$ expressed in terms of E_{cut}. The result is

$$L_{coll}(E, E_{cut}) = \frac{\rho Z \mathcal{C}}{2A\beta^2} \left[2\ln(\epsilon/\bar{I}) + \ln(1+\epsilon/2) + G^{\pm}(\epsilon, \eta) - \delta \right], \tag{4.131}$$

in which $\eta \equiv E_{cut}/E$. The factor G^- for electrons is given by

$$G^-(\epsilon, \eta) = (1-\beta^2)\left[\epsilon^2\eta^2/2 + (2\epsilon+1)\ln(1-\eta)\right] - 1 - \beta^2 + \ln\left[4\eta(1-\eta)\right] + (1-\eta)^{-1}. \tag{4.132}$$

The factor G^+ for positrons is given by

$$\begin{aligned} G^+(\epsilon, \eta) = \ln 4\eta - \beta^2[1 &+ (2-\xi^2)\eta - (3+\xi^2)(\xi\epsilon/2)\eta^2 \\ &+ (1+\epsilon\xi)(\xi^2\epsilon^2/3)\eta^3 - (\xi^3\epsilon^3/4)\eta^4], \end{aligned} \tag{4.133}$$

in which $\xi \equiv (\epsilon+2)^{-1}$.

Electron Radiative LET No simple formula can describe the stopping power or LET for electron radiative energy losses (bremsstrahlung). The total stopping power can be written as the sum of stopping powers associated with radiative losses in the force fields of nuclei and electrons, namely, $L_{rad}(E) = L_{rad,n}(E) + L_{rad,e}(E) = L_{rad,n}(E)(1+\xi/z)$, in which ξ is the "correction term" $L_{rad,e}/L_{rad,n}$. According to ICRU [1984], ξ depends hardly at all on the medium and is less than 1.2 in magnitude for all E. It is about 0.5 at $E = 700$ keV and approaches zero at low E. The radiative stopping power may be written as [ICRU 1984]

$$L_{rad}(E) = Nr_e^2(E + m_e c^2)Z^2\alpha(1+\xi/Z)\Phi(E, Z), \tag{4.134}$$

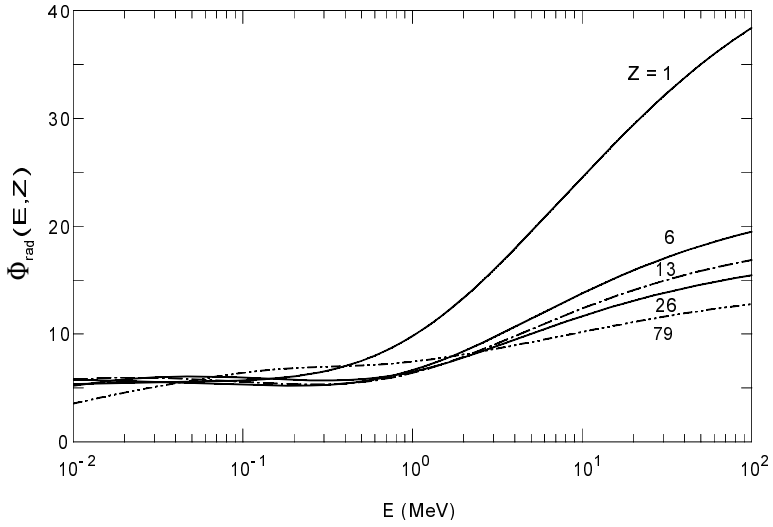

Figure 4.21. Scaled dimensionless radiative energy loss cross sections $\Phi_{rad}(E, Z)$ for electrons in various media. Based on data from Seltzer and Berger [1986].

in which N is the atomic density, $\alpha \simeq 1/137$ is the *fine-structure constant*, and $\Phi(E, Z)$ is the dimensionless scaled radiative energy-loss cross section given by

$$\Phi(E, Z) = \frac{1}{\alpha r_e^2 Z^2 (E + m_e c^2)} \int_0^E dE' \; E' \sigma_{rad}(E, E'). \tag{4.135}$$

The function Φ, too, is not strongly dependent on Z, as is illustrated in Fig. 4.21 for several values of Z. Tables of data are given by Seltzer and Berger [1985, 1986].

Electron Range The mean crow-flight range of electrons in a material with density ρ can be approximated by [Katz and Penfold 1952]

$$\rho R_p \text{ (g cm}^{-2}) = \begin{cases} 0.412 E^{1.265 - 0.0954 \ln E} & 0.1 \text{ MeV} \le E \le 3 \text{ MeV} \\ .530E - 0.106 & 2.5 \text{ MeV} \le E \le 20 \text{ MeV} \end{cases}, \tag{4.136}$$

where E is the energy of the incident electron. Notice that this empirical approximation is independent of the Z number of the attenuating material, a result that follows from the observation that, when the range is expressed in terms of mass thickness, the range is almost the same for all materials (as can be seen from Fig. 4.23).

When determining the maximum range of beta particles, then the maximum particle emission energy should be used. Notably, Eq. (4.136) implies that the electron mass range ρR_p is independent of the target material. The usefulness of this outcome allows easy range estimations between differing materials. Hence, the result of Eq. (4.136) need only be divided by the mass density of the target material to determine the actual range. However, in reality there is a difference in particle range between materials, and modern computer programs can provide better range estimates than the older empirical formulas.

Beta particles (electrons or positrons) produce numerous ionizations and electronic excitations as they move through a medium. Most interactions are small deflections accompanied by small energy losses. However, beta particles, having the same mass as the electrons of the medium, can also undergo large-angle

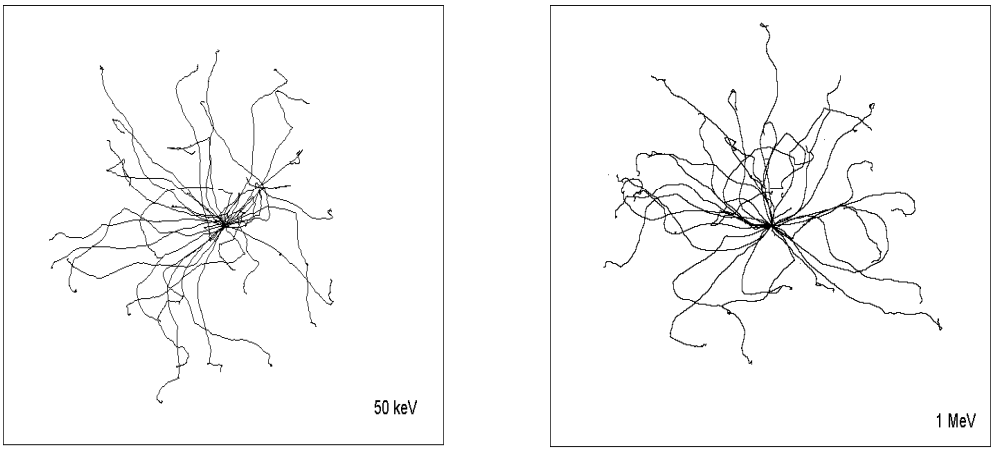

Figure 4.22. Tracks of 30 electrons from a 50-keV (left) and a 1-MeV (right) point isotropic source in water, shown as orthographic projections of tracks into a single plane. The box has dimensions $2r_o \times 2r_o$ where r_o is the CSDA range of the electrons. Calculations performed using the EGS4 code, courtesy of Robert Stewart, Kansas State University.

scatters producing secondary electrons with substantial recoil energy. These energetic secondary electrons (called *delta* rays) in turn pass through the medium causing additional ionization and excitation. Large-angle deflections from atomic nuclei can also occur with negligible energy loss. Consequently, the paths traveled by beta particles as they transfer their energy to the surrounding medium are far from straight. Examples of such paths are shown in Fig. 4.22.

For such paths, it is seen that the distances beta particles travel into a medium vary tremendously. The range of beta particles is defined as the path length of the particles, i.e., the distance they travel along their twisted trajectories. This range is well approximated by the CSDA range and is the maximum distance a beta particle can penetrate, although most, because of the twisting of their paths, seldom penetrate this far (see Section 4.6.3).

It may be inferred from data given by Cross, Freedman, and Wong [1992] that for a beam of electrons, ranging in energy from 0.025 to 4 MeV, normally incident on water, about 80% of the electron energy is deposited within a depth of about 60% of the CSDA range, 90% of the energy within about 70% of the range, and 95% of the energy within about 80% of the range. For a point isotropic source of monoenergetic electrons of the same energies in water, 90% of the energy is deposited within about 80% of the range, and 95% of the energy within about 85% of the range. In either geometry, all of the energy is deposited within about 110% of the CSDA range. Electron CSDA ranges are presented in Fig. 4.23.

4.6.5 Spatial Distribution of the Electron Energy Absorption

In both the design of radiation detectors and radiation dosimetry, it is important to know where the energy of a charged particle is deposited at different distances from the source of the charged particles. Because of the tortuous trajectories of electrons, the spatial distribution of this absorbed energy is not easily calculated from first principles. This section considers point and uniform-beam sources of monoenergetic electrons in infinite homogeneous media. In particular, spatial distributions of the absorbed dose (absorbed energy per unit mass) are expressed in terms of point and plane kernels and associated scaled dimensionless dose distributions.

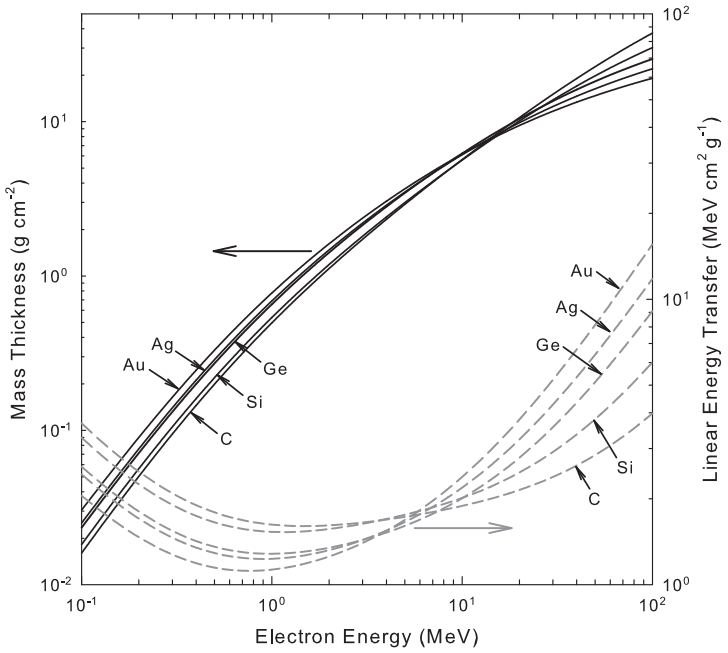

Figure 4.23. The CSDA range or path length ρR, in mass thickness (g/cm^2), for electrons in various materials. The CSDA ranges are shown as solid black lines. Also shown, as gray dotted lines, are linear energy transfer (LET) as functions of energy. Data are from the STAR series of codes [Berger 1992].

Point and Plane Kernels Defined

The expected absorbed dose at distance r from a unit point isotropic source of monoenergetic charged particles of energy E is denoted as $\mathcal{G}(r, E)$. Typical units for $\mathcal{G}$ are MeV/g. The point kernel $\mathcal{G}$ is very conveniently expressed in terms of the dimensionless dose distribution $\mathcal{F}(r/r_o, E)$, with radial distance r scaled by the CSDA range $R_{CSDA} \equiv r_o$, namely,

$$\mathcal{G}(r, E) = \frac{E}{4\pi r^2 \rho r_o} \mathcal{F}(r/r_o, E) = \frac{E}{4\pi r^2 \hat{r}_o} \mathcal{F}(\hat{r}/\hat{r}_o, E), \tag{4.137}$$

in which $\hat{r} = \rho r$ and $\hat{r}_o$ is the CSDA range of Eq. (4.126) in mass units. A useful interpretation of $\mathcal{F}$, which is illustrated in Fig. 4.24, is that the fraction of E deposited between radii r and $r + dr$ is $(dr/r_o)\mathcal{F}(r/r_o, E)$. Note that, without a subscript, $\mathcal{F}$ and $\mathcal{G}$ refer to a point isotropic source.

Similarly, for an infinite plane perpendicular[15] source of monoenergetic particles in an infinite homogeneous medium, the expected absorbed dose at distance r along the beam is denoted as $\mathcal{G}_{pl}^{\perp}(r, E)$. This is conveniently expressed in terms of a scaled dimensionless dose distribution as

$$\mathcal{G}_{pl}^{\perp}(r, E) = \frac{E}{\rho r_o} \mathcal{F}_{pl}^{\perp}(r/r_o, E), \tag{4.138}$$

which is illustrated in Fig. 4.25.

[15] The source is an area source with all particles released in a parallel beam normal to the source area.

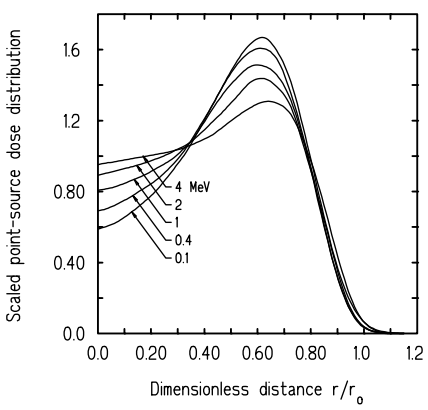

Figure 4.24. Scaled dimensionless dose distributions, $\mathcal{F}(r/r_o, E)$, for point isotropic electron sources in water. From Cross, Freedman, and Wong [1992].

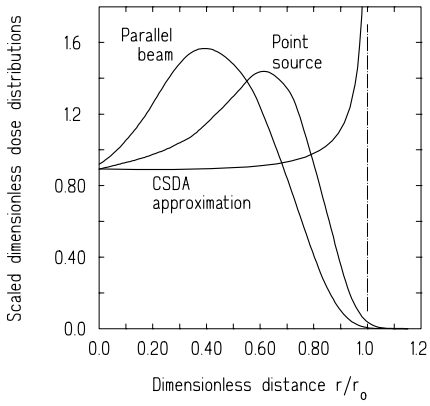

Figure 4.25. Comparison of $\mathcal{F}(r/r_o, E)$ point-source, $\mathcal{F}^{\perp}_{pl}(r/r_o, E)$ parallel-beam-source, and CSDA scaled dimensionless dose distributions for 2-MeV electron sources in water. Data for the point and parallel-beam sources from Cross, Freedman, and Wong [1992].

CSDA Absorbed Energy Distribution

In the continuous slowing-down approximation, all particle tracks are straight and of length r_o. It is easily shown that in this approximation,

$$\left[\mathcal{F}^{\perp}_{pl}(r, E)\right]_{\text{CSDA}} = \left[\mathcal{F}(r, E)\right]_{\text{CSDA}} = \frac{L(r_o - r)}{E/r_o}, \quad r < r_o. \tag{4.139}$$

Note that the linear energy transfer L is evaluated at the energy of the particle after passage through distance r, that is, for a particle with residual range $r_o - r$. The residual range[16] determines both the energy and the LET of a particle. The denominator of Eq. (4.126) is just the average LET along the entire path of the particle. Point and plane dose distributions are compared with the distribution in the CSDA approximation in Fig. 4.25.

Electron Absorbed Energy Distributions

The pioneering moments-method electron-transport calculations of Spencer [1959] were used by Berger [1971] and Cross et al. [1982] to construct scaled dimensionless dose distributions for monoenergetic electrons and beta-particle sources. These were revised by Berger in 1973, based on Monte Carlo calculations. Cross, Freedman, and Wong [1992] also used Monte Carlo methods to prepare comprehensive tables of dose distributions for point, plane parallel, and plane isotropic sources of electrons and beta particles in water. Example dose distributions for point sources are illustrated in Fig. 4.25. Tabulations of $\mathcal{F}(r/r_o, E)$ versus r/r_o are given by Shultis and Faw [2000] and Cross et al. [1992].

Figure 4.25 compares kernels for 2-MeV point and plane parallel electron sources in water. In contrast, the point kernel based on the CSDA approximation is shown to be a very poor approximation for electrons. The reason is apparent from examination of Fig. 4.22, which shows the spatial distributions of energy deposition from point isotropic sources of monoenergetic electrons. Not only is much of the energy deposited well within

[16] A charged particle energetic enough to penetrate a distance x and emerge with energy E' has a residual range $R_{CSDA}(E')$ in the same material. So the range $R_{CSDA}(E)$ of the particle with initial energy E must have been $x + R_{CSDA}(E')$.

distance r_o, but the spatial distribution of the energy distribution scaled by r_o is insensitive to E. The scaled patterns shown in Fig. 4.22 for 50-keV and 1-MeV electrons reinforce the logic for the similarity in shapes of the curves in Fig. 4.24.

Kernels in Non-Aqueous Media

It has long been observed [Cross 1967; Berger 1971] that when distance is measured in mass thickness $\hat{r} = \rho r$, the point kernel in medium m at distance $\hat{r}$ is proportional to that in water, medium w, at a scaled distance $\eta\hat{r}$. The scale factor η was found to depend on medium m but only very weakly on the energy, so that the same scale factor could be applied to beta-particle sources as well as monoenergetic electron sources. Conservation of energy for a point source requires that

$$\int_0^\infty d(\hat{r}/\rho_m)\,(\hat{r}/\rho_m)^2\rho_m\,\mathcal{G}_m(\hat{r},E) = \int_0^\infty d(\eta\hat{r}/\rho_w)\,(\eta\hat{r}/\rho_w)^2\rho_w\,\mathcal{G}_w(\eta\hat{r},E). \tag{4.140}$$

It therefore follows that

$$\mathcal{G}_m(\hat{r},E) = \eta^3\left[\frac{\rho_m}{\rho_w}\right]^2\mathcal{G}_w(\eta\hat{r},E). \tag{4.141}$$

Similarly,

$$\mathcal{G}^{\perp}_{m,pl}(\hat{r},E) = \eta\,\mathcal{G}^{\perp}_{w,pl}(\eta\hat{r},E). \tag{4.142}$$

In terms of the dimensional dose distribution $\mathcal{F}$ the point kernel for medium m is

$$\mathcal{G}_m(\hat{r},E) = \frac{E}{4\pi r^2(\hat{r}_o/\eta)}\mathcal{F}\left(\frac{\hat{r}}{\hat{r}_o/\eta},E\right) = \frac{E}{4\pi r^2\hat{r}_m}\mathcal{F}\left(\frac{\hat{r}}{\hat{r}_m},E\right), \tag{4.143}$$

in which the mass CSDA range $\hat{r}_m(E)$ of electrons in medium m, in terms of that in water, is given by $\hat{r}_m(E) = \hat{r}_o(E)/\eta$. Thus, $\mathcal{F}$ may be interpreted as a universal function of the ratio $\hat{r}/\hat{r}_m = r/r_m$, the distance from the point source in units of the CSDA range.

Cross, Freedman, and Wong [1992] recommend that η be computed using the following formula, which is based on experiments and calculations for beta-particle attenuation in various media relative to that in water:

$$\eta = 0.77(1 + 0.0491\overline{Z} - 0.0009\overline{Z}^2)\frac{(L/\rho)_m}{(L/\rho)_w}, \tag{4.144}$$

in which the mean atomic number is given as follows, based on mass fractions of the atomic constituents in the medium:

$$\overline{Z} = \frac{\sum_i w_i Z_i^2/A_i}{\sum_i w_i Z_i/A_i}. \tag{4.145}$$

The ratio of stopping powers is insensitive to energy, and Berger [1971] recommends that they be evaluated at 0.2 MeV. Cross, Freedman, and Wong [1992] recommend that, instead, $(L/\rho)_m/(L/\rho)_w$ be replaced by $\hat{r}_w/\hat{r}_m$ evaluated at 500 keV. These formulas predict that $\eta = 0.89$ for air. Note that the ratio of the mass CSDA range in water to that in air varies from 0.89 for 0.01-MeV electrons to 0.91 for 3-MeV electrons. For the human body, η is 0.98 for soft tissue and 0.97 for compact bone.

4.6.6 Heavy Charged-Particle Energy Loss

Rossi [1952] describes the stopping power for relativistic *heavy charged particles* as

$$L_{coll}(E) = \frac{\rho Z z^2\mathcal{C}}{A\beta^2}\left[\ln\left(\frac{2\beta^2}{(1-\beta^2)\bar{I}}\right) - \beta^2\right]. \tag{4.146}$$

This approximation is mainly used for protons with energies between about 10 and 1000 MeV or other heavy particles with comparable speeds. Note that L_{coll} is directly proportional to z^2 and that $N_e = \rho(Z/A)N_a$. It does not vary independently with mass and kinetic energy of the incident charged particle. Instead, L_{coll} is a function of the particle velocity or β^2.

At low energies, β becomes small and Eq. (4.146) reduces to

$$L_{coll}(E) = \frac{\rho Z z^2 \mathcal{C}}{A\beta^2} \ln\left(\frac{2m_e v^2}{I}\right). \tag{4.147}$$

Note that L_{coll} is only weakly dependent on the mean excitation energy I. For a non-relativistic particle,[17] $v = \sqrt{2T/M}$. Thus, in a given medium, a 1-MeV proton has roughly the same collisional stopping power as a 2-MeV deuteron and roughly one-fourth that of a 4-MeV alpha particle. In this way, stopping-power data for protons may be used to approximate stopping powers for other heavy charged particles. Equation (4.146) overestimates the LET by less than about 10% for proton energies between 1 and 10^4 MeV and for stopping media such as air, water, and elements ranging in atomic number from aluminum to gold. For proton energies much below 1 MeV, the formula fails utterly. For low energies, Anderson and Ziegler [1977] recommend a general relation

$$L_{coll}(E) \simeq A_1 E^{A_2}, \tag{4.148}$$

where A_1 is an experimentally determined constant and $A_2 \simeq 0.5$. The collisional stopping power for protons and alpha particles, as a function of the particle's energy, is shown in Fig. 4.20.

Corrections to Eq. (4.146) account for shell and density effects, among other minor effects. Shell corrections compensate for the fact that the atomic binding of inner-shell electrons reduces their participation in charged-particle slowing down. Density corrections compensate for the polarization of the stopping medium induced by passage of the charged particle and the resulting perturbation of the electronic structure and reduction in stopping power. Stopping of low-energy charged particles is affected by neutralization of the charge of the particle and by collisions with atomic nuclei of the stopping medium. Detailed data on the LET and range of heavy charged particles are given in reports by Janni [1982], Hubert et al. [1990], and the ICRU [1993]. Computer codes are also available for calculation of ranges, stopping powers, and related quantities for electrons, protons, helium nuclei, and heavy ions [Berger 1992; Ziegler et al. 2013].

4.6.7 Heavy Charged-Particle Range

When a heavy charged particle (HCP) with mass M and energy E_M scatters from an electron, the maximum energy loss by the HCP and the maximum energy of the recoil electron is [Shultis and Faw 2017]

$$(E_e)_{\max} = 4\frac{m_e}{M}E_M. \tag{4.149}$$

As an example, consider a 4-MeV alpha particle. From Eq. (4.149), the maximum energy loss of such an alpha particle when it interacts with an electron is found to be 2.2 keV. Most such alpha-electron interactions result in far smaller energy losses, although usually sufficient energy transfer to free the electron from its atom or at least to raise the atom to a high excitation state. Consequently, many thousands of these interactions are required for the alpha particle to lose its kinetic energy.

Moreover, the mass of the alpha particle being over 7000 times that of an electron, the alpha particle experiences negligible deflection from its path of travel. An important characteristic of such heavy charged particles, as they move through a medium, is that they travel in almost straight lines, unless they are

[17] By this is meant a particle whose kinetic energy is very much less than its rest-mass energy: 511 keV for electrons, about 930 MeV for protons or neutrons, and about 3727 MeV for alpha particles.

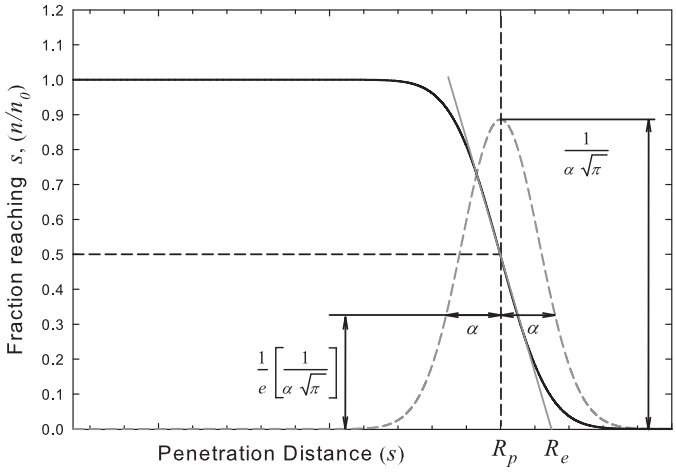

Figure 4.26. Fraction of α-particles that penetrate a distance s. The gray dotted line shows the derivative $dn(s)/ds$ and is termed the straggling curve, a result of the large-angle scattering near the end of the particles' paths and the statistical fluctuations in the number of interactions needed to absorb the particles' initial energy.

deflected by a nucleus. Such nucleus-particle interactions are rare and usually occur only when the charged particles have lost most of their kinetic energy.

Many measurements of the *range* of heavy particles have been made. In Fig. 4.26, the fraction of alpha particles, with the same initial energy, that travel various distances s into a medium is illustrated. We see from this figure, that the number of alpha particles penetrating a distance s into a medium remains constant until near the end of their range. The number penetrating beyond this maximum distance falls rapidly.

The distance a heavy charged particle travels in a medium before it is stopped is not a precise quantity because of the stochastic nature of the number and energy losses of all the particle-medium interactions, and because of possible large-angle deflections near the end of the path. From Fig. 4.26, we see that the range of a heavy charged particle is not an exact quantity. Several measures of the range can be defined. We can define R_p as the *mean* or *projected* range, that is, the distance at which the intensity of heavy particles has been halved. This projected range is at the maximum of the differential energy curve or *straggling curve* $dn(s)/ds$, shown as the dotted curve in Fig. 4.26. Alternatively, the range can be taken as R_e, the *extrapolated* range, that is, the value obtained by drawing the tangent to the curve at its inflection point and extrapolating the tangent until it crosses the s-axis. Finally, if we treat the slowing down of heavy charged particles as a continuous process, a unique range, called the *continuous slowing-down approximation* (CSDA), a unique CSDA range can be calculated. Although slightly different, all three of these definitions of a heavy particle's range are, for practical purposes, nearly the same. The mean and CSDA ranges for protons and alpha particles are presented in Fig. 4.27.

Because of the large number of interactions with electrons of the ambient medium, heavy charged particles, of the same mass and initial kinetic energy, travel in straight lines and penetrate almost the same distance into a medium before they are stopped. Because of the stochastic nature of the particle-medium interactions and because, near the end of their paths, some heavy particles experience large angle deflections from atomic nuclei, the penetration distances exhibit a small variation called *straggling*. The straggling is defined by a range-straggling parameter α_0, where $\alpha_0 \simeq 0.015R_p$ [Evans 1955]. The straggling curve indicates the final

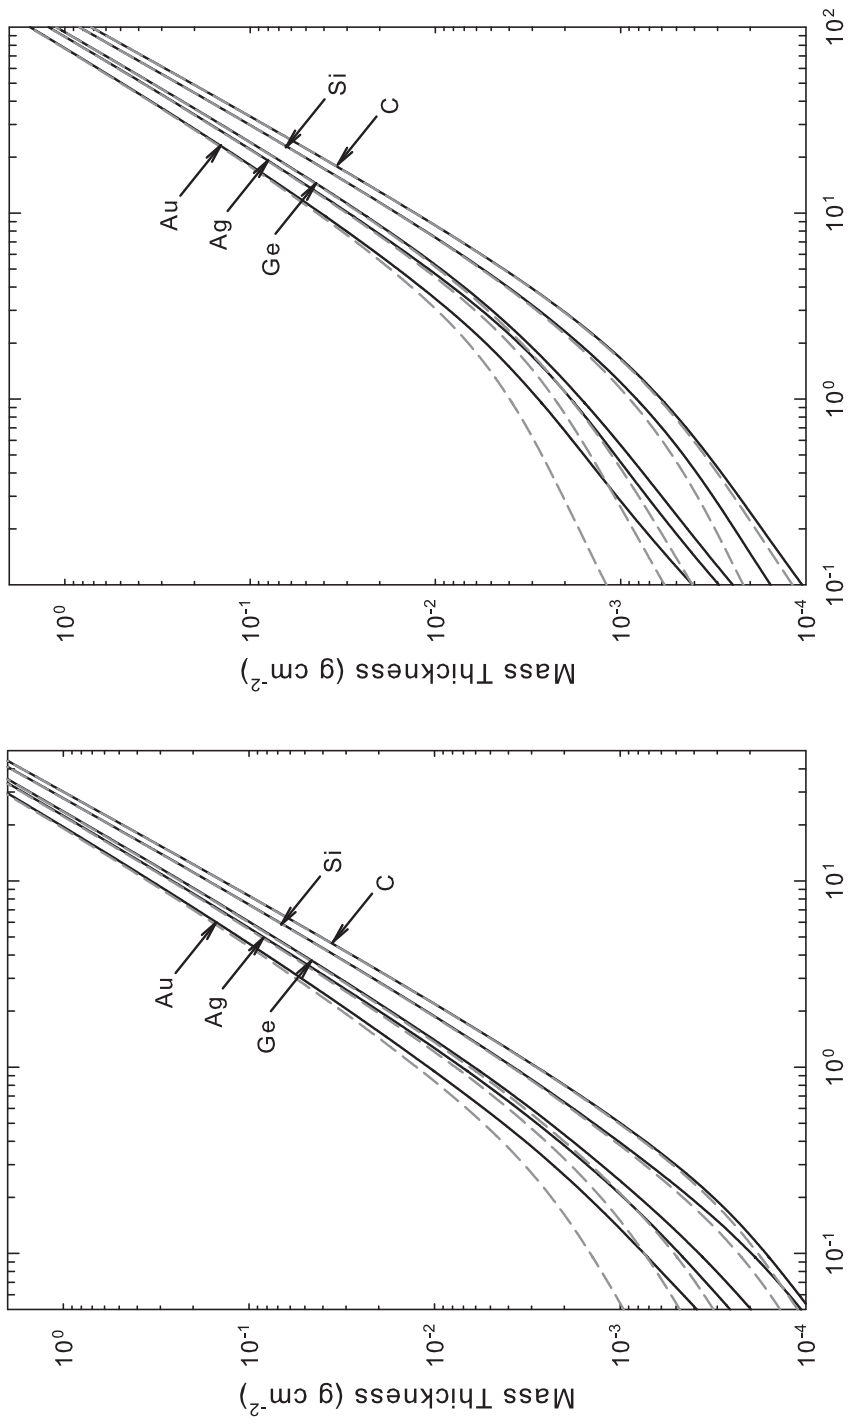

Figure 4.27. Range or path length ρR, in mass thickness (g/cm^2), for protons and alpha particles in several materials. The average (or projected) ranges are shown as black solid lines while the CSDA ranges are shown as gray dotted lines. Data are from the STAR series of codes [Berger 1992].

resting distribution of ions in the target material, and is modeled as a Gaussian distribution

$$\frac{1}{n_0}\frac{dn(s)}{ds} = \frac{1}{\alpha\sqrt{\pi}}e^{-[(s-R_p)/\alpha]^2}, \tag{4.150}$$

where n_0 is the total number of ions and $\alpha \simeq \sqrt{2}\alpha_0$. Notably, the width 2α marks the locations in the number-range curve where the maximum of Eq. (4.150) is reduced by e^{-1}.

For *heavy* charged particles, we may use Eq. (4.126) to obtain the dependence of the range on the particle's mass m and charge z. Because bremsstrahlung is seldom important for heavy charged particles with energies below several tens of MeV, we may take $(-dE/ds)_{tot} \simeq (-dE/ds)_{coll}$. From Eq. (4.146) we see the collisional stopping power is of the form $(-dE/ds)_{coll} = \rho(Z/A)z^2 f(v)$ where $f(v)$ is a function only of v or $\beta = v/c$. From Eq. (4.126), the mass thickness range, ρR_{CSDA} is

$$\rho R_{CSDA} = \rho\int_0^{E_o}\frac{dE}{(-dE/ds)_{coll}} = \rho\int_0^{E_o}\frac{1}{(-dE/ds)_{coll}}\frac{dE}{dv}\,dv. \tag{4.151}$$

Substitution of $dE/dv = mv$ and $(-dE/ds)_{coll} = \rho(Z/A)z^2 f(v)$ then gives

$$\rho R_{CSDA} = \left(\frac{A}{Z}\right)\frac{m}{z^2}\int_0^{v_o}\frac{v\,dv}{f(v)} = \left(\frac{A}{Z}\right)\frac{m}{z^2}g(v_o), \tag{4.152}$$

where $g(v_o)$ is a function only of the initial speed v_o of the particle. From this result, three useful "rules" for relating different ranges follow.

1. The mass-thickness range ρR_{CSDA} is independent of the density of the medium.
2. For particles of the *same initial speed* in the same medium, ρR_{CSDA} is *approximately* proportional to m/z^2, where m and z are for the charged particle.
3. For particles of the *same initial speed*, in different media, ρR is *approximately* proportional to $(m/z^2)(Z/A)$, where Z is the atomic number of the stopping medium and A is its atomic weight.

Thus, from rule 2, in a given medium, a 4-MeV alpha particle has about the same range as a 1-MeV proton. However, these rules fail for particle energies less than about 1 MeV per atomic mass unit. For example, the CSDA range of a 0.4-MeV alpha particle in aluminum is about twice that of a 0.1-MeV proton.

4.6.8 The Bragg Curve

In reporting on his 1904 research on the ionization produced along the track of an alpha-particle, W.H. Bragg plotted a graph of the ion pairs produced per unit distance as a function of the distance penetrated by alpha particles in air. Known as the *Bragg curve*, this type of graph has been used countless times to illustrate the concepts of range and stopping power. A Bragg ionization curve is the average distribution of energy deposited, through ionization, per unit distance over the particle range and is described by

$$I(s) = \int_r^{\infty}\frac{i(r-s)}{\alpha\sqrt{\pi}}e^{-[(r-R)/\alpha]^2}dx, \tag{4.153}$$

where α is the straggling parameter, $i(r-s)$ is the *specific ionization* along the path of an *individual* particle at a distance of $(r-s)$, s is the penetration distance in the medium, r is the range of an *individual* particle, and R_p is the average particle range.

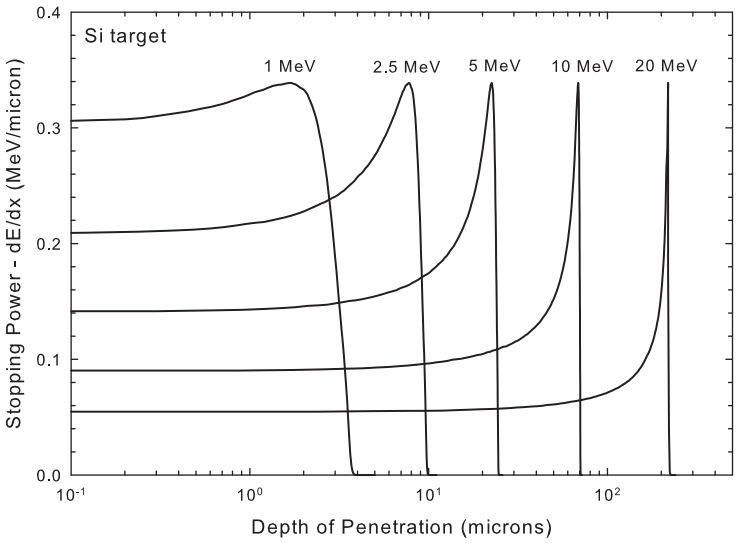

Figure 4.28. "Bragg curves" for alpha particles (helium nuclei) in silicon showing the stopping power versus depth of penetration. Data obtained using the SRIM program [Ziegler et al. 2013].

Closely related to the Bragg ionization curve is a graph of stopping power versus distance penetrated along the track of an alpha particle or other charged particle. Examples are shown in Fig. 4.28, illustrating energy loss along the tracks of alpha particles in silicon. In silicon, the stopping power is maximum for alpha particles of energy about 460 keV. For alpha particles with initial energies above 460 keV, stopping power increases along the particle path, reaches a maximum, and then decreases rapidly as the particle releases most of its kinetic energy near the end of its path.

4.6.9 Approximate Range Formula for Charged Particles

An empirical mass range ρR_{CSDA} for electrons, protons and alpha particles can be obtained by fitting the equation

$$\rho R_{\mathrm{CSDA}}\ (\mathrm{cm^2 g^{-1}}) = 10^{a+bx+cx^2} \tag{4.154}$$

to calculated CSDA range data. Here $x = \log_{10} E$ with the initial energy E of the particle in units of MeV. The empirical constants a, b, and c depend on the stopping material. This material dependence ameliorates a deficiency of the empirical formula of Eq. (4.136) for the mean electron range. Values of a, b, and c for a few materials are given in Table 4.3 for electrons and Table 4.4 for protons and alpha particles. Values of these parameters for other materials can be obtained from the STAR computer code package [Berger 1992].

If computer codes, empirical data, and/or particles ranges, such as listed in Table 4.4, are not available, then alternative relations do exist that can yield an acceptable result. For instance, from the analysis of Bragg and Kleeman [1905], an expression is available for heavy ions as a ratio of ranges for monoenergetic particles in different media

$$\frac{R_1}{R_2} = \frac{\rho_2}{\rho_1}\sqrt{\frac{A_1}{A_2}}, \tag{4.155}$$

where R_1 and R_2 are the ranges for alpha particles in two materials of density ρ_1 and ρ_2, and atomic masses A_1 and A_2. Eq. (4.155) is commonly called the *Bragg-Kleeman Rule*, and is best used for materials with similar atomic masses. The use of Eq. (4.155) is straightforward for elemental materials, but requires

a conversion to an *effective atomic mass* when used with mixtures and compounds [Henriksen and Baarli 1957]. There are various expressions for the effective atomic mass, some fairly complicated [see for example, Birgani et al. 2012]. Offered here is a relatively simple variation [Birks 1964]

$$A_{\mathit{eff}} = \left[\sum_{i=1} f_i A_i \Big/ \sum_{i=1} f_i \sqrt{A_i}\right]^2, \tag{4.156}$$

where f_i and A_i are the atomic fraction and atomic mass of element i. Knowledge of alpha particle range data for one material will allow estimations of alpha particle ranges in another material.

Example 4.1: Estimate the range in water of a 6-MeV triton (nucleus of ^{3}H). Data for the empirical range formula of Eq. (4.154) are not provided for a triton. We must, therefore, estimate the triton's range from the observation that, for a given medium, the range R of heavy charged particles with the same speed is proportional to m/z^2, where m and z are the mass and charge of the particle.

Solution:

Step 1: First find the kinetic energy of a proton with the same speed as the 6-MeV triton. Classical mechanics, appropriate for these energies, gives

$$\frac{E_p}{E_T} = \frac{(1/2)m_p v_p^2}{(1/2)m_T v_T^2} = \frac{m_p}{m_T} = \frac{1}{3}.$$

The proton energy with the same speed as a 6-MeV triton is, thus, $E_p = E_T/3 = 2$ MeV.

Step 2: Now we find the range in water of a 2-MeV proton using the empirical formula of Eq. (4.154) and the data in Table 4.4. With $x = \log_{10} 2 = 0.30103$

$$\rho R_p(2 \text{ MeV}) = 10^{-2.6144+1.4975x+0.23219x^2} = 0.007202 \text{ g/cm}^2.$$

Since $\rho = 1$ g/cm^3, $R_p(2 \text{ MeV}) = 0.007202$ cm.

Step 3: From the range "rule" for the same medium (following Eq. (4.152)), we have

$$\frac{R_T(6 \text{ MeV})}{R_p(2 \text{ MeV})} = \frac{m_T}{m_p}\frac{z_p^2}{z_T^2} = \frac{3}{1}\frac{1}{1} = 3.$$

The range of the triton is then $R_T(6 \text{ MeV}) = 3R_p(2 \text{ MeV}) = 0.0216$ cm.

Example 4.2: What is the range of 5.5 MeV alpha particles in silicon dioxide (SiO_2)?

Solution:

Step 1: Determine the effective atomic mass of SiO_2. From Eq. (4.156),

$$\begin{aligned} A_{eff} &= \left[\sum_{i=1} f_i A_i \Big/ \sum_{i=1} f_i \sqrt{A_i}\right]^2 \\ &= \left[\left(f_{\text{Si}} A_{\text{Si}} + f_{\text{O}} A_{\text{O}}\right) \Big/ \left(f_{\text{Si}}\sqrt{A_{\text{Si}}} + f_{\text{O}}\sqrt{A_{\text{O}}}\right)\right]^2 \\ &= \left[\left(0.333(28) + .666(16)\right) \Big/ \left(0.333\sqrt{28} + .666\sqrt{16}\right)\right]^2 = 20.38 \text{ g mol}^{-1} \end{aligned}$$

Step 2: Determine the range of 5.5 MeV alpha particles in a material with similar atomic mass. Here, Si is chosen for the material with a known range. From Eq. (4.154) and Table 4.4, with $x = \log_{10} 5.5 = 0.7404$,

$$\rho R_\alpha(5.5 \text{ MeV}) = 10^{-3.0813+0.98208(0.7404)+0.29625(0.7404)^2} = 0.0064 \text{ g/cm}^2.$$

The density of Si is 2.32 g cm^{-3}, yielding

$$R_\alpha(5.5 \text{ MeV}) = \frac{0.0064}{2.32} = 0.00277 \text{ cm} = 27.7 \ \mu\text{m}.$$

Step 3: Use Eq. (4.155) to find the range in SiO_2 (quartz). The density of quartz is 2.65 g cm^{-3}. Therefore,

$$R_{SiO_2} = (0.00277 \text{ cm}) \left(\frac{2.32 \text{ g cm}^{-3}}{2.65 \text{ g cm}^{-3}} \right) \sqrt{\frac{20.38}{28}} = 0.0021 \text{ cm} = 21 \ \mu\text{m}.$$

By comparison to the SRIM code [Ziegler et al. 2013], the answers are $R_{Si} = 28$ microns and $R_{SiO_2} = 22$ microns.

4.6.10 Range of Fission Fragments

The range of a *fission fragment* is difficult to calculate because the fission fragment's charge changes as it slows down. The lighter of the two fragments, having more initial kinetic energy, has a somewhat longer range. An empirical formula with an accuracy of ±10% for the range (in units of mass thickness) of a fission product, with initial kinetic energy E (in MeV), is [Alexander and Gazdik 1960]

$$\rho R \text{ (mg/cm}^2) \simeq C \, E^{2/3}, \quad \frac{E_{H,L}}{2} \leq E \leq E_{H,L} \tag{4.157}$$

where $E_{H,L}$ refers to the initial energy of either the midpoint heavy or light fission fragment (nominally 67.9 MeV and 99.9 MeV, respectively), and

$$C = \begin{cases} 0.14, & \text{air} \\ 0.19, & \text{aluminum} \\ 0.27, & \text{nickel} \\ 0.50, & \text{gold} \end{cases} \tag{4.158}$$

Measurements by Fulmer [1957] indicate slightly longer ranges than predicted by Eq. (4.157). Figures 4.29 and 4.30 demonstrate the residual energy after a fission fragment passes through a mass thickness ρR. The x-axis intercept is the range of the fragment.

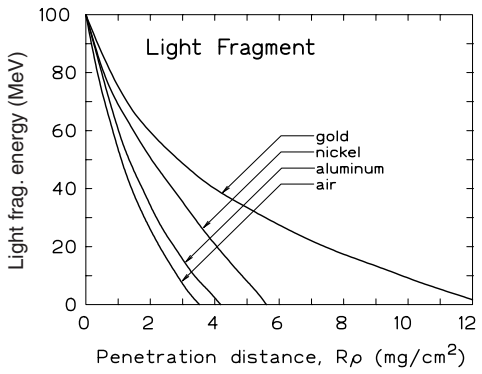

Figure 4.29. Energy of the median light fission product (initial energy 99.9 MeV) after penetrating a distance R into various materials. After Fulmer [1957].

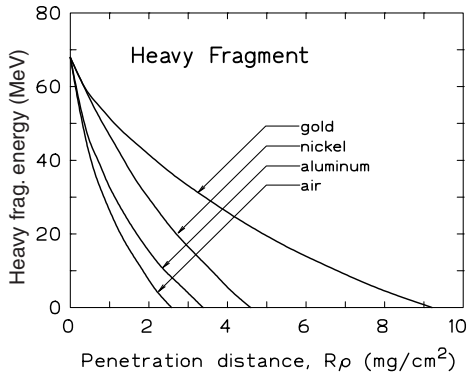

Figure 4.30. Energy of the median heavy fission product (initial energy 67.9 MeV) after penetrating a distance R into various materials. After Fulmer [1957].

PROBLEMS

1. A broad beam of neutrons is normally incident on a homogeneous slab 6-cm thick. The intensity of neutrons transmitted through the slab without interactions is found to be 30% of the incident intensity. (a) What is the total interaction coefficient μ_t for the slab material? (b) What is the average distance a neutron travels in this material before undergoing an interaction?

2. Based on the interaction coefficients tabulated in Appendix B, plot the tenth-thickness (in centimeters) versus photon energy from 0.1 to 10 MeV for water, concrete, iron, and lead.

3. With the data of Table B.5, calculate the half-thickness for 1-MeV photons in (a) water, (b) iron, and (c) lead.

4. A material is found to have a tenth-thickness of 2.3 cm for 1.25-MeV gamma rays. (a) What is the linear attenuation coefficient for this material? (b) What is the half-thickness? (c) What is the mean-free-path length for 1.25-MeV photons in this material?

5. Calculate the linear interaction coefficients in pure air at 20°C and 1 atm pressure for a 1-MeV photon and a thermal neutron (2200 m s^{-1}). Assume that air has the composition 75.3% nitrogen, 23.2% oxygen, and 1.4% argon *by mass*. Use the following data:

	Photon	Neutron
Element	μ/ρ (cm^2 g^{-1})	σ_{tot} (b)
Nitrogen	0.0636	11.9
Oxygen	0.0636	4.2
Argon	0.0574	2.2

6. In natural uranium, 0.720% of the atoms are the isotope ^{235}U, 0.0055% are ^{234}U, and the remainder ^{238}U. From the data in Table B.3, what is the total linear interaction coefficient (macroscopic cross section) for a 2200 m s^{-1} neutron in natural uranium? What is the total macroscopic fission cross section for 2200 m s^{-1} neutrons?

7. At a particular position, the flux density of particles is 2×10^{12} cm^{-2} s^{-1}. (a) If the particles are photons, what is the density of photons at that position? (b) If the particles are thermal neutrons (2200 m/s), what is the density of neutrons?

8. A beam of 2-MeV photons with intensity 10^8 $cm^{-2}s^{-1}$ irradiates a small sample of water. (a) How many photon-water interactions occur in one second in one cm^3 of the water? (b) How many positrons are produced per second in one cm^3 of the water?

9. A small homogeneous sample of mass m (g) with atomic mass A is irradiated uniformly by a constant flux density ϕ (cm^{-2} s^{-1}). If the total atomic cross section for the sample material with the irradiating particles is denoted by σ_t (cm^2), derive an expression for the fraction of the atoms in the sample that interact during a 1-h irradiation. State any assumptions made.

10. A 1-mCi source of ^{60}Co is placed in the center of a cylindrical water-filled tank with an inside diameter of 20 cm and depth of 100 cm. The tank is made of iron with a wall thickness of 1 cm. What is the uncollided flux density at the outer surface of the tank nearest the source?

11. Derive the Compton formula, Eq. (4.32), given that the momentum of a photon of energy E is equal to E/c and the momentum of an electron of kinetic energy T is equal to $(1/c)\sqrt{T(T+2m_ec^2)}$.

12. Verify Eqs. (4.34) to (4.39).

13. Verify Eq. (4.61); that is, given Eq. (4.63), carry out the integration

$$\sigma_T = \int_{4\pi} d\Omega \; \frac{a\sigma_T(\theta_s)}{d\Omega_s}.$$

14. What is the maximum possible kinetic energy (keV) of a Compton electron and the corresponding minimum energy of a scattered photon resulting from scattering of **(a)** a 100-keV photon, **(b)** a 1-MeV photon, and **(c)** a 10-MeV photon? Estimate for each case the range the electron would have in air of 1.2 mg/cm^3 density and in water of 1 g/cm^3 density.

15. Compute and plot the energy spectrum $F(T)$ of Compton recoil electrons for incident photons of 0.5 and 2.0 MeV. Here $F(T)\,dT$ is the fraction of electrons with energies between T and $T+dT$.

16. Consider the classical mechanics of neutron inelastic scattering by a target atom initially at rest. Derive Eq. (4.40), which relates the angle of scattering in the laboratory system and the neutron energies before and after scattering. *Suggestion*: Apply the law of cosines to the triangle of Fig. 4.2(b). Note that $p^2 = 2mE$, $(p')^2 = 2mE'$, $p_r^2 = 2MT$, and $T = E - E' + Q$.

17. From Fig. 4.14, the total microscopic cross section in iron for neutrons with energy of 27 keV is about 0.4 b, and for a neutron with an energy of 28 keV about 90 b. (a) Estimate the fraction of 27-keV neutrons that pass through a 10-cm thick slab without interaction. (b) What is this fraction for 28-keV neutrons?

18. Consider the classical mechanics of neutron inelastic scattering by a target atom initially at rest. Derive Eq. (4.47), which relates the angles of scattering in the laboratory and center-of-mass systems. *Suggestion*: From Fig. 4.3(c) note that $v_c' \sin\theta_c = v' \sin\theta_s$, and $v_o + v_c' \cos\theta_c = v' \cos\theta_s$. Apply trigonometric identities and the definition $\gamma \equiv v_o/v_c'$ to reach the solution.

19. What is the maximum possible kinetic energy (keV) of a Compton electron and the corresponding minimum energy of a scattered photon resulting from scattering of **(a)** a 100-keV photon, **(b)** a 1-MeV photon, and **(c)** a 10-MeV photon? Estimate for each case the range the electron would have in air of 1.2 mg/cm^3 density and in water of 1 g/cm^3 density.

20. Consider the classical mechanics of neutron inelastic scattering by a target atom initially at rest. Derive Eq. (4.49) for the ratio of the speed of the target atom before scatter to the speed of the neutron after scatter. Show that for elastic scatter, $\gamma = m/M = 1/A$. *Suggestion*: Note that the total kinetic energy relative to the center of mass is equal to the kinetic energy of the reduced mass $\mu \equiv mM/(M+m) = mA/(1+A)$ moving at the relative velocity between the neutron and atom. Note, too, that the kinetic energy in the center-of-mass system after scatter differs from that before scatter by the Q value. That is, $\frac{1}{2}\mu(v_c' + V_c')^2 = \frac{1}{2}\mu v^2 + Q$ so that $(v_c')^2 = [2A/m(A+1)][EA/(1+A) + Q]$. Similarly, $(m+M)v_o \equiv mv$, so that $v_o^2 = 2E/m(A+1)^2$.

21. Consider the classical mechanics of neutron inelastic scattering by a target atom initially at rest. Derive Eq. (4.50), which relates the angle of scattering in the center-of-mass system and the neutron energies before and after scattering. *Suggestion*: Apply the law of cosines to Fig. 4.3c, with the result that $v'^2 = (v_c')^2 + v_o^2 + 2v_o v_c' \omega_c$ and apply the results of Problem 20 for v_o and v_c'.

22. Take as given that elastic scattering of neutrons by hydrogen atoms is isotropic in the center-of-mass system. How would you determine the fraction of neutrons scattered at angles less than 45 degrees in the laboratory system?

23. The differential scattering cross section (b/sr) for 1-MeV neutrons on Mg in the laboratory system is

$$\frac{d\sigma_s(E,\omega_s)}{d\Omega_s} = \frac{2.7}{4\pi}[1 + 1.2P_1(\omega_s) + 0.75P_2(\omega_s) + 0.08P_3(\omega_s)].$$

(a) Evaluate the total scattering cross section $\sigma_s(E)$. (b) Evaluate the mean cosine of the laboratory scattering angle $\langle\omega_s\rangle$. (c) Evaluate the mean cosine of the center-of-mass scattering angle $\langle\omega_c\rangle$. (d) Evaluate the average energy lost by such neutrons in scattering. (e) Compute and plot versus ω_c the scattering cross section $\sigma_s(E,\omega_c)$ for such neutrons.

24. When an electron moving through air has 5 MeV of energy, what is the ratio of the rates of energy loss by bremsstrahlung to that by collision? What is this ratio for lead?

25. About what thickness of aluminum is needed to stop a beam of (a) 2.5-MeV electrons, (b) 2.5-MeV protons, and (c) 10-MeV alpha particles? Hint: For parts (a) and (b), use Tables 4.4 and 4.3 and compare your values to ranges shown in Figs. 4.23 and (4.27). For part (c), use the range interpolation rules on page 143.

26. Estimate the range of a 10-MeV tritium nucleus in air.

27. Verify that under the continuous slowing-down approximation for charged particles,

$$\mathcal{F}_{pl}^{\perp}(r,E) = \mathcal{F}(r,E) = \frac{L(r_o - r)}{E/r_o},$$

in which $L(r_o - r)$ is the LET evaluated at the energy of the particle with residual CSDA range $r_o - r$.

Chapter 5

Sources of Radiation

I proposed the word radioactivity which has since become generally adopted; the radioactive elements have been called radio elements.

Marie Curie

5.1 Introduction

In our world ionizing radiation is ever present, though rarely noticed by our human senses. It is with radiation sensors that such radiation is detected and its characteristics measured. However, the type of sensor to use depends on the type of radiation, its energy, and what information is sought about the radiation. In this book many types of radiation detectors are discussed, each designed for specific types of radiation measurements. Key to any radiation measurement is an understanding of the type and characteristics of the radiation being measured. In this chapter, the most common sources of ionizing radiation are reviewed and many of their properties examined. Much of the material presented here has been excerpted from expanded treatments given in Shultis and Faw [2000] and Faw and Shultis [2012].

5.1.1 Origins of Ionizing Radiation

Ionizing radiation is invariably the consequence of physical reactions, involving subatomic particles, at the atomic or nuclear level. The possible radiation-producing reactions are many and, usually, although not always, involve altering the configuration of neutrons and protons in an atomic nucleus or the rearrangement of atomic electrons about a nucleus. These radiation producing reactions can be divided into the following two categories.

Radioactive Decay

In the first type of reaction, the nucleus of an atom spontaneously changes its internal arrangement of neutrons and protons to achieve a more stable configuration. In such spontaneous *radioactive* transmutations, ionizing radiation is almost always emitted. The number of known different atoms, each with a distinct combination of Z and A, is about 3200. Of these, only 266 are stable and 65 are very long-lived radioisotopes still found in nature. The remaining nuclides have been made by humans and are radioactive with lifetimes much shorter than the age of the solar system. Both naturally occurring and manufactured radionuclides are the most commonly encountered sources of ionizing radiation.

Binary Reactions

The second category of radiation-producing interactions involves two impinging atomic or subatomic particles that react to form one or more reaction products. Examples include neutrons interacting with nuclei of atoms, photons interacting with nuclei or atomic electrons, and cosmic rays interacting with nuclei in our atmosphere. Such reactions invariably produce, as reaction products, ionizing radiation.

5.1.2 Physical Characterization of Radiation Sources

The most fundamental type of source is a *point source*. Clearly no real source can have zero size, but a real source can be approximated as a point source provided (1) that the volume is sufficiently small, that is, it has dimensions much smaller than the dimensions of the attenuating medium between source and detector, and (2) that there is negligible interaction of radiation with the matter in the source volume. The second requirement may be relaxed if source characteristics are modified to account for source self-absorption and other source-particle interactions.

In general, a point source may be characterized as depending on energy, direction, and time. In almost all cases, time is not treated as an independent variable because the time delay between a change in the emission rate of the source and the resulting change in the radiation field is usually negligible so that the time dependence of the radiation field is that of the source.[1] Therefore, the most general characterization of a point source used here is in terms of energy and direction. Most radiation sources treated in radiation measurements are isotropic, so that source characterization requires only knowledge of energy dependence. Radioisotope sources are certainly isotropic, as are fission sources and capture gamma-ray sources.

Radiation sources may also be distributed along a line, over an area, or within a volume. Source characterization requires, in general, spatial and energy dependence. Occasionally it is necessary to include angular dependence. This is especially true for effective area sources associated with computed angular flows across certain planes.

Energy dependence may be discrete, such as for radionuclide sources, or continuous, as for bremsstrahlung or fission neutrons and photons. When discrete energies are numerous, an energy multigroup approach is often used. The same multigroup approach may be used to approximately characterize a source whose emissions are continuous in energy.

5.2 Sources of Gamma Rays

Radioactive sources abound in our technological age and are used for a wide variety of purposes in many educational, medical, research, industrial, governmental, and commercial facilities. The radionuclides in these sources almost always leave their progeny in excited nuclear states whose subsequent transitions to lower-energy states usually result in the emission of one or more gamma photons. Consequently, these radioactive sources are frequently encountered in radiation measurements and in verifying the proper operation of a radiation detector.

In characterizing the gamma radiation emitted by a radioactive source, a careful distinction must be made between the activity of a radioisotope and its source strength. *Activity* is precisely defined as the expected number of atoms undergoing *radioactive transformation* per unit time. The SI unit of activity is the becquerel (Bq), equivalent to 1 transformation per second, while the older unit for activity is the curie (Ci) equal to 3.7×10^{10} transformations per second. Activity is *not* defined as the number of particles emitted per unit time, and the decay of two common laboratory radioisotopes, ^{60}Co and ^{137}Cs, can be used to illustrate this point. Each transformation of ^{60}Co results in the emission of *two* gamma rays, one at 1.173 MeV and the other at 1.333 MeV. However, each transformation of ^{137}Cs, accompanied by a transformation of its decay product ^{137m}Ba, results in emission of a 0.662-MeV gamma ray with an 85% probability.

Extensive compilations of the energies and intensities of the gamma and x rays emitted by radionuclides are available, for example [Kocher 1981; ICRP 1983; Weber et al. 1989; Eckerman et al. 1994], or computer programs that can be used to prepare specialized compilations [Dillman 1980]. Especially useful is the on-line decay data base for radionuclides that is found at https://www.nndc.bnl.gov/nudat2.

[1] Exceptions include nuclear explosions or supernovae where the radiation field is very far from the source.

5.2.1 Naturally Occurring Radionuclides

Radionuclides existing on earth arise from two sources. First, earth has always been bombarded by cosmic rays coming from the sun and from intergalactic space. For the most part, cosmic rays consist of protons and alpha particles, with heavier nuclei contributing less than 1% of the incident nucleons.[2] These cosmic rays interact with atoms in the atmosphere and produce a variety of light radionuclides.

The second source of naturally occurring radionuclides is the residual radioactivity in the matter from which the earth was formed. These heritage or primordial radionuclides were formed in the stars from whose matter the solar system was formed. Most of these radionuclides have long since decayed away during the 4 billion years since the earth was formed.

When making measurements of a gamma-ray source, there is always a background source of radiation as a consequence of the ubiquitous presence of naturally occurring radionuclides. Here the major sources of such radionuclides are discussed.

Cosmogenic Radionuclides

Cosmic rays interact with constituents of the atmosphere, sea, or earth, but mostly with the atmosphere, leading directly to radioactive products. Capture of secondary neutrons produced in primary interactions of cosmic rays leads to many more. Only those produced from interactions in the atmosphere lead to significant radiation exposure to humans.

The most prominent of the cosmogenic radionuclides are tritium ^{3}H and ^{14}C. The ^{3}H (symbol T or t) is produced mainly from the ^{14}N$(n,\mathrm{T})^{12}$C and ^{16}O$(n,\mathrm{T})^{14}$N reactions. Tritium has a half-life of 12.3 years and, upon decay, emits one β^- particle with a maximum energy of 18.6 (average energy 5.7) keV. Tritium exists in nature almost exclusively as HTO.[3]

The nuclide ^{14}C is produced mainly from the ^{14}N$(n,p)^{14}$C reaction. It exists in the atmosphere as CO_2, but the main reservoirs are the oceans. ^{14}C has a half-life of 5730 years and decays by β^- emission with a maximum energy of 157 keV and average energy of 49.5 keV.

Over the past century, combustion of fossil fuels with the emission of CO_2 without any ^{14}C has diluted the cosmogenic content of ^{14}C in the environment. Moreover, since the use of nuclear weapons in World War II, artificial introduction of ^{3}H and ^{14}C (and other radionuclides) by human activity has been significant, especially from atmospheric nuclear-weapons tests. Consequently, these isotopes no longer exist in natural equilibria in the environment.

Singly Occurring Primordial Radionuclides

Of the many radionuclide species present when the solar system was formed 4.57 billion years ago, some 17 very long-lived radionuclides still exist as singly occurring or isolated radionuclides, that is, as radionuclides not belonging to a radioactive decay chain. These radionuclides are listed in Table 5.1, and all but one are seen to have half-lives greater than the age of the solar system. Of these radionuclides, the most significant (from a human exposure perspective) are ^{40}K and ^{87}Rb because they are inherently part of our body tissue.

Decay Series of Primordial Origin

Each naturally occurring radioactive nuclide with $Z > 83$ is a member of one of three long decay chains, or radioactive series, stretching through the upper part of the Chart of the Nuclides. These radionuclides decay by α or β^- emission and they have the property that the number of nucleons (mass number) A for each member of a given decay series can be expressed as $4n + i$, where n is an integer and i is a constant (0, 2, or 3) for each series. The three naturally occurring series are named the thorium ($4n$), uranium ($4n + 2$),

[2] Electrons, primarily from the sun, also are part of the cosmic rays incident on the earth. But they are deflected by earth's magnetosphere and do not produce cosmogenic radionuclides.

[3] H_2O with one hydrogen replaced by tritium.

Table 5.1. The 17 isolated primordial radionuclides. Data taken from GE-NE [1996].

[a] Gy = 10^9 y, ky = 10^3 y, μs = 10^{-6} s.

and actinium $(4n + 3)$ series, named after the radionuclide at, or near, the head of the series. The head of each series has a half-life much greater than any of its daughters.

There is no naturally occurring series represented by $4n + 1$. This series was recreated after $^{241}_{94}$Pu was made in nuclear reactors. This series does not occur naturally since the half-life of the longest lived member of the series, $^{237}_{93}$Np, is only 2.14×10^6 y, much shorter than the age of the earth (4.54×10^9 y). Hence, any members of this series that were in the original material of the solar system have long since decayed away.

The principal radioisotopes produced by the two most important naturally occurring series (the uranium and thorium series) are given in Table 5.2. In both of these decay chains, a few members decay by both α and β^- decay causing the decay chain to branch (see Shultis and Faw [2000]). Nevertheless, each decay chain ends in the same stable isotope.

5.2.2 Prompt Fission Gamma Photons

Whenever a heavy nucleus fissions, copious gamma photons are produced either within the first 6×10^{-8} s after the fission event (the *prompt fission gamma photons*) or from the subsequent decay of the fission products. If radiation measurements are being made in the presence of fission sources, for example, these prompt and delayed gamma rays are of great importance.

Most investigations of prompt fission gamma photons have centered on the thermal-neutron-induced fission of ^{235}U. For this nuclide it has been found that the number of prompt fission photons is 8.13 ± 0.35 photons per fission over the energy range 0.1 to 10.5 MeV, and the energy carried by this number of photons is 7.25 ± 0.26 MeV per fission [Keepin 1965]. The energy spectrum of prompt gamma photons from the thermal fission of ^{235}U between 0.1 and 0.6 MeV is approximately constant at 6.6 photons MeV^{-1} fission^{-1}. At higher energies the spectrum falls off sharply with increasing energy. The measured energy distribution of the prompt fission photons can be represented by the following empirical fit over the range 0.1 to 10.5 MeV [Keepin 1965]:

$$N(E) = \begin{cases} 6.6 & 0.1 < E < 0.6 \text{ MeV} \\ 20.2e^{-1.78E} & 0.6 < E < 1.5 \text{ MeV} \\ 7.2e^{-1.09E} & 1.5 < E < 10.5 \text{ MeV}, \end{cases}$$

where E is in MeV and $N(E)$ is in units of photons MeV^{-1} fission^{-1}.

Investigation of ^{233}U, ^{239}Pu, and ^{252}Cf indicates that the prompt fission photon energy spectra for these isotopes resembles very closely that for ^{235}U, and hence for most purposes it is reasonable to use the ^{235}U spectrum for other fissioning isotopes.

5.2.3 Fission-Product Gamma Photons

With the widespread application of nuclear fission, an important concern is the consideration of the very long lasting gamma-ray activity produced by the decay of fission products. In the fission process, most often two fragments are produced (*binary fission*). About 0.3% of the time a third light fragment is produced (*ternary fission*), most often ^{3}H. The mass distribution or *fission-product chain yield* is bi-modal, with many products having atomic mass number around 95 and around 140. Among the former are the important long-lived radionuclide ^{90}Sr, several isotopes of the halogen bromine, and various isotopes of the noble gas krypton. Among the heavy fragments are the important long-lived radionuclide ^{137}Cs, radioisotopes of halogen iodine, notably ^{131}I, and isotopes of the noble gas xenon. The fission-products are neutron-rich and decay almost exclusively by β^- emission, often forming long decay chains. From the range of mass numbers produced, about 100 different decay chains are formed. An example of a short chain is

$$^{140}_{54}\text{Xe} \xrightarrow[16\text{ s}]{\beta^-} {}^{140}_{55}\text{Cs} \xrightarrow[66\text{ s}]{\beta^-} {}^{140}_{56}\text{Ba} \xrightarrow[12.8\text{ d}]{\beta^-} {}^{140}_{57}\text{La} \xrightarrow[40\text{ h}]{\beta^-} {}^{140}_{58}\text{Ce (stable)}.$$

The total gamma-ray energy released by the fission product chains is comparable to that released as prompt fission gamma photons. The gamma-ray energy release rate declines rapidly with time after fission. About three-fourths of the delayed gamma-ray energy is released in the first thousand seconds after fission. In most calculations involving spent nuclear fuel, the gamma activity at several months or even years after removal of fuel from the nuclear reactor is of interest and so only the long-lived fission products need be considered.

It has been found that the gamma energy released from fission products is relatively independent of the energy of the neutrons causing the fissions. However, the gamma-ray energy released and the photon energy spectrum depend significantly on the fissioning isotope, particularly in the first 10 s after fission. Generally, fissioning isotopes, having a greater proportion of neutrons to protons, produce fission-product chains of longer average length, with isotopes richer in neutrons and hence with greater available decay energy. Also, the photon energy spectrum generally becomes less energetic as the time after fission increases.

The delayed gamma photon energy spectrum from the fission of ^{235}U, at times up to about 5 s, may be approximated by the proportionality

$$N(E) \sim e^{-1.1E}, \tag{5.1}$$

where $N(E)$ is the delayed gamma-ray yield (photons MeV^{-1} fission^{-1}) and E is the photon energy in MeV. The time dependence for the total gamma photon energy emission rate $F(t)$ (MeV s^{-1} fission^{-1}) is often described by the simple decay formula

$$F(t) = 1.4t^{-1.2}, \quad 10 \text{ s } < t < 10^7 \text{ s}, \tag{5.2}$$

where t is in seconds. More complicated (and accurate) expressions for $F(t)$ have been obtained from fits to experimental data (see, for example, Shultis and Faw [2000]); but for preliminary calculations the simpler result is usually adequate. It is observed that both ^{235}U and ^{239}Pu have roughly the same total gamma-ray-energy decay characteristics for up to 200 days after fission, at which time ^{235}U products begin to decay more rapidly. At 1 year after fission, the ^{239}Pu gamma-ray emission rate is about 60% greater than that of ^{235}U.

For accurate calculations involving fission products, the variation with time after fission of the energy spectra of the photons must be taken into account. Often the energy spectra are averaged over discrete energy intervals and the energy emission rate in each energy group is considered as a function of time after fission. Computer codes, based on extensive libraries of radionuclide data, have been developed to compute the abundances and decay rates of the hundreds of fission-product radionuclides. One such code is ORIGEN [Hermann and Westfall 1981; RSIC 1991].

5.2.4 Capture Gamma Photons

The compound nucleus formed by neutron absorption is initially created in a highly excited state with excitation energy equal to the kinetic energy of the incident neutron plus the neutron binding energy, which averages about 7 MeV. The decay of this nucleus, usually within 10^{-12} s, and usually by way of intermediate states, typically produces several energetic photons. Generally, the probability a neutron causes an (n, γ) reaction is greatest for slow moving *thermal neutrons*, i.e., neutrons whose speed is in equilibrium with the thermal motion of the atoms in a medium. At high energies, it is more likely that a neutron scatters, thereby losing some of its kinetic energy and, thus, slows towards thermal energies. Table B.4 in Appendix B lists the number of capture gamma photons by 1-MeV energy bin when a thermal neutron is absorbed in various elements

Capture photons may be created intentionally by placing a material with a high thermal-neutron (n, γ) cross section in a thermal neutron beam. The energy spectrum of the resulting capture gamma photons can

then be used to identify trace elements in the sample. More often, however, capture gamma photons are an undesired secondary source of radiation.

The absorption of a thermal neutron by an isotope or element typically produces dozens of capture photons, each with a unique energy and probability of emission. Detailed compilations of the energies and frequencies are provided by Révay et al. [2004]. Analysis of the capture gamma photon spectrum emitted by an unknown sample can be used to infer the elemental composition of the sample. Generally, only a few of the most intense capture photons for a particular element are needed. In Table B.5 (Appendix B), the energies of the three capture photons recommended for each element for elemental identification are given.

5.2.5 Inelastic Scattering Gamma Photons

The excited nucleus formed when a neutron is inelastically scattered decays to the ground state usually within about 10^{-14} s, with the excitation energy being released by one or more photons. Because of the constraints imposed by the conservation of energy and momentum in all scattering interactions, inelastic neutron scattering cannot occur unless the incident neutron energy is greater than $(A + 1)/A$ times the energy required to excite the scattering nucleus to its first excited state (see Section 4.3.5). Except for the heavy nuclides, neutron energies above about 0.5 MeV are typically required for inelastic scattering.

The detailed calculation of secondary photon source strengths from inelastic neutron scattering requires knowledge of the fast-neutron flux, the inelastic scattering cross sections, and spectra of resultant photons, all as functions of the incident neutron energy. The cross sections and energy spectra of the secondary photons depend strongly on the incident neutron energy and the particular nuclide. Such inelastic scattering data are known only for the more important structural and shielding materials, and even the known data require extensive data libraries. Often inelastic scattered gamma rays are ignored in routine radiation measurements. But in some cases their identification is vital because, from their energies and intensities, isotopic abundances of a sample can be inferred.

5.2.6 Activation Gamma Photons

For many materials, absorption of a neutron or a proton produces a radionuclide with a half-life ranging from a fraction of a second to many years. Many radionuclides encountered in research laboratories, medical facilities, and industry are produced as activation nuclides from neutron or proton absorption in some parent material (see Table 5.3). Such nuclides decay, usually by beta emission, leaving the daughter nucleus in an excited state which usually decays quickly to its ground state with the emission of one or more gamma photons. Thus, the apparent half-life of the photon emitter is that of the parent (or activation nuclide), while the number and energy of the photons are characteristic of the nuclear structure of the decay daughter.

5.2.7 Positron Annihilation Photons

Positrons, generated either from the positron decay of radionuclides or from pair production interactions induced by high energy photons, slow down in matter within about 10^{-10} s and are subsequently annihilated with ambient electrons. With rare exception, the rest-mass energy of the electron and positron is emitted in the form of two annihilation photons, each of energy $m_e c^2$ $(= 0.511$ MeV).

5.3 Sources of X Rays

The interaction of photons or charged particles with matter leads inevitably to the production of secondary x-ray photons which have energies $\lesssim 100$ keV. Because the energies of the x rays are unique to the element that emits them, their energies and intensities can be used to determine the elemental composition of an irradiated sample. For measurements of these x rays it is necessary to understand how the x rays are produced and some characteristics of the production mechanisms. There are two principal methods whereby secondary

x-ray photons are generated: the rearrangement of atomic electron configurations leads to characteristic x rays, and the deflection of charged particles in the nuclear electric field results in bremsstrahlung. Both mechanisms are discussed below.

5.3.1 Characteristic X Rays

The electrons around a nucleus are arranged in shells or layers, each of which can hold a maximum number of electrons (see Section 3.4.6). The two electrons in the innermost shell (K shell) are the most tightly bound, the six electrons in the next shell (L shell) are the next most tightly bound, and so on outward for the M, N,... shells. If the normal electron arrangement around a nucleus is altered through ionization of an inner electron or through excitation of electrons to higher energy levels, the electrons begin a complex series of transitions to vacancies in the lower shells (thereby acquiring higher binding energies) until the unexcited state of the atom is achieved. In each electronic transition, the difference in binding energy between the final and initial states is either emitted as a photon, called a *characteristic x ray*, or given up to an outer-shell electron which is ejected from the atom, called an *Auger electron*. The discrete electron energy levels and the transition probabilities between levels vary with the Z number of the atom and, thus, the characteristic x rays provide a unique signature for each element.

The number of x rays with different energies is greatly increased by the multiplicity of electron energy levels available in each shell (1, 3, 5, 7,... distinct energy levels for the K, L, M, N,... shells, respectively). To identify the various characteristic x rays for an element, many different schemes have been proposed. One of the more popular uses the letter of the shell whose vacancy is filled together with a numbered Greek subscript to identify a particular electron transition (e.g., $K_{\alpha 1}$ and $L_{\gamma 5}$). In Fig. 5.1 the electron-energy-level diagram is shown for lead, and the more probable and energetic transitions are indicated together with the nomenclature for the associated characteristic x rays. The notation shown in this example is valid for any element; that is, $K_{\beta 1}$ refers to the characteristic x ray produced when an electron from the third energy level of the M shell fills a vacancy in the K shell. Fortunately, in many radiation measurements such detail is seldom needed, and often only the dominant K series of x rays is considered, with a single representative energy being used for all x rays.

Production of Characteristic X Rays

There are several methods commonly encountered in radiation measurement applications whereby atoms may be excited and characteristic x rays produced. A photoelectric absorption leaves the absorbing atom in an ionized state. If the incident photon energy is sufficiently greater than the binding energy of the K-shell electron, which ranges from 14 eV for hydrogen to 115 keV for uranium, it is most likely (80 to 100%) that a vacancy is created in the K shell and thus that the K series of x rays dominates the subsequent secondary radiation. These x-ray photons produced from photoelectric absorption are often called *fluorescent radiation* and are widely used to identify trace elements in a sample by bombarding the sample with low-energy photons from a radioactive source or with x rays from an x-ray machine and then observing the induced fluorescent radiation.

Characteristic x rays can also arise following the decay of a radionuclide. In the decay process known as *electron capture*, an orbital electron, most likely from the K shell, is absorbed into the nucleus, thereby decreasing the nuclear charge by one unit. The resulting K-shell vacancy then gives rise to the K series of characteristic x rays. A second source of characteristic x rays, which occurs in many radionuclides, is a result of *internal conversion*. Most daughter nuclei formed as a result of any type of nuclear decay are left in excited states. This excitation energy may be either emitted as a gamma photon or transferred to an orbital electron which is ejected from the atom. Again it is most likely that a K-shell electron is involved in this internal conversion process.

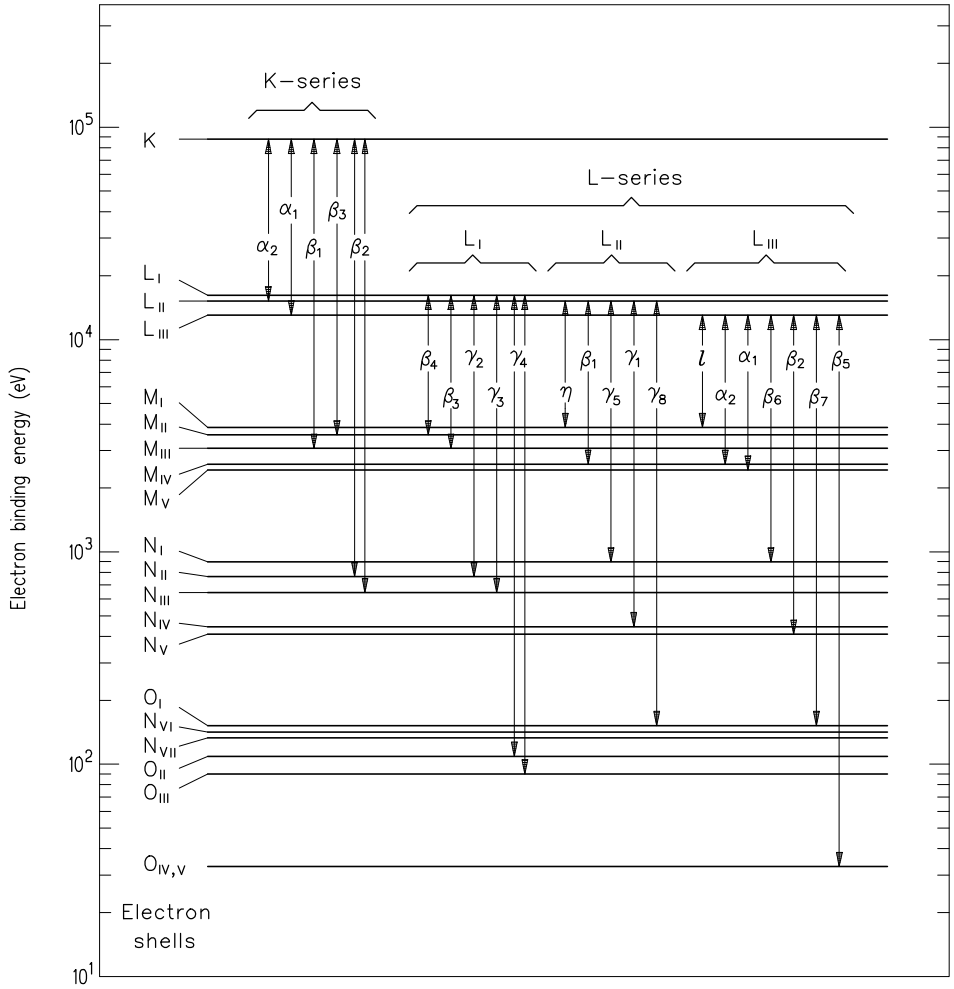

Figure 5.1. X-ray energy-level diagram for lead ($Z = 82$) showing the principal characteristic x-ray transitions and their standard nomenclature. After Flügge [1957].

Energies of Characteristic X Rays

To generate a particular series of characteristic x rays, an electron vacancy must be created in an appropriate electron shell. Such vacancies are created only when sufficient energy is transferred to an electron in that shell so as to allow it to break free of the atom or at least be transferred to an energy level above all the other electrons. In Chapter 4 it was seen that the photoelectric cross section changed abruptly at well-defined energies, called *edge energies*, corresponding to the ionization or binding energy for electrons in the various shells. Below the edge energy for a shell, vacancies can no longer be created in the shell and the photoelectric cross section, therefore, is smaller because fewer electrons are now available to interact with the incident photon. These shell edge energies increase with the atomic number Z of the atom as a result of the electrons becoming more tightly bound in the atom. The edge energies or ionization energies for different shells and even for the different electron states within the same shell can be found in many books on x-ray analysis [e.g., Flügge 1957], and in photon data libraries [e.g., Trubey et al. 1989]. A reasonably accurate approximation

Table 5.4. Values of the constants a b and c used to express principal characteristic x-ray energies and the K-edge energy as $E = aZ^c \exp(-bZ^3)$. Maximum error is less than 100 eV, and mostly less than 30 eV.

X Ray or Edge	a (eV)	b	c	Fit Range
K-edge	6.85198	1.168×10^{-7}	2.13240	$7 < Z < 95$
$K_{\alpha 1}$	7.51002	1.489×10^{-7}	2.07109	$7 < Z < 95$
$K_{\alpha 2}$	7.63540	1.079×10^{-7}	2.06582	$7 < Z < 95$
$K_{\beta 1}$	7.37998	1.208×10^{-7}	2.10694	$7 < Z < 95$
$K_{\beta 2}$	6.95769	1.138×10^{-7}	2.12778	$7 < Z < 95$
$K_{\beta 3}$	7.39760	1.116×10^{-7}	2.10624	$7 < Z < 95$
$L_{\alpha 1}$	0.34810	-8.338×10^{-8}	2.35265	$30 < Z < 95$
$L_{\alpha 2}$	0.35173	-9.667×10^{-8}	2.34975	$30 < Z < 95$
$L_{\beta 1}$	0.31810	1.514×10^{-7}	2.38418	$30 < Z < 95$
$L_{\beta 2}$	0.21302	-1.346×10^{-7}	2.51145	$30 < Z < 95$

for the K-edge energy is

$$E_K \text{ (eV)} = a\, Z^c \exp[-bZ^3], \tag{5.3}$$

where the parameters for a, b, and c are listed in Table 5.4.

The characteristic x rays emitted when electrons fill a vacancy in a shell always have less energy than that required to create the vacancy. Extensive tabulations of characteristic x-ray energies are available [ICRP 1983; Weber et al. 1989; Eckerman et al. 1994]. From these results it is seen that the K_α x-ray energy varies from only 0.52 keV for oxygen ($Z = 8$) to 6.4 keV for iron ($Z = 26$) to 98 keV for uranium ($Z = 92$). By comparison, the L series of x rays for uranium occurs at energies around 15 keV.

Intensity of Characteristic X Rays

The *fluorescent yield* of a material is the fraction of the atoms with a vacancy in an inner electron shell that emit an x ray upon the filling of the vacancy. Values for the fluorescent yield are found in Browne and Firestone [1986] or in nuclear data libraries such as Eckerman et al. [1994]. For vacancies in the K shell, the fluorescent yield can be approximated for $1 < Z < 100$ by [Hubbell 1989]

$$\omega_K = \frac{B^4}{1 + B^4}\ , \tag{5.4}$$

where the parameter B is given by

$$B = 0.0370 + 0.03112Z + 5.44 \times 10^{-5} Z^2 - 1.250 \times 10^{-6} Z^3. \tag{5.5}$$

From the results of Eqs. (5.4) and (5.5) it is seen that the fluorescent yield increases dramatically with the Z number, varying from 0.0069 for oxygen ($Z = 8$) to 0.97 for uranium ($Z = 92$). Thus, the secondary fluorescent radiation is of more concern for heavy materials.

5.3.2 Bremsstrahlung

A charged particle gives up its kinetic energy either by collisions with electrons along its path or by photon emission as it is deflected, and hence accelerated, by the electric fields of nuclei. The photons produced by the deflection of the charged particle are called *bremsstrahlung* (literally, "braking radiation"). For a given type of charged particle, the radiative stopping power, L_{rad}, increases with the particle energy and with the square of the atomic number (Z) of the absorber [see Eq. (4.134)], while the collisional (ionization) stopping power, L_{coll}, decreases with particle energy and increases only with the first power of Z [see Eq. (4.131)].

For a relativistic particle of rest mass M (i.e., $E \gg Mc^2$) it can be shown that the ratio of radiative to ionization losses is approximately [Evans 1955]

$$\frac{L_{rad}}{L_{coll}} \simeq \frac{EZ}{700}\left(\frac{m_e}{M}\right)^2, \tag{5.6}$$

where E is in MeV. From this result it is seen that bremsstrahlung is more important for high energy particles of small mass incident on high-Z material. In most radiation measurement situations, only electrons ($m_e/M = 1$) are ever of importance for their associated bremsstrahlung. All other charged particles are far too massive to produce significant amounts of bremsstrahlung. Bremsstrahlung from electrons, however, is of particular radiological interest for devices that accelerate electrons, such as betatrons and x-ray tubes, or for situations involving radionuclides that emit only beta particles.

Thick-Target Bremsstrahlung for Monoenergetic Electrons

The energy distribution of the photons produced by the bremsstrahlung mechanism is continuous up to a maximum energy corresponding to the maximum kinetic energy of the incident charged particles. The exact shape of the continuous bremsstrahlung spectrum depends on many factors, including the energy distribution of the incident charged particles, the thickness of the target, and the amount of bremsstrahlung absorbed in the target and other masking material.

For monoenergetic electrons of energy E_o incident on a target thicker than the electron range, the number of bremsstrahlung photons of energy E, per unit energy and per incident electron, emitted as the electron is completely slowed down can be approximated by the distribution [Wyard 1952]

$$N_{br}(E_o, E) = 2kZ\left[\left(\frac{E_o}{E} - 1\right) - \frac{3}{4}\ln\left(\frac{E_o}{E}\right)\right], \qquad E \le E_o, \tag{5.7}$$

where k is a normalization constant independent of E. The fraction of the incident electron's kinetic energy that is subsequently emitted as bremsstrahlung can then be calculated from this approximation as

$$Y(E_o) = \frac{1}{E_o}\int_0^{E_o} dE\, E N_{br}(E_o, E) = \frac{5}{8}kZE_o, \tag{5.8}$$

which is always a small fraction in most situations. For example, only 4% of the energy of a 0.5-MeV electron, when stopped in lead, is converted into bremsstrahlung. Equation (5.8) can be used to express the normalization constant k in terms of $Y(E_o)$, namely $kZ = 8Y(E_o)/(5E_o)$. With this choice for k, the approximation of Eq. (5.7) agrees quite well with the thick-target bremsstrahlung spectrum calculated by much more elaborate methods, such as the continuous slowing-down model (see Fig. 5.2).

The angular distribution of bremsstrahlung is generally quite anisotropic and varies with the incident electron energy. Bremsstrahlung induced by low-energy electrons ($\lesssim$ 100 keV) is emitted predominantly at 90° to the direction of the incident electron. As the electron energy increases, the direction of the peak intensity shifts increasingly toward the forward direction, until for electrons above a few MeV, the bremsstrahlung is confined to a very narrow forward beam [NCRP 1977]. The angular distribution of radiation leaving a target is very difficult to compute since it depends on the target size and orientation. For thin targets the anisotropy of the bremsstrahlung resembles that for a single electron-nucleus interaction, while for thick targets multiple electron interactions and photon absorption in the target must be considered.

Bremsstrahlung from Beta Particles

The electrons and positrons emitted by radionuclides undergoing beta decay produce bremsstrahlung as they slow down in the source material. In beta decay, the electrons or positrons are emitted with a continuous distribution of energies from zero to a maximum energy $E_{\max}$. The shape of the spectrum is a complicated

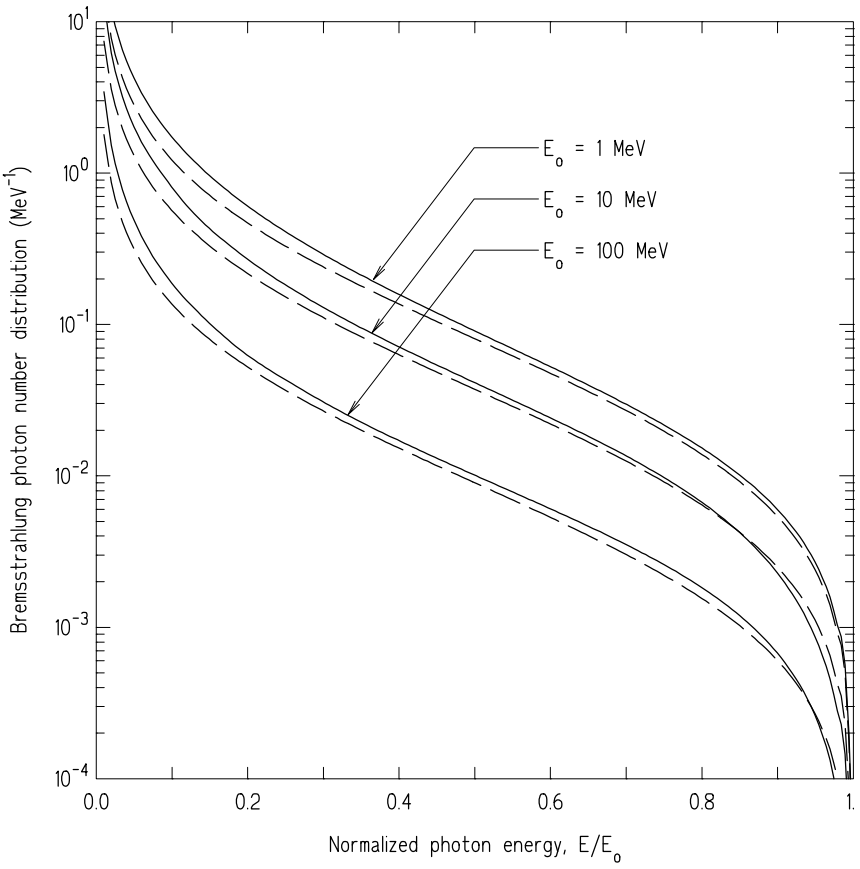

Figure 5.2. Distribution of bremsstrahlung photons, $N_{br}(E_o, E)$, produced by monoenergetic electron beams (energy E_o) incident on a thick lead target. The solid lines are calculations based on the continuous slowing-down approximation (CSDA) and the dashed lines are based on the Wyard approximation of Eq. (5.7).

function of the quantum mechanical properties of the parent nucleus (see Section 5.5.1), although computer codes are available to calculate the beta spectrum for most radionuclides [Dillman 1980]. If the number of beta particles emitted in unit energy about E (normalized to one electron) is denoted by $N_\beta(E)$, the energy distribution $N_{br}(E')$ of the resulting bremsstrahlung intensity produced in a target thicker than the range of the most energetic beta particles can be computed from Eq. (5.7) as

$$N_{br}(E') = \int_E^{E_{\max}} dE\, N_\beta(E) N_{br}(E, E'). \tag{5.9}$$

This energy distribution of bremsstrahlung from beta decay is quite different from that from monoenergetic electrons, the former being much softer and comparatively less intense at higher energies for $E_{\max} = E_o$.

The average fraction of the beta-particle energy that is emitted as bremsstrahlung is

$$f_\beta = \int_0^{E_{\max}} dE\, E\, Y(E) N_\beta(E) \Big/ \int_0^{E_{\max}} dE\, E\, N_\beta(E). \tag{5.10}$$

Table 5.5. Characteristic X-ray properties of target materials used in X-ray tubes.

Element	X-ray line	Wavelength (10^{-10} m)	Energy (keV)	Excitation voltage (kV)

Inner Bremsstrahlung

During the beta-decay process, the beta particle is accelerated by the positive charge of the nucleus, and consequently, a small amount of bremsstrahlung is emitted. These x rays, called "inner" bremsstrahlung, can usually be ignored because only a small fraction of the beta-decay energy, on the average, is emitted as this type of radiation.

5.3.3 X-Ray Machines

The production of x-ray photons as bremsstrahlung and fluorescence occurs in any device that produces high energy electrons. Devices that can produce significant amount of x rays are those in which a high voltage is used to accelerate electrons, which then strike an appropriate target material. Such is the basic principle of all x-ray tubes used in medical diagnosis and therapy, industrial applications, and research laboratories.

Although there are many different designs of x-ray sources for different applications, most designs for low to medium voltage sources ($\lesssim$ 180 kV) place the electron source (cathode) and electron target (anode) in a sealed glass tube. The anode and cathode extend from the glass tube, which acts as an insulator between these electrodes. Further, the glass tube contains the necessary vacuum through which electrons are accelerated by the applied high voltage between the anode and cathode. The anodes of x-ray tubes incorporate a suitable metal upon which the electrons impinge and generate bremsstrahlung and characteristic x rays. Most of the electron energy is deposited in the anode as heat rather than being radiated away as x rays and, thus, heat removal is an important aspect in the design of x-ray tubes. Tungsten is the most commonly used target material because of its high atomic number and because of its high melting point, high thermal conductivity, and low vapor pressure. Occasionally, other target materials are used when different characteristic x-ray energies are desired (see Table 5.5). Generally, the operating conditions of a particular tube (current, voltage, and operating time) are limited by the rate at which heat can be removed from the anode. For most medical and dental diagnostic units, voltages between 40 and 150 kV are used, while medical therapy units may use 6 to 150 kV for superficial treatment or 180 kV to 50 MV for treatment requiring very penetrating radiation.

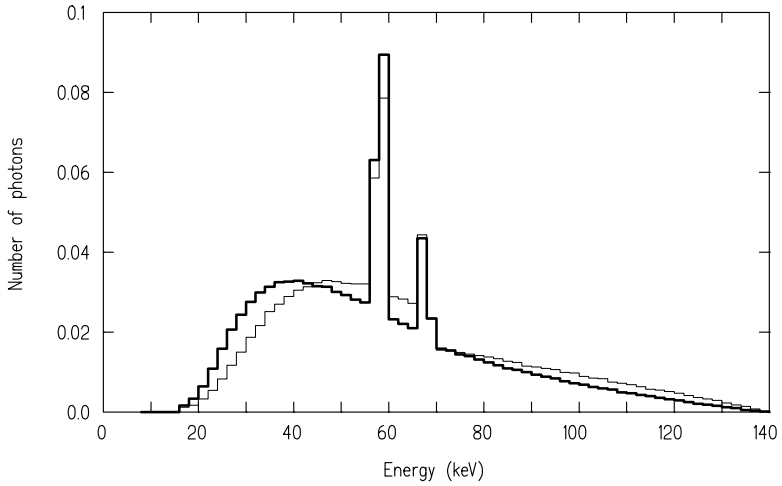

Figure 5.3. Measured photon spectra from a Machlett Aeromax x-ray tube (tungsten anode) operated at a constant 140 kV potential. This tube has an inherent filter thickness of 2.50-mm aluminum equivalent and yields the spectrum shown by the thick line. The addition of an external 6-mm aluminum filter hardens the spectrum (thin line). Both spectra are normalized to unit area. Data are from Fewell, Shuping, and Hawkins [1981].

The energy spectrum of x-ray photons emitted from an x-ray tube has a continuous bremsstrahlung component up to the maximum electron energy (i.e., the maximum voltage applied to the tube). If the applied voltage is sufficiently high as to cause ionization in the target material, there will also be characteristic x-ray lines superimposed on the continuous bremsstrahlung spectrum. In Fig. 5.3 two calculated exposure spectra of x rays are shown for the same operating voltage but for different amounts of beam filtration (i.e., different amounts of material attenuation in the x-ray beam). As the beam filtration is increased, the low-energy x rays are preferentially attenuated and the x-ray spectrum hardens and becomes more penetrating. Also readily apparent in these spectra are the tungsten $K_{\alpha 1}$ and $K_{\beta 1}$ characteristic x rays.

The characteristic x rays may contribute a substantial fraction of the total x-ray emission. For example, the L-shell radiation from a tungsten target is between 20% and 35% of the total energy emission when voltages between 15 kV and 50 kV are used [ICRU 1970]. Above and below this voltage range, the L component rapidly decreases in importance. However, even a small degree of filtering of the x-ray beam effectively eliminates the low-energy portion of the spectrum containing the L-shell x rays. The higher-energy K-series x rays from a tungsten target contribute a maximum of 12% of the total x-ray exposure for operating voltages between 100 and 200 kV [ICRU 1970].

An ideal x-ray spectrum can be estimated from Eq. (5.7). The rate $\dot{N}(E)$ at which bremsstrahlung energy, per unit energy about E, is produced in the target (MeV per second) when bombarded by a current of I amperes of electrons which have been accelerated through a potential of V volts is

$$\dot{N}(E) = \frac{I}{q_e} E N_{br}(E_o, E) \simeq I k' \left[E_o - E - \frac{3}{4} E \ln\left(\frac{E_o}{E}\right) \right], \tag{5.11}$$

in which q_e is the electron charge, k' a constant, and $E_o = 10^{-6} V$. This spectrum, which is proportional to the exposure spectrum, is an ideal *thick target spectrum* in that the incident electron is completely stopped and no absorption of photons is considered. It is accepted practice in x-ray technology to use the dimensional (not Compton) x-ray wavelength λ rather than the photon energy E. Since these two quantities are related by $\lambda = hc/E$, the ideal spectral distribution of bremsstrahlung energy emission rate per unit wavelength,

$\dot{N}(\lambda)$, is

$$\dot{N}(\lambda) = \dot{N}(E)\left|\frac{dE}{d\lambda}\right| = Ik''\frac{1}{\lambda^3}\left[\left(\frac{\lambda}{\lambda_o} - 1\right) - \frac{3}{4}\ln\left(\frac{\lambda}{\lambda_o}\right)\right], \tag{5.12}$$

where the minimum wavelength $\lambda_o = hc/E_o$ and k'' is a constant. As the voltage increases above the critical voltage for ionization of the target atoms, the emission rate of the characteristic x rays also increases. For voltages up to six times the critical voltage for K-shell ionization, V_K, the emission of the K_α x rays increases approximately as $(V - V_K)^2$ [Flügge 1957].

The shape of the x-ray spectrum from a real x-ray machine, such as those of Fig. 5.3, differs considerably from the ideal spectrum discussed above. The high-voltage power supply of most units usually does not provide a constant voltage across the x-ray tube but rather gives a pulsating or fluctuating voltage.[4] This results in fewer high energy bremsstrahlung photons near the cutoff than would be expected on the basis of the peak voltage alone. In effect, electrons with a distribution of energies up to the peak voltage impinge on the anode and cause a shift of the bremsstrahlung spectrum toward lower energies (longer wavelengths). On the other hand, the low-energy photons are preferentially absorbed by the target material, the glass envelope of the x-ray tube, and the air outside the tube. In addition, metal filters are often placed in the beam path to absorb preferentially the low-energy photons and thus to shift the spectrum toward higher energies. The strength of the x-ray beam thus depends on the target material, tube voltage, tube current, and the type and amount of filtering experienced by the x rays.

5.3.4 Synchrotron X Rays

When a charged particle initially moving in a straight line is accelerated by deflecting it in an electromagnetic field, the perturbation in the particle's electric field travels away from the particle at the speed of light and is observed as electromagnetic radiation (photons). Such is the origin of bremsstrahlung produced when fast electrons (beta particles) are deflected by the electric field of a nucleus.

This same mechanism can be used to produce intense photon radiation by deflecting an electron beam by magnetic fields. In a special accelerator called a *synchrotron*, highly relativistic electrons are forced to move in a circular path inside a storage ring by placing *bending magnets* along the ring. Photons are emitted when the beam is accelerated transversely by (1) the bending magnets (used to form the circular electron beam), and by (2) insertion device magnets such as *undulators*, *wigglers*, and *wave-length shifters*.

Because the electrons are highly relativistic, the synchrotron radiation is emitted in a very narrow cone in the direction of electron travel as they are deflected. Undulators cause the beam to be deflected sinusoidally by a weak oscillatory magnetic field, thereby producing nearly monochromatic photons. By contrast, a wiggler uses a strong oscillatory magnetic field which, because of relativistic effects, produces distorted sinusoidal deflections of the electron beam and synchrotron radiation with multiple harmonics, i.e., a line spectrum. If very strong magnetic fields are used, many harmonics are produced that merge to yield a continuous spectrum ranging from the infrared to hard x rays. By placing undulators or wigglers at a specific location in the storage ring, very intense and narrowly collimated beams of photons with energies up to a few keV can be produced, useful in x-ray diffraction analyses.

5.4 Sources of Neutrons

5.4.1 Fission Neutrons

Many heavy nuclides fission after the absorption of a neutron, and some nuclides fission spontaneously, producing several energetic fission neutrons. Almost all of the fast neutrons produced from a fission event

[4] If a constant potential is applied to the x-ray tube, the designation "kVcp" is sometimes used, while the peak voltage for a pulsating applied voltage is often indicated by "kVp."

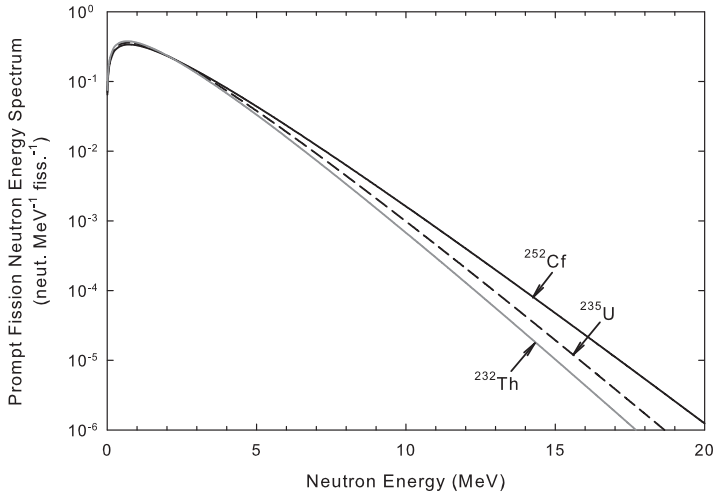

Figure 5.4. Energy spectra of prompt neutrons produced from the fission of fissionable nuclei as calculated by Walsh [1989].

are emitted within 10^{-14} s of the fission event, and are called *prompt neutrons*. Generally less than 1% of the total fission neutrons are emitted as *delayed neutrons*, which are produced by the neutron decay of fission products at times up to many seconds or even minutes after the fission event. As the energy of the neutron which induces the fission in a heavy nucleus increases, the average number of fission neutrons also increases. For example, the fission of ^{235}U by a thermal neutron (average energy 0.025 eV) produces, on the average, 2.43 fission neutrons. A fission caused by a 10-MeV neutron, by contrast, yields 3.8 fission neutrons. For ^{239}Pu, fission by thermal or 10 MeV neutrons yields 2.87 or 4.2 neutrons. The fission of ^{238}U is induced only by fast neutrons, with a 10-MeV neutron yielding 3.9 fission neutrons.

Since the advent of fission reactors, many transuranic isotopes have been produced in significant quantities. Many of these isotopes have appreciable spontaneous fission probabilities, and consequently they can be used as very compact sources of fission neutrons. For example, 1 g of ^{252}Cf releases 2.3×10^{12} neutrons per second, and very intense neutron sources can be made from this isotope, limited in size only by the need to remove the fission heat through the necessary encapsulation. Almost all spontaneously fissioning isotopes decay much more frequently by α emission than by fission.

The energy dependence of the fission neutron spectrum has been investigated extensively, particularly for the important isotope ^{235}U. All fissionable nuclides produce prompt-fission neutrons with energy frequency distributions that go to zero at low and high energies (see Fig. 5.4), reaching a maximum at about 0.7 MeV, and have an average energy of about 2 MeV. The fraction of prompt fission neutrons emitted per unit energy about E, $\chi(E)$, can be described quite accurately by a Watt distribution

$$\chi(E) = ae^{-E/b}\sinh\sqrt{cE}, \tag{5.13}$$

where the parameters a, b and c depend on the fissioning isotope (see Table 5.6). The fission-neutron spectrum for thermal-neutron fission of ^{235}U is often used as an approximation for other fissioning isotopes.

5.4.2 Fusion Neutrons

Neutrons can be produced as products of nuclear reactions in which energetic charged particles hit target atoms. Most such reactions require accelerators to produce the energetic charged particles and hence such neutrons are to be encountered only near accelerator targets.

Table 5.6. Parameters for the Watt approximation of Eq. (5.13).

Nuclide	Type of Fission	a	b	c
^{233}U	thermal	0.6077	1.1080	1.2608
^{235}U	thermal	0.5535	1.0347	1.6214
^{239}Pu	thermal	0.5710	1.1593	1.2292
^{232}Th	fast (2 MeV)	0.5601	0.9711	1.8262
^{238}U	fast (2 MeV)	0.5759	1.0269	1.5776
^{252}Cf	spontaneous	0.6400	1.1750	1.0401

One major exception to the insignificance of charged-particle-induced reactions are those in which light elements fuse exoergically to yield a heavier nucleus and which are accompanied quite often by the release of energetic neutrons. Neutron-producing fusion reactions of most interest in the development of thermonuclear fusion power are

$$^2\mathrm{H} + {}^2\mathrm{H} \longrightarrow {}^3\mathrm{He}\ (0.82\ \mathrm{MeV}) + {}^1n\ (2.45\ \mathrm{MeV})$$

$$^2\mathrm{H} + {}^3\mathrm{H} \longrightarrow {}^4\mathrm{He}\ (3.5\ \mathrm{MeV}) + {}^1n\ (14.1\ \mathrm{MeV}).$$

When these reactions are produced by accelerating one nuclide toward the other, the velocity of the center of mass must first be added to the center-of-mass neutron velocity before determining the neutron energy in the laboratory coordinate system. In most designs for fusion power, the velocity of the center of mass is negligible, and the concern is with monoenergetic 2.45- or 14.1-MeV fusion neutrons. The 14.1-MeV fusion neutrons are also produced copiously in a thermonuclear explosion.

A beam of relatively low energy deuterons (100 to 300 keV) incident on a deuterium or tritium target can produce a significant number of thermonuclear neutrons. Thus, these D-D or D-T reactions are used in relatively compact accelerators, called *neutron generators*, in which deuterium ions are accelerated through a high voltage (100 to 300 kV) and allowed to fall on a thick deuterium- or tritium-bearing target. Typically in such devices, a 1-mA beam current produces up to 10^9 14-MeV neutrons per second from a thick tritium target.

5.4.3 Photoneutrons

A gamma photon with energy sufficiently large to overcome the neutron binding energy (about 7 MeV in most nuclides) may cause a (γ, n) reaction. Very intense and energetic photoneutron production can be realized in an electron accelerator where the bombardment of an appropriate target material with the energetic electrons produces intense bremsstrahlung (see Section 5.3.2) with a distribution of energies up to that of the incident electrons. The probability a photon will cause a (γ, n) reaction increases with the photon energy, reaching a maximum over a broad energy range of approximately 20 to 23 MeV for light nuclei ($A \lesssim 40$) and 13 to 18 MeV for medium and heavy nuclei. The peak energy of this *giant resonance* can be approximated by $80A^{-1/3}$ MeV for $A > 40$. The width of the resonance varies from about 10 MeV for light nuclei to 3 MeV for heavy nuclei. Consequently, in medical or accelerator facilities that produce photons with energies above about 15 MeV, neutron production in the surrounding walls can lead to significant neutron fields.

The photoneutron mechanism can be used to create laboratory neutron sources by mixing intimately a beryllium or deuterium compound with a radioisotope that decays with the emission of high energy photons.

Alternatively, the encapsulated radioisotope may be surrounded by a beryllium- or deuterium-bearing shell. A common reactor photoneutron source is an antimony-beryllium mixture, which has the advantage of being rejuvenated by exposing the source to the neutrons in a nuclear reactor to transmute the stable ^{123}Sb into the required ^{124}Sb isotope (half-life of 60.2 days). Characteristics of some (γ, n) sources are given in Table 5.7.

One very attractive feature of such (γ, n) sources is the nearly monoenergetic nature of the neutrons if the photons are monoenergetic. However, in large sources, the neutrons may undergo significant scattering in the source material and thereby degrade the nearly monoenergetic nature of their spectrum. These photoneutron sources generally require careful use because of their inherently large photon emission rates. Because nominally only one in a million high energy photons actually interacts with the source material to produce a neutron, these sources generate gamma rays that are of far greater biological concern than are the neutrons. A particularly useful combination is an SbBe neutron source coupled with an ^{56}Fe shield. The ^{56}Fe 24 keV anti-resonance allows the passage of the SbBe 23 keV neutrons while working to shield other emissions.

Table 5.7. Characteristics of some important (γ, n) sources.

5.4.4 Alpha-Neutron Sources

Many compact laboratory neutron sources use energetic alpha particles from various radioisotopes (*emitters*) to induce (α, n) reactions in appropriate materials (*converters*). Although a large number of nuclides emit neutrons if bombarded with alpha particles of sufficient energy, the energies of the alpha particles from radioisotopes are capable of penetrating the potential barriers of only the lighter nuclei.

Of particular interest are those light isotopes for which the (α, n) reaction is exoergic ($Q > 0$) or, at least, has a low threshold energy. For endoergic reactions ($Q < 0$), the threshold alpha energy is $-Q(1 + 4/A)$. Thus, for an (α, n) reaction to occur, the alpha particle must (1) have enough energy to overcome the repulsive Coulombic force field of the nucleus, and (2) exceed the threshold energy for the reaction. Converter materials used to make practical (α, n) sources include lithium, beryllium, boron, carbon, fluorine and sodium.

A neutron source can be fabricated by mixing intimately a light converter element, such as lithium or beryllium, with a radioisotope that emits energetic alpha particles. Most of the practical alpha emitters are actinide elements, which form intermetallic compounds with beryllium. Such a compound, e.g., $PuBe_{13}$, ensures both that the emitted alpha particles immediately encounter converter nuclei, thereby producing a maximum neutron yield, and that the radioactive actinides are bound into the source material, thereby reducing the risk of leakage of the alpha-emitting component.

The neutron yield from an (α, n) source varies strongly with the converter material, the energy of the alpha particle, and the relative concentrations of the emitter and converter elements. The degree of mixing between converter and emitter and the size, geometry, and source encapsulation may also affect the neutron yield. For example, a ^{239}Pu/Be source has an optimum neutron yield of about 60 neutrons per 10^6 primary alpha particles. Characteristics of some (α, n) sources are given in Table 5.8.

Table 5.8. Characteristics of some (α, n) sources.

Source	Half-life	Principal alpha energies (MeV)	Average neutron energy (MeV)	Optimum neutron yield per 10^6 primary alphas[a]
^{210}Po / Li	138.4 d	5.305	0.48	1.3

^{210}Po / Na	138.4 d	5.305		1

[a] Yield for alpha particles incident on a target thicker than the alpha-particle ranges.

[b] Does not include a 4% contribution from the spontaneous fission of ^{244}Cm.

[c] Yield is dependent on the proportion of daughters present. Value for ^{226}Ra corresponds to a 22-year-old source (50% contribution for ^{210}Po).

Sources: Jaeger [1968], GPO [1970], and Knoll [1989].

The energy distributions of neutrons emitted from (α, n) sources are continuous below some maximum neutron energy with definite structure at well-defined energies determined by the energy levels of the converter and the excited product nuclei (see Fig. 5.5). The use of the same converter material with different alpha emitters produces similar neutron spectra with different portions of the same basic spectrum accentuated or reduced as a result of the different alpha-particle energies. Average energies of neutrons typically are several MeV. For example, the neutrons produced by a ^{239}Pu/Be source have an average energy of 4.6 MeV.

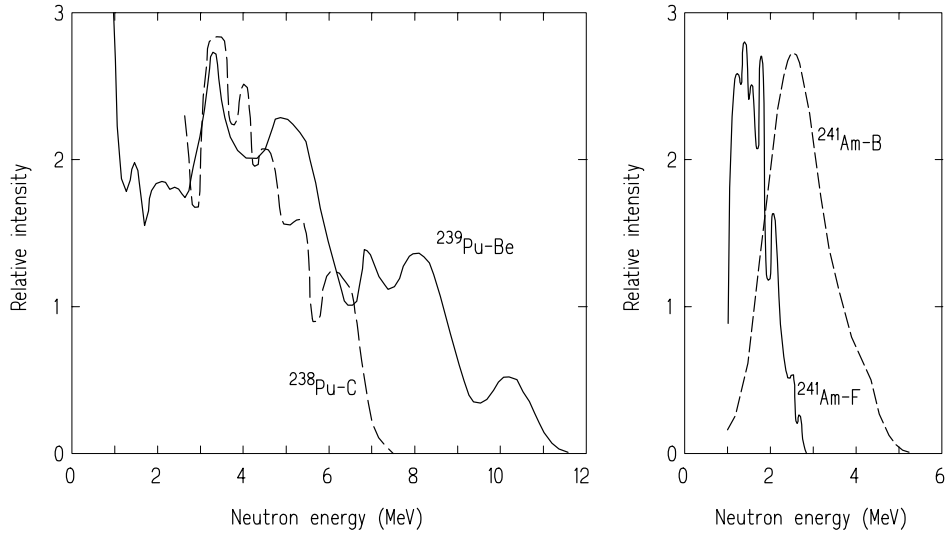

Figure 5.5. Neutron energy spectra produced by four (α, n) sources. The spectral structure is determined by the converter material, while the relative intensity of various portions of the spectrum depends on the energies of the alpha particles emitted by the radioactive component. Based on experiment data from Anderson and Neff [1972] and Lorch [1973].

5.4.5 Activation Neutrons

A few highly unstable nuclides decay by the emission of a neutron. The delayed neutrons associated with fission arise from such decay of the fission products. However, there are nuclides other than those in the fission-product decay chain which also decay by neutron emission. Only one of these nuclides, ^{17}N, is of importance in nuclear reactor situations. This isotope is produced in water-moderated reactors by an (n, p) reaction with ^{17}O (threshold energy, 8.0 MeV). The decay of ^{17}N by beta emission (half-life 4.4 s) produces ^{17}O in a highly excited state, which in turn decays rapidly by neutron emission. Most of the decay neutrons are emitted within $\pm$ 0.2 MeV of the most probable energy of about 1 MeV, although neutrons with energies up to 2 MeV may be produced.

5.4.6 Spallation Neutron Sources

In a spallation neutron source, pulses of very energetic protons (up to 1 GeV), produced by an accelerator, strike a heavy metal target such as mercury or liquid bismuth. Such an energetic proton when it strikes a target nucleus "spalls" or knocks out neutrons. Additional neutrons boil off as the struck nucleus heats up. Typically, 20 to 30 neutrons are produced per spallation reaction. These pulses of neutrons are then slowed down or thermalized by passing them through cells filled with water, or even liquid hydrogen if very slow neutrons are needed.

5.5 Sources of Charged Particles

Charged particles are directly ionizing radiations and, unlike photons and neutrons, have well-defined ranges as they interact with the long-range Coulombic forces of the atoms of the medium through which they pass. Such particles arise from several sources. Radioactive decay products almost always produce charged particles such as alpha and beta particles.[5] Likewise, photon and neutron induced reactions with an atom usually produce secondary charged particles. Indeed it is these secondary charged particles that are used to detect the presence of these indirectly ionizing radiations. Finally in our technological modern world there are many machines that produce energetic charged particles. Indeed accelerators that produce energetic charged particles are used for a myriad of tasks such as industrial processing, production of medical radioisotopes, or numerous research purposes.

5.5.1 Beta Decay

Beta decay of a radionuclide, in effect, involves either (1) a transformation within the nucleus of a neutron into a proton accompanied by the emission of an electron, or beta particle, and an antineutrino, or (2) a nuclear transformation of a proton in the decaying nucleus to a neutron accompanied by emission of a positron and a neutrino. The energy released in the process—the Q value—is shared by the electron and the antineutrino or by the positron and the neutrino. Beta decay of a nucleus may occur by any of several different nuclear transitions. For each there is a unique endpoint energy, the maximum kinetic energy of the electron or positron. Also, for each transition, there is a unique statistical distribution of energy between the electron and antineutrino or positron and neutrino, and to a very minor extent the residual nucleus. The balance of this discussion deals with the more common beta-particle emissions, with the recognition that positron emission may be treated very similarly.

ΔJ	$\Delta\Pi$	Transition classification	n
0,1	-1	Allowed	0
0,1	$+1$	Non-unique, first-forbidden	0
2	$+1$	Unique, first-forbidden	1
2	-1	Non-unique, second-forbidden	1
3	-1	Unique, second-forbidden	2

Although the energy spectrum of the beta particles for any one transition certainly depends on the endpoint energy, the spectrum also depends, in a complicated way, on the nuclear spin and parity quantum numbers of the nucleus before and after beta-particle emission. As shown to the left, these quantum numbers determine whether the transition is referred to as *allowed* or *forbidden*, and if forbidden, whether the transition is *unique* (U) or *non-unique* (non-U). In a transition, the spin quantum number J may remain constant or it may change by one or more units, that is, $\Delta J = 0, 1, 2, \ldots$. The parity quantum number Π may or may not change, that is, $\Delta\Pi = -1$ (no change) or $+1$ (change). To a first approximation, a single classification index n may be used to characterize the energy spectrum. For $\Delta J \geq 2$, $n = \Delta J - 1$. Otherwise, the various combinations of $\Delta\Pi$ and ΔJ establish the following selection rules, which determine the *shape factor*, which, in part, governs the beta-particle energy spectrum for a particular transition.

As an example, consider the decay of ^{38}Cl to ^{38}Ar. Three beta transitions are possible, with the following characteristics:

[5] Only in gamma-ray decay of nuclear isomers, electron capture, and neutron radioactive decay (from fission fragments, for instance) are no charged particles emitted.

Frequency (%)	$E_{\max}$ (keV)	E_{av} (keV)	ΔJ	$\Delta\Pi$	n	Classification
32.5	1107	420	1	−1	0	Allowed

56.0	4917	2244	2	+1	1	Unique, first forbidden

The energy spectrum of beta particles arising from a transition is conveniently expressed in terms of the electron total energy W (including rest-mass energy), that is, $W = E + m_e c^2$, and the momentum $p = \sqrt{E^2 + 2m_e c^2 E}/c$. The energy spectrum $N_i(E)$ for transition i is defined in such a way that $N_i(E)dE$ is the probability that, in a transformation of the radionuclide via transition i, a beta particle is emitted with kinetic energy in the range dE about E. This spectrum can be expressed as

$$N_i(E) = C_i\, p\, W [E_{\max,i} - E]^2 F(Z, A, W)\; S_n(Z, A, E_{\max,i}, W), \tag{5.14}$$

in which $E_{\max,i}$ represents the maximum (or endpoint) energy, Z and A are the charge and mass numbers of the nucleus after the transition, F is the *Fermi function*, S_n is a *shape factor* determined by the selection-rule classification index n, and C_i is a normalization constant.

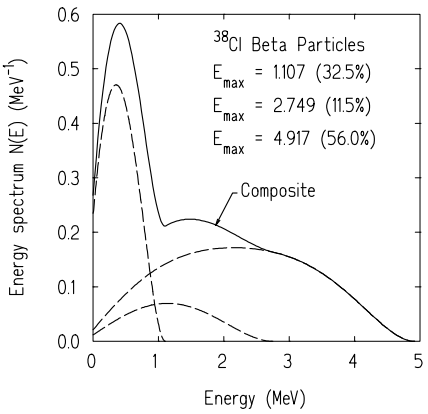

Figure 5.6. Energy spectra of ^{38}Cl beta particles.

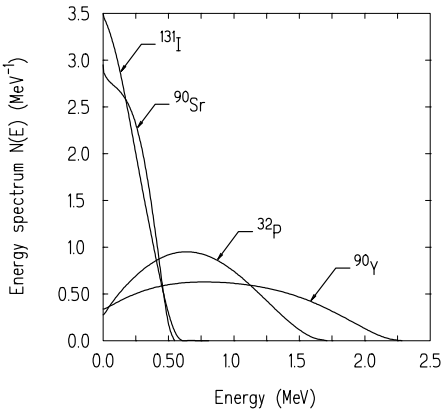

Figure 5.7. Energy spectra of selected beta-particle sources.

The product $p\,W\,[E_{\max,i} - E]^2$ is a statistical factor and is a major determinant of the energy spectrum. The shape factor S_n is unity for allowed and nonunique first-forbidden transitions; for other transitions it is a complicated function. Suffice to say here that it is an extremely tedious task to evaluate the Fermi function and the shape factor. Procedures are clearly described by Dillman and Von der Lage [1975] and by Dillman [1980], as are procedures required to account for screening by atomic electrons, an effect that is especially important for positron decay. Figure 5.6 illustrates individual and composite spectra for the three transitions involved in the beta decay of ^{38}Cl. In Fig. 5.7 the spectra for four important beta-emitting radionuclides are given. Table 5.9 lists commonly encountered radionuclide sources that emit beta particles.

If f_i is the frequency for the ith transition, then the spectrum normalization constant C_i is determined by the requirement that

$$\int_0^{E_{\max,i}} dE\, N_i(E) = f_i. \tag{5.15}$$

Table 5.9. Half-lives of common beta-particle emitters, maximum emission energies, and yields. Positron emission is indicated by (+).

The average beta-particle energy for a particular transition is

$$\langle E_i \rangle = \frac{1}{f_i} \int_0^{E_{\max,i}} dE\, E N_i(E). \tag{5.16}$$

The average beta-particle energy released per transformation of the radionuclide is given by $\sum_i f_i \langle E_i \rangle$.

5.5.2 Alpha Decay

Radioactive decay by alpha-particle emission is possible only in the heavier elements. One radionuclide may have several transitions involving alpha-particle emission; but for each transition, the particles are monoenergetic and usually of several MeV energy. The Geiger-Nuttall rule [Kaplan 1962] accounts for the strong inverse relationship between the half-life of a radionuclide and the energy of its alpha particle. Table 5.10, which lists several important alpha-particle emitters, illustrates this inverse relationship.

Table 5.10. Half-lives of common alpha-particle emitters. Also listed are the prominent energies and frequencies of particles emitted.

†Also a spontaneous neutron emitter.

5.5.3 Photon Interactions

In all the principal photon interactions, secondary electrons are produced. The photoelectric interactions lead to photoelectrons and, perhaps, Auger electrons. In a Compton scattering interaction, an orbital electron recoils from the atom, and in pair production a positron-electron pair are created. The energetics of these secondary electrons are discussed in Sections 4.3.3 and 4.4. X- and gamma-ray detectors then measure the ionization and excitation of the ambient atoms produced by these secondary electrons.

5.5.4 Neutron Interactions

Scattering

Often, when neutrons interact with a nucleus, secondary charged particles are produced. When fast neutrons scatter from a nucleus, the recoil nucleus is a charged particle which gives up its kinetic energy through ionization and excitation of the ambient atoms. The energy transfered from the neutrons to the recoil nucleus is described in Section 4.3.4. As the mass of the scattering nucleus decreases ever more energy is transferred to the recoil nucleus. In particular, for scattering from hydrogen, the recoil nucleus (a proton) can receive up to all of the incident neutron's energy. By measuring the energy distribution of the recoil protons, the energy distribution of the fast incident neutrons can be inferred.

Because the neutron has an internal charge distribution that is not uniform throughout the neutron, it is possible for neutrons to interact with electrons. However, such neutron-electron interactions are exceedingly rare and are of little importance in radiation detection.

Charged-Particle Reactions

Neutron detectors are often designed to detect the charged particles produced in neutron reactions that produce secondary charged particles. Most such reactions such as $^{3}\mathrm{He}(n,p)^{3}\mathrm{H}$, $^{10}\mathrm{B}(n,\alpha)^{7}\mathrm{Li}$, or $^{6}\mathrm{Li}(n,t)^{4}\mathrm{He}$, occur predominately at thermal neutron energies. However, for neutrons with energies in the MeV region (n,p), (n,α) and other knockout reactions can also occur. These reactions are especially important when light elements are involved. The (n,α) reaction cross sections for Be, N, and O are appreciable fractions of the total cross sections and may exceed the inelastic scattering contributions. This situation is probably true for most light elements, although only partial data are available. For heavy and intermediate nuclei, the charged-particle emission interactions are at most a few percent of the total inelastic interaction cross sections and, hence, are usually ignored.

Fission

A special case of charged-particle producing reactions is that of neutron-induced fission. Any very heavy nucleus can be made to fission accompanied by a net release of energy if hit sufficiently hard by some incident particle. However, very few nuclides can fission by the absorption of a neutron with negligible incident kinetic energy. The binding energy of this neutron in the compound nucleus provides sufficient excitation energy that the compound nucleus can deform sufficiently to split spontaneously. Nuclides, such as $^{235}\mathrm{U}$, $^{233}\mathrm{U}$, and $^{239}\mathrm{Pu}$, that fission upon the absorption of a slow moving neutron, are called *fissile* nuclei and play an important role in thermal neutron fission detectors. Nuclides that fission only when struck with a neutron with one or more MeV of kinetic energy, such as $^{238}\mathrm{U}$ and $^{240}\mathrm{Pu}$, are said to be *fissionable*, i.e., they undergo fast fission.

The highly excited compound nucleus almost always splits assymetrically producing a heavy fission fragment Y_H and a lighter fission fragment Y_L.[6] The initial fission fragments are highly charged, missing 10 to 15 electrons. They are also in such highly excited states that, within 10^{-17} s of the scission, several prompt neutrons "boil" away, and, within 2×10^{-14} s, more excitation energy is lost from the emission of prompt fission gamma rays.

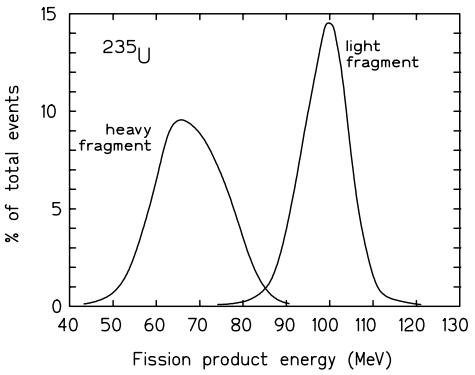

Figure 5.8. Energy distribution of fission products produced by the thermal fission of $^{235}\mathrm{U}$. The mean energy of the light fragment is 99.2 MeV and that of the heavy fragment is 68.1 MeV. After Keepin [1965].

[6] Sometimes three fission fragments are formed in *ternary* fission with the third being a small nucleus. Alpha particles are created in about 0.2% of the fissions and nuclei of $^{2}\mathrm{H}$, $^{3}\mathrm{H}$, and other nuclei up to about $^{10}\mathrm{B}$ with much less frequency.

The highly charged fission fragments pass through the surrounding medium causing millions of Coulombic ionization and excitation interactions with the electrons of the medium. As the fission fragments slow, they gradually acquire electrons that reduce their ionization charge, until, by the time they are stopped, they have become electrically neutral atoms. This transfer of the fission fragments' kinetic energy to the ambient medium takes about 10^{-12} s. It is this enormous energy transfer to the ambient medium that makes neutron fission detectors possible.

Because the mass distribution of the fission fragments is bimodal (two peaks), one would expect the initial kinetic energy of the fragments to also be bimodal. In Fig. 5.8, the kinetic energy distribution of the fission fragments produced in the thermal fission of ^{235}U is shown.

5.5.5 Accelerators

Beginning in the 1930s, machines were developed to accelerate charged subatomic particles such as protons and alpha particles to speeds that could induce nuclear reactions. The first such *particle accelerator* produced protons with 700 keV of energy. Recently an accelerator became operational that produces 7-TeV protons or heavy ions such as lead with 1200 TeV of kinetic energy.

Today the development of ever more energetic particle accelerators is driven by the high energy physics community. With these enormous and costly machines, physicists will perform experiments that will reveal information about the fundamental physics governing the subatomic world. Accelerators with lower energies are also central to other areas of research such as the study of atomic and nuclear physics. A 1-GeV proton accelerator is now used at the Spallation Neutron Source at Oak Ridge National Laboratory to bombard a liquid mercury target. The resulting spallation reactions release copious neutrons which are ideal probes to determine molecular structures. Accelerators can also be used to produce intense x-ray beams that in turn can be used in fundamental research on materials. As in most areas of fundamental research, accelerator technology has spun off many practical applications such as cancer therapy, production of important radionuclides, ion implanting, and food preservation to name a few.

For high energy physics research, special radiation detectors are needed to detect the myriad of subatomic particles that are produced in these machines. Such detectors are huge, very expensive, and usually one of a kind. Consequently, only brief consideration of such detectors is given in this book.

5.6 Cosmic Rays

At the beginning of the twentieth century, the reason why electrometers would discharge for no apparent reason was a mystery. One postulated explanation was that earth itself emitted ubiquitous ionizing radiation. But in 1911 Victor Hess, using electrometers on a balloon, found that ionizing radiation increased in strength with altitude, thereby showing that this radiation came from outer space.

Although much is now known about this *cosmic* radiation, there are many aspects of it that are still mysterious. Cosmic radiation has been measured from a few GeV to over 10^{20} eV. At a few GeVs the composition is 98% nuclei (of which 87% are protons, 12% helium nuclei, and 1% heavier nuclei), $< 2\%$ electrons, and $< 10^{-4}\%$ gamma rays. One unsettled question is how the most energetic cosmic rays are produced. For example, since 1991 more that 20 protons with energies $\geq 3 \times 10^{20}$ eV have been observed. This energy corresponds to 48 J, which is the kinetic energy of a 58-g tennis ball moving at about 150 km/h! The energy spectrum of cosmic rays follows a "power law" $E^{-\alpha}$ where $\alpha \simeq 2.7$ for $10^{10} < E < 3 \times 10^{15}$ eV and, above 3×10^{15} eV, $\alpha \simeq 3$.

At times, some stars throw off their outer sheath, forming a shock wave rapidly moving outward. In 1949 Enrico Fermi suggested that charged particles moving back and forth through a moving and magnetized shock front would statistically gain energy. As a particle gains energy, the shorter is the time that the

charged particle stays in the front of the shock wave, and the higher the probability it will escape. In such a case, the charged particles leaving the front would have a power-law distribution in energies.

But where are such cosmic accelerators located? Prime suspects are Active Galactic Nuclei (AGN), which are galaxies that produce more electromagnetic emission than can be deduced from their stellar content, stellar remnants, and their interstellar medium. Such AGNs are assumed to harbor at their centers a supermassive black hole, millions to billions more massive that our sun. Such a black hole accretes matter from the surrounding galaxy, forming an accretion disk and two "jets," each up to several thousand light-years in length, perpendicular to the disk. In these jets it is thought that charged particles can be accelerated to the highest possible energies and, in the process, more radiation is produced than by the entire galaxy.

Another possible source is a supernova remnant. The ejected outer shell of the supernova builds into a spherically shaped nebula (the *supernova remnant*). The inner core of the supernova becomes a black hole, a neutron star, or a white dwarf, depending on the mass of the progenitor star. A shock front is formed when the ejected material flows into the interstellar medium. And in this shock front, Fermi acceleration can occur that produces enormous numbers of relativistic particles.

A neutron star produced by a supernova explosion that spins with a period of less than a few seconds is called a *pulsar*. Because pulsars have very strong corotating magnetic fields ($> 10^{12}$ G), a strong electric field is induced, which in turns accelerates charged particles.

Finally, *microquasars*, are binary systems consisting of a compact neutron star or black hole and a massive companion star. The compact object accretes matter from the star forming an accretion disk that produces a pair of perpendicular relativistic jets in which charged particles are accelerated, as occurs in AGNs.

5.6.1 High Energy Gamma Rays

Another cosmic ray mystery is how cosmic gamma rays with energies above several MeV are produced, the so-called high energy (HE) and very high energy (VHE) gamma rays. The hottest structures in the universe are accretion disks around compact objects. Yet their thermal peak emissions produce x rays with energies up to only a few tens of keVs. Moreover, the energy spectrum of HE and VHE gamma rays is found to follow a power law $E^{-\alpha}$, a distribution not followed by the thermal black body spectrum. Hence, high energy gamma photons cannot be produced by thermal emissions.

The HE and VHE gamma rays undoubtedly arise because of the interaction of high energy charged particles with matter. If a cosmic proton accelerator is surrounded by dense matter, copious numbers of neutral pions π^0 are produced by the highest energy protons. The main decay mode of these pions (98.8%) is into two very energetic gamma photons. Another mechanism involves relativistic electrons. In strong magnetic fields these electrons lose energy through synchrotron and curvature emissions. Alternatively, in inverse Compton scattering, a low energy photon scatters from a high energy electron to produce a high energy photon.

Beginning in the 1960s it was revealed that bursts of gamma rays appeared randomly in the sky. Today it is known that these gamma ray bursts (GRB) occur about once a day lasting from milliseconds to hundreds of seconds and originate far outside our galaxy. The energy release is enormous and the mechanism(s) for the creation of such bursts is not well established. Conjectured possibilities include the merging of two black holes or two neutron stars and the collapse of a hypernova.

PROBLEMS

1. The average mass of potassium in the adult human body is about 140 g of which 0.0117% of the radioisotope ^{40}K. (a) Estimate the average activity (Bq) of ^{40}K in the body. (b) From the data in Ap. C, estimate the energy and number of gamma photons emitted per second from the body.

2. An obsolete unit of activity, although still widely used, is the curie (Ci) which equals 3.7×10^{10} Bq. How many atoms and what mass of the isotope ^{3}H are needed to produce a radioactive source with an activity of 1 Ci? Perform the same calculation for the isotopes ^{60}Co and ^{239}U.

3. Why does coal contain no ^{14}C?

4. How many alpha particles are emitted per second from a 1-gram sample of vanadium? Compare this emission rate to that for one gram of ^{238}U.

5. A 1-g sample of ^{235}U is placed in a thermal flux of 4×10^4 cm^{-2} s^{-1}. How many prompt fission gamma photons are emitted per second from this sample?

6. The global inventory of ^{14}C is about 8.5 EBq. If all that inventory is a result of cosmic ray interactions in the atmosphere, how many kilograms of ^{14}C are produced each year in the atmosphere?

7. Calculate the neutron emission rate from a 20-GBq point source of ^{124}Sb surrounded by 40 g of beryllium. The ^{9}Be(γ, n) cross section is about 1 mb.

8. An isotope that decays by ejecting alpha particles with energies 6.82 MeV (10%) and 4.30 MeV (90%) is mixed intimately with a large amount of beryllium. For an (α, n) source using 40 GBq of this mixture, estimate the neutron emission rate and sketch the energy spectrum of the emitted neutrons.

9. Estimate the rate at which activation product neutrons from the decay of ^{17}N are produced in a water-moderated, uranium-fueled reactor which is operating at a steady thermal power of 3000 MW.

10. Estimate the number of spontaneous-fission neutrons emitted from a 1 kilogram sample of ^{238}U.

11. A thermonuclear device (^{2}H-^{3}H reaction only) is detonated in space with a yield of 1.00 MWd. What is the resulting neutron fluence 1 km from the detonation point?

12. One gram of natural iron is present in a uniform thermal flux density of 10^{12} cm^{-2} s^{-1}. Describe quantitatively the resulting emission of capture gamma rays from the iron.

13. A beam of thermal neutrons (10^{10} neutrons cm^{-2} s^{-1}) irradiates a 2-g sample of calcium for 30 s. What is the flux density (in vacuum) of gamma photons with energies greater than 1 MeV at a point 1 m from the sample 2 min after the irradiation ceases? Consider the decay of both ^{47}Ca and ^{49}Ca.

14. Cadmium is commonly used to attenuate thermal neutrons because of its large (n, γ) cross section. However, capture gamma photons are produced as a result of the neutron capture. As an example, use Table B.4 to sketch the energy-dependent flux density of capture photons above 1 MeV at 10 m (in vacuum) from a point where a thermal neutron beam of 10^{8} neutrons s^{-1} is stopped by a cadmium sheet.

15. Electrons accelerated through a potential of 100 kV strike a gold target. Sketch the spectrum of the resulting x rays, first as a function of x-ray energy down to 50 keV, and, then as a function of wavelength. Show both the bremsstrahlung and characteristic x rays. If the electron beam current and voltage were

doubled and the target replaced by an aluminum one, by what percentage would the bremsstrahlung power change?

16. Calculate the flux-density energy spectrum of the bremsstrahlung at 1 m (in vacuum) from a small tungsten target bombarded by 10 mA of electrons accelerated through a constant potential of 500 kV. Neglect x-ray absorption and assume isotropic emission of the x rays.

Chapter 6

Probability and Statistics for Radiation Counting

To understand God's thoughts we must study statistics,
for these are the measure of His purpose.

Florence Nightingale[1]

6.1 Introduction

The science of probability can be traced to 1654 with a study of gambling, in which Blaise Pascal and Pierre de Fermat were challenged with a die rolling problem. It was Chevalier de Méré who approached Pascal and asked what the remaining chance of winning a game of dice would be between two players at any moment during the progression of the game, with the idea that the two players would split the stakes fairly if they wished to discontinue playing. The correspondence between Pascal and Fermat and their early observations on probability and expected values have developed over time into a valuable science used to interpret data and predict scientific outcomes. Although there are numerous definitions for statistics, an accepted definition is that statistics is the branch of mathematics dealing with the collection, analysis, interpretation, and presentation of numerical data. Presently, the fields of probability and statistics are combined, in which collections of observed data are described by probabilistic models, making possible predictions and categorization of observed phenomena.

The proper analysis of any type of experimental data requires an assessment of the uncertainties associated with each measurement. Without such an estimate, the data have limited value. There are several types of uncertainties or errors associated with any experimental measurement. These errors include stochastic uncertainties, sampling errors and systematic errors. For example, the decay of radioactive atoms occurs randomly or stochastically so that a measurement of the number of decays observed in a fixed time interval has an inherent *stochastic uncertainty*. Repeated measurements would give slightly different results. *Systematic* errors are introduced by some constant bias or error in the measuring system and are often very difficult to assess because they may arise from biases unknown to the experimenter. *Sampling errors* arise from making measurements on a different population from the one desired. These latter two errors are often hard to detect, let alone quantify.

Engineers and scientists must always be aware of the difference between *accuracy* and *precision*, even though popular usage often blurs or ignores the important distinction. Precision refers to the degree of

[1] Lesser known are Florence Nightingale's contributions to the discipline of statistics. She collected much data on hospital conditions and correlated her findings with death rates. She presented these results with her invention of statistical coxcomb graphics, emphasizing the need for cleanliness in hospitals, ultimately leading to reformed hospital practices.

measurement quantification as determined, for example, by the number of significant figures. Accuracy is a measure of how closely the measured value is to the true (and usually unknown) value. A precise measurement may also be very inaccurate. In radiation counting, methods of probability and statistics are used to provide accurate measurements together with an estimate of the precision of the measurement, often termed the error or uncertainty associated with the measurement. In this chapter, the fundamental probability and statistical concepts used for radiation counting are introduced, along with associated probability models and error analyses.

6.1.1 Types of Measurement Uncertainties

Data measured with an ionizing-radiation detection system contain both random uncertainties and systematic errors. Uncertainty assignment requires knowledge of both. Even with a perfect measurement system capable of operating over a long time period without introducing significant systematic error, one must always consider the random nature of the data caused by the stochastic nature of all radiation sources. This chapter deals only with one component of the total uncertainty—the random or statistical uncertainty, which can be estimated through various probability distribution functions (PDFs), most commonly the Gaussian (or normal) distribution.

Radiation counting *is* a stochastic process. Further complications in the data analysis can be introduced if the source emission rate changes in time. For example, the activity of a single radionuclide sample exponentially decays in time or the radiation leaking from a reactor increases in time as the reactor power increases. In this chapter, unless otherwise noted, it is assumed that the strength of any radiation source is constant in time.

6.1.2 Probability and Statistics

The term *probability* refers to the study of randomness and uncertainty in a series of non-deterministic or stochastic measurements, and naturally arises from the study of an expected value of certain possible outcomes as compared to all possible outcomes. One common example would be the toss of a fair coin, where it is assumed that one side or the other (heads or tails) lands horizontally up when the tossed coin comes to rest. Suppose that *heads* is selected as a "success" should it land face up. Because there are only two possible outcomes from a coin toss and only one method by which a heads can be observed, the probability is equal to the one possible method of observing a heads divided by two possible outcomes, or 1/2. Another example is that of rolling a six-sided die, and each side of the die has a different number ranging from one to six. Suppose that rolling a number *one* is considered a "success". There are six possible outcomes, of which only one outcome results in the observation of the number *one*. The anticipated outcome is divided by the total number of possible outcomes to determine that there is a 1/6 probability of observing a number *one* after one roll of the die. Chances are that the reader is already familiar with these examples, and the results are intuitive. Yet, what of large sample sets, as expected with the observation of radioactive decay in radioactive materials? Most materials have atomic densities between 10^{21} cm^{-3} and 10^{23} cm^{-3}; hence even tiny radioactive samples have enormous numbers of atoms which may decay within a certain time period (or may not). For radioactive materials, how is the probability of observing an average number of radiation emissions within a set time period predicted, and how is the uncertainty for experimental observations determined and reported? To understand the models and methods used to predict, report, and analyze radiation counting data, it is important to first define certain terms and statistical distributions commonly used in probability theory and statistics.

6.2 Probability and Cumulative Distribution Functions

6.2.1 Continuous Random Variable

The probability distribution function (PDF) describes the expected outcomes for a random variable x over the entire range of possible outcomes. A proper PDF has the following three properties: (1) it is defined on an interval $[a, b]$, where $a < b$, (2) it is non-negative on this interval although it can be zero for some $x \in [a, b]$, and (3) the PDF must be normalized such that $\int_a^b f(x)\,dx = 1$. Here a and b represent real number or infinite limits (i.e., $a \to -\infty$ and/or $b \to \infty$) and the interval can be either closed or open.

A PDF is a *density* function, i.e., it specifies the probability *per unit of* x, so $f(x)$ has units that are the inverse of the units of x. The probability that x falls within the interval $a \le x_1 < x < x_2 \le b$ is

$$\text{Prob}\{x_1 \le x \le x_2\} = \int_{x_1}^{x_2} f(x)\,dx. \tag{6.1}$$

The integral defined by

$$\boxed{F(x) \equiv \int_a^x f(x')\,dx',} \tag{6.2}$$

where $f(x)$ is a PDF over the interval $[a, b]$, is called the *cumulative distribution function* (CDF) of f. Note that, from this definition, a CDF has the following properties: (1) $F(a) = 0$, (2) $F(b) = 1$, and (3) $F(x)$ is monotone increasing, because f is always non-negative.

The CDF is a direct measure of probability. The value $F(x_i)$ represents the probability that a random sample of the stochastic variable x has a value between a and x_i, i.e., $\text{Prob}\{a \le x \le x_i\} = F(x_i)$. More generally,

$$\text{Prob}\{x_1 \le x \le x_2\} = \int_{x_1}^{x_2} f(x)\,dx = F(x_2) - F(x_1). \tag{6.3}$$

6.2.2 Discrete Random Variable

Some PDFs are defined only for discrete values of a random variable x. For example, in rolling a die the number of dots on the upward face has only six possible outcomes, namely $x_1 = 1, x_2 = 2, \ldots, x_6 = 6$. In such cases, $f_i \equiv f(x_i)$ represents the probability of event i, where $i = 1, 2, \ldots, I$. In general, the number of outcomes I can be finite or unbounded. Then for $f_1, f_2, \ldots, f_I$ to be a PDF it is required that (1) $f_i \ge 0$ and (2) $\sum_{i=1}^{I} f_i = 1$. Further, the discrete CDF

$$F_i \equiv \sum_{j=1}^{i} f_j \tag{6.4}$$

can be interpreted as the probability that one of the first i events occurs. This discrete CDF has the properties that (1) $F_1 = f_1$, (2) $F_I = 1$, and (3) $F_i \ge F_j$, if $i \ge j$.

6.3 Mode, Mean and Median

Radiation measurements may consist of a single measurement or a series of measurements of a radioactive source. Consider a set of measurements $x_1, x_2, \ldots, x_N$, where each x_i is an observed value and N represents the number of measurements taken. How are certain properties of this set of data determined, and which properties contain important information to the experimenter? One such property may be a central value of the data set, referred to as a *location index* [Kendall and Stuart 1977]. The location index may be the

true value or an experimentally determined value. Further, the location index may be the *mode* (or most probable value), the average (or *mean* value), or it may be the *median* (or middle) value of the data set. An example of these three location indices is shown in Fig. 6.1.

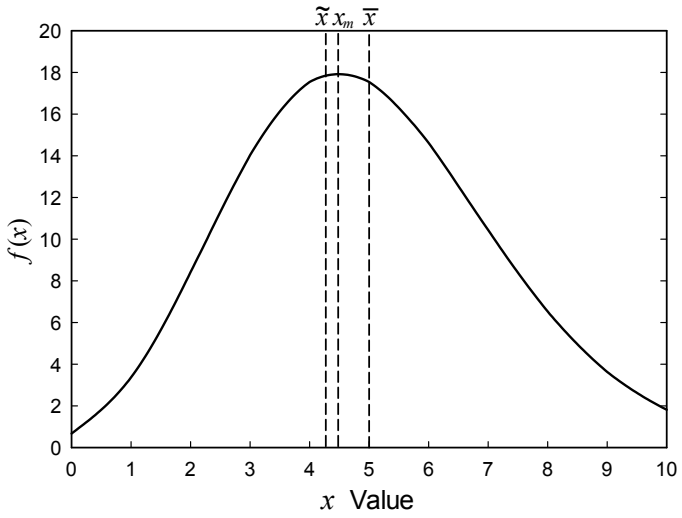

Figure 6.1. Three often quoted location indices of a distribution function, the mode x_m, the median $\tilde{x}$, and the mean $\overline{x}$.

6.3.1 Mode

The mode of a numerical data set is the most probable value, or the most frequently observed value, of that data set. For a continuous function $f(x)$ the mode is the value x_m at which $f(x)$ is maximum and is found from

$$\left.\frac{df(x)}{dx}\right|_{x=x_m} = 0. \tag{6.5}$$

For a discrete data set, the mode can be determined by noting the frequency at which a result is observed, and selecting the most commonly observed result.

Unfortunately, $f(x)$ may actually have several points that yield maxima in the distribution, hence the mode may not be a unique attribute. For such a case, the PDF is said to be multimodal and each maximum can be called a mode. However, in this book, the distribution functions that describe radiation counting always have a single mode.

6.3.2 Mean

The mean of some random variable x, also referred to as the *average* or *expected value* of x, is defined for any continuous function $g(x)$ defined on the interval $[a, b]$ as

$$\mu(x) \equiv \int_a^b xg(x)\,dx \Big/ \int_a^b g(x)\,dx. \tag{6.6}$$

If $g(x)$ is also a PDF, now represented by $f(x)$, then $\int_a^b f(x)\,dx = 1$ and the mean for a continuous PDF is given by

$$\mu(x) = \int_a^b xf(x)\,dx. \tag{6.7}$$

The mean of a PDF is sometimes denoted by $\langle x \rangle$ or by $E(x)$ (for the expected value of x). More generally, the *central moments* of a PDF are defined as

$$\mu(x^n) = \int_{-\infty}^{\infty} x^n f(x)\, dx, \qquad n = 1, 2, \ldots. \tag{6.8}$$

Thus, the mean of a PDF is just the first central moment. The higher central moments give information about the shape of the PDF. In fact, a PDF can be uniquely expressed in terms of its moments so that knowing *all* the moments is tantamount to knowing the PDF itself [Cramèr 1946]. For a *discrete* PDF, the mean is calculated as

$$\mu(x) = \frac{1}{I} \sum_{i=1}^{I} x_i f_i. \tag{6.9}$$

6.3.3 Median

The median and mean of a variable are not the same, yet are often erroneously used synonymously as the average. The word median actually refers to "middle," not average. For a PDF the median $\tilde{x}$ or med(x) is that value of x for which half the area under the distribution lies to the left of $\tilde{x}$ and half to the right of $\tilde{x}$, i.e.,

$$\int_{-\infty}^{\tilde{x}} f(x)\, dx = \int_{\tilde{x}}^{\infty} f(x)\, dx = \frac{1}{2}, \tag{6.10}$$

or, in words, the probability that $x < \tilde{x}$ is exactly equal to the probability that $x > \tilde{x}$.

To find the median of a discrete PDF, the f_i are rearranged in ascending (or descending) order, from smallest to the largest (or largest to smallest). The ordered sequence is denoted by $f_{(1)}, f_{(2)}, \ldots, f_{(I)}$. The median is then defined as

$$\tilde{x} = \begin{cases} \text{middle value of } f_{(i)}, & \text{if } I \text{ is odd} \\ \text{mean value of two middle } f_{(i)}\text{'s}, & \text{if } I \text{ is even} \end{cases}. \tag{6.11}$$

6.4 Variance and Standard Deviation of a PDF

As discussed above, PDFs have three location indices that give a measure of where the central portion of the PDF is located, with the mean value $\overline{x}$ the most commonly used. However, this value gives no information about the spread of the PDF for values above and below $\overline{x}$. Typically, a location index, such as $\overline{x}$, is quoted along with a *dispersion index*, where the dispersion index is a measure of the spread of data relative to the mean. From the definition of the mean one has for any PDF

$$\int_a^b (x - \overline{x}) f(x) dx = 0 \qquad \text{or} \qquad \sum_{i=1}^{I} (f_i - \mu(x)) = 0. \tag{6.12}$$

This result says that the average deviation from the mean is always equal to 0, and does little to assist with a description of the spread of the PDF. Instead, the two most used dispersion indices in radiation counting statistics are the *variance* and the *standard deviation*.

The variance for a continuous PDF $f(x)$ is defined as

$$\sigma^2(x) \equiv \text{var}(x) = \int_a^b (x - \mu(x))^2 f(x) dx, \tag{6.13}$$

where $\sigma(x)$ is the *standard deviation* (or standard error) of the PDF $f(x)$ and $\mu(x)$ is the mean of the PDF given by Eq. (6.7). From Eq. (6.13) the variance is seen to be the average value of $(x-\mu(x))^2$ and the standard deviation is the positive root of that average value. Equation (6.13) can be rearranged as

$$\sigma^2(x) = \int_a^b (x-\mu(x))^2 f(x)\,dx = \int_a^b x^2 f(x)dx - 2\mu(x)\int_a^b xf(x)\,dx + \mu^2(x)\int_a^b f(x)\,dx$$

$$= \mu(x^2) - 2\mu(x)\,\mu(x) + \mu^2(x) = \mu(x^2) - \mu^2(x). \tag{6.14}$$

Thus, the variance is the difference between the second central moment and the square of the first central moment of the PDF. This result is a far more meaningful and useful result compared to Eq. (6.13). The standard deviation $\sigma(x) = \sqrt{\sigma^2(x)}$ relates the spread about the mean value of a distribution function, and hence allows an experimenter to quickly assess the expected error when designing an experiment that closely follows a known PDF. For a *discrete* PDF a similar result is obtained for the variance:

$$\sigma^2(x) \equiv \sum_{i=1}^{I}(x_i-\mu)^2 f_i = \mu(x^2) - \mu^2(x). \tag{6.15}$$

6.5 Probability Data Distribution

Closely related to a discrete PDF is the *data distribution function* $f_{\mathcal{D}}(x_i)$, which is an *experimentally* determined distribution function as distinct from a theoretical model. The data distribution function is defined by a set of observed data. Suppose an outcome x is observed on occasion from a set of N trial experiments. Typically, the number of times n_i the desired outcome x_i is observed is divided by the number of trials conducted N. The only exact method to determine the probability $f(x_i)$ of observing the outcome x_i is to perform an *infinite* number of trials, namely

$$f(x_i) = \lim_{N\to\infty} \frac{n_i}{N}. \tag{6.16}$$

Conducting an infinite number of trials is obviously impractical. In reality, an experimenter must decide upon some practical finite number of N trials that can produce an estimate of $p(x_i)$, within some acceptable margin of error, as

$$f(x_i) \simeq f_{\mathcal{D}}(x_i) = \frac{n_i}{N}. \tag{6.17}$$

In general, accuracy increases for the estimate of $f(x_i)$ given by Eq. (6.17) as the number of trials N increases. However, in some cases, an experimenter may be unable to perform a desired number of trials, because, for example, of time constraints, and consequently must instead rely upon a smaller number of trials. In such a case reporting the uncertainty associated with the estimated value of $f_{\mathcal{D}}(x_i)$ is imperative.

As an example of constructing a data PDF, consider an experiment in which a radiation detector is used to obtain a series $\hat{C}_1, \hat{C}_2, \ldots, \hat{C}_N$ of N measurements or counts (each under identical conditions).[2] In this set of N measurements, the number of resulting counts for some measurements may be equal; others may be unique. The number of times n_i identical counts x_i are observed is tallied. This tallying leads to a tally sequence $n_1, n_2, \ldots, n_M$ of observation of counts $x_1, x_2, \ldots, x_M$, where $M(N) \leq N$. Note $\sum_{i=1}^{M} n_1$ equals the total number N of measurements made. The data distribution function is then determined by dividing each tally by N, i.e.,

[2] Throughout the text, a *measurement* is defined as the process of collecting counting data from a radiation detector, and a *count* is defined as the single observation of a radiation event during a measurement.

$$f_{\mathcal{D}}(x_i) \equiv f_{\mathcal{D}i} = \frac{n_i}{N}, \quad i = 0, 1, 2, \ldots, M. \tag{6.18}$$

Here $f_{\mathcal{D}i}$ is the *estimate* of the true probability $f(x_i)$ of observing x_i. Summation of all these estimates gives

$$\sum_{i=0}^{M} f_{\mathcal{D}}(x_i) = \frac{n_0}{N} + \frac{n_1}{N} + \frac{n_2}{N} + \ldots + \frac{n_M}{N} = 1. \tag{6.19}$$

This result shows that a proper *data* PDF must be normalized to unity.

Example 6.1: Suppose the number of washing loads brought into a laundromat per person between the hours of 1:00 pm and 4:00 pm one day are observed to be 1, 2, 1, 3, 2, 2, 3, 1, 4, 2, 1, 2. What is the data distribution function?

Solution:

From the 12 persons observed, 4 people had 1 load, 5 people had 2 loads, 2 people had 3 loads, and only 1 person had 4 loads. Values for the data distribution function are as follows:

$$f_{\mathcal{D}1} = \frac{n_1}{12} = \frac{4}{12} \qquad f_{\mathcal{D}2} = \frac{n_2}{12} = \frac{5}{12}$$
$$f_{\mathcal{D}3} = \frac{n_3}{12} = \frac{2}{12} \qquad f_{\mathcal{D}4} = \frac{n_4}{12} = \frac{1}{12}$$

and $f_{\mathcal{D}n} = 0$ for $n = 0$ and $n \geq 5$. By summing all possibilities, the data distribution function is shown to be normalized, i.e.,

$$\sum_{i=0}^{\infty} f_{\mathcal{D}}(x_i) = 0 + \frac{4}{12} + \frac{5}{12} + \frac{2}{12} + \frac{1}{12} + 0 + 0 + ... = 1. \tag{6.20}$$

6.5.1 Sample Mean

In most experiments, counts are accumulated and an average value is determined from the observations $\widehat{C}_i$. Hence, the data generally are in the form of discrete observations rather than as a continuous function. The *true mean* of an experimentally observed random variable is correctly written as

$$\mu(x) = \sum_{i=1}^{I} x_i f_i = \lim_{N\to\infty} \frac{1}{N} \sum_{i=1}^{N} \widehat{C}_i = \lim_{N\to\infty} \sum_{i=1}^{M(N)} x_i f_{\mathcal{D}i}, \tag{6.21}$$

where as $N \to \infty$ then $M(N) \to I$, the number of possible different observations. The above result indicates that the exact value of an average can be determined only if an infinite number of measurements are recorded. The luxury of conducting infinite measurements for an experiment is rare, hence a more practical method of estimating the mean is to use an arithmetic average. This estimate is called the *sample mean*. The sample mean (or experimental mean) is

$$\boxed{\mu(x) \simeq \overline{x} = \frac{1}{N} \sum_{i=1}^{N} \widehat{C}_i.} \tag{6.22}$$

It should be remembered that the sample mean is only an approximation or estimate of the true mean, As more measurements are made, thereby increasing N, it is expected that the value $\overline{x}$ approaches the true mean $\mu(x)$. Usually, $\overline{x}$ is believed to yield a more accurate result of the expected value if a series of measurements is made rather than any single measurement, all experimental conditions being the same for each measurement. In other words, accuracy increases as data are accumulated. Typically, only one significant digit of precision is added to $\overline{x}$ above that reported for the individual x_i.

The result $\overline{x}$ can be defined in a similar fashion as Eq. (6.9), provided that the data distribution function $f(x_i)$ is known, namely

$$\boxed{\overline{x} = \sum_{i=0}^{N} x_i f_{\mathcal{D}}(x_i)} \quad . \tag{6.23}$$

For instance, a given set of data can be cataloged according to the frequency of observations. The observed frequency becomes a legitimate estimate of the probability distribution for the random variable. This experimentally determined data distribution function changes as more data are accumulated, yet converges on the true probability distribution function as the number of sampled data points approaches infinity.

Example 6.2: Suppose a local farmer sells apples each day at the farmer's market. He sells the following number of apples for each day of the week, starting on Sunday and ending Saturday: 28, 14, 19, 24, 18, 21, 32. What is the sample mean for the week of sales?

Solution:

The sample mean of apples sold per day from these 7 x_i's is found to be

$$\overline{x} = \frac{1}{7}\sum_{i=1}^{7} x_i = \frac{28+14+19+24+18+21+32}{7} = \frac{156}{7} = 22.3.$$

From the limited data set, it is concluded that the farmer sells 22.3 apples per day on average.

Example 6.3: Given two fair dice, what is the probability distribution function for expected numbers resulting from tosses of the die compared to a an experimental distribution function composed of 100 experimental trials?

Solution:

For two dice there are 36 possible number combinations. The probability distribution function representing the summed die values and expected frequencies are shown in Table 6.1 and Fig. 6.2.

Table 6.1. Probabilities associated with throwing two dice.

Value of Thrown x_i	1	2	3	4	5	6	7	8	9	10	11	12
No. of Combinations	0	1	2	3	4	5	6	5	4	3	2	1
$f(x_i)$	0	$\frac{1}{36}$	$\frac{2}{36}$	$\frac{3}{36}$	$\frac{4}{36}$	$\frac{5}{36}$	$\frac{6}{36}$	$\frac{5}{36}$	$\frac{4}{36}$	$\frac{3}{36}$	$\frac{2}{36}$	$\frac{1}{36}$

Because there is no possibility of throwing a 0 or 1, the following is found.

$$\sum_{x=1}^{12} f(x_i) = \frac{0}{36} + \frac{1}{36} + \frac{2}{36} + \frac{3}{36} + \frac{4}{36} + \frac{5}{36} + \frac{6}{36} + \frac{5}{36} + \frac{4}{36} + \frac{3}{36} + \frac{2}{36} + \frac{1}{36} = 1,$$

which is the expected result for a probability distribution function. Because the actual PDF is known, the true mean is calculated to be

$$\mu(x) = \sum_{x=1}^{12} x_i f(x_i) = 1\left(\frac{0}{36}\right) + 2\left(\frac{1}{36}\right) + 3\left(\frac{2}{36}\right) + 4\left(\frac{3}{36}\right) + 5\left(\frac{4}{36}\right) +$$
$$6\left(\frac{5}{36}\right) + 7\left(\frac{6}{36}\right) + 8\left(\frac{5}{36}\right) + 9\left(\frac{4}{36}\right) + 10\left(\frac{3}{36}\right) + 11\left(\frac{2}{36}\right) + 12\left(\frac{1}{36}\right) = 7.$$

That the expectation value is 7 is intuitively correct because the die-tossing PDF is symmetric about the number 7.

By comparison, the data distribution function for an experiment in which 100 tosses of two dice were observed is shown in Table 6.2 and in Fig. 6.2. Equation (6.23) is used to determine the experimental mean

Table 6.2. Observed data for 100 throws of two dice.

Value of Thrown x_i	1	2	3	4	5	6	7	8	9	10	11	12
No. of Combinations	0	1	2	3	4	5	6	5	4	3	2	1
Observed Occurences	0	3	5	11	7	15	16	13	10	10	7	3
$f_{\mathcal{D}}(x_i)$	.00	.03	.05	.11	.07	.15	.16	.13	.10	.10	.07	.03

of the observed data from the dice tosses, i.e.,

$$\overline{x} = \sum_{x=1}^{12} x_i f_{\mathcal{D}_i} = 1\,(.00) + 2\,(.03) + 3\,(.05) + 4\,(.11) + 5\,(.07) + 6\,(.15)$$
$$7\,(.16) + 8\,(.13) + 9\,(.10) + 10\,(.10) + 11\,(.07) + 12\,(.03) = 7.09$$

Here it is found that the sample mean $\overline{x}$ is close to the true mean $\mu(x)$. Should the experiment be conducted again, the outcome of the experimental mean would once again be near the true mean (although not necessarily the same as the previous result), and the data distribution function would be slightly different. If more data are accumulated in the experiment, thereby increasing the number of trials N, the data distribution function approaches that of the probability distribution function, and the experimental mean approaches the value of the true mean.

6.5.2 Sample Median

Consider the *sample median* $\tilde{x}$ from a set of measurements $x_1, x_2, ..., x_N$, where each x_i is a non-negative number and N represents the number of measurements taken. To find the sample median, the x_i are rearranged in ascending (or descending) order, from smallest to largest (or largest to smallest). The ordered sequence is denoted by $x_{(1)}, x_{(2)}, \ldots, x_{(N)}$. The sample median is defined as

$$\tilde{x} = \begin{cases} \text{middle value of } x_{(i)}, & \text{if } N \text{ is odd} \\ \text{mean value of the two middle } x_{(i)}, & \text{if } N \text{ is even} \end{cases}. \tag{6.24}$$

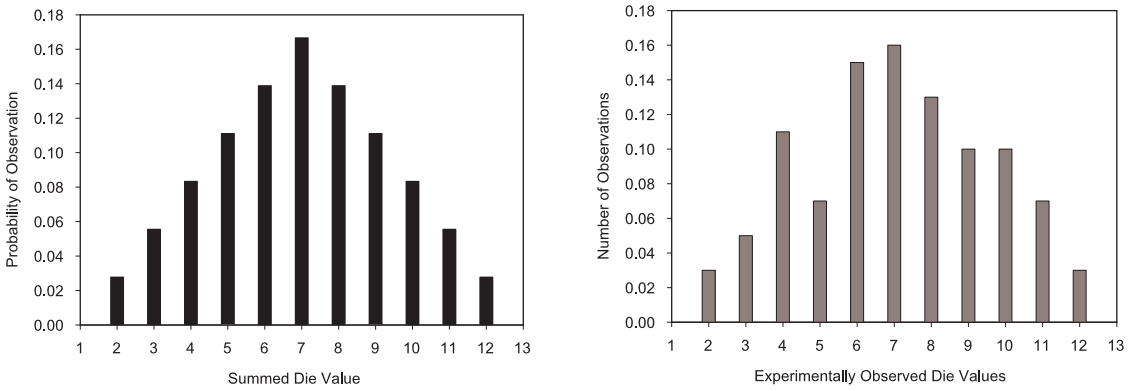

Figure 6.2. The PDFs for the tossing of two dice. Left: theoretical probabilities for obtaining all possible summed values of the dice. Right: experimental probabilities obtained after 100 throws.

Example 6.4: Revisit Example 6.2, in which a farmer sold the following number of apples in consecutive days of a single week: $x_1, x_2, \ldots, x_N = 28,\ 14,\ 19,\ 24,\ 18,\ 21,\ 32$. Find the experimental median.

Solution:

Reordering the data from lowest to highest values produces the set

$$x_{(1)}, x_{(2)}, \ldots, x_{(N)} = 14, 18, 19, 21, 24, 28, 32.$$

Here $N = 7$ is odd and the sample median (or middle value) is represented by the 4th entry in the ordered list, i.e., $\tilde{x} = x_{(4)} = 21$. Notice the sample median is not equal to the sample mean found in Example 6.2.

Example 6.5: Suppose a well pumping company accumulates data regarding the lifetimes of 1/2 horsepower pumps. Over a period of 12 years, the following failure times, in months, for 20 different pumps were observed,

$$31, 29, 60, 49, 30, 95, 37, 85, 39, 47, 135, 50, 52, 21, 54, 45, 58, 12, 64, 40$$

What are the sample mean and median values for these data?

Solution:

The sample mean is

$$\overline{x} = \frac{1}{20}\sum_{i=1}^{20} x_i = \frac{1}{20}(31 + 60 + 29 + 49 + 30 + 95 + 37 + 85 + 39 + 47 + 135 + 50 + 52 + 21 + 54 + 45 + 58 + 12 + 64 + 40) = \frac{1033}{20} = 51.7.$$

Hence, the average lifetime of the 1/2 horsepower pump is found to be 51.7 months. To find the sample median, the order is arranged from smallest to largest values,

$$12, 21, 29, 30, 31, 37, 39, 40, 45, 47, 49, 50, 52, 54, 58, 60, 64, 85, 95, 135$$

Because $N = 20$ is even, the sample median is the average of the 10th and 11th values in the ordered list,

$$\tilde{x} = \frac{x_{(10)} + x_{(11)}}{2} = \frac{47 + 49}{2} = 48.0.$$

It should be noticed that the sample median is close to, but not equal to, the sample mean in this case.

6.5.3 Trimmed Sample Mean

It is common to encounter experimental data in which some measurements yield values that are quite far from either the sample mean or sample median. Such points are commonly referred to as "outliers," which an analyst may regard as non-representative for the data set. Hence, it is important to notice a major distinction between the sample mean and the sample median. The sample mean takes into account all observed values, whereas the sample median eliminates those values that are not in the middle of the ordered distribution. The sample mean is affected by outlying values, whereas the sample median is not affected by outlying values at all, thereby representing two opposite extremes for interpreting the data distribution.

The sample mean uses all data values, even those from the extreme ends of the distribution, whereas the sample median is insensitive to the extreme values at the two ends of the distribution. One method to eliminate the outliers' influence on the sample mean is to use a *trimmed mean*. As an example, a 5% trimmed mean is computed by eliminating the smallest 5% and the largest 5% of the sample values, and then calculating the sample mean from the remaining data.

There are instances when a standard percentage trimmed mean is prescribed, but the number of measurements does not allow this to be exactly done. For instance, one might have 23 data points, in which case a 10% trimmed mean would need to have 2.3 data points eliminated from the smallest and largest extremes of the ordered distribution. Clearly, this is not possible. Instead, interpolation between the nearest possible points is generally used. For instance, the 10% trimmed mean should be calculated by determining the trimmed mean with only 2 data points removed from upper and lower portions of the distribution, and then repeated with 3 data points removed from upper and lower portions of the distribution. The 10% trimmed mean is determined by appropriate interpolation between the two trimmed means.

Example 6.6: The ordered data in Example 6.5 of the lifetime of pumps, in months, are

$$12, 21, 29, 30, 31, 37, 39, 40, 45, 47, 49, 50, 52, 54, 58, 60, 64, 85, 95, 135$$

It appears that some pumps had very short lifetimes (possibly due to manufacturing defects or ove use) and some had very long lifetimes (possible due to low usage). To avoid these outliers, one should calculate a trimmed mean, for example, a 10% trimmed mean.

Solution:

With this data censoring, the trimmed data are

$$29, 30, 31, 37, 39, 40, 45, 47, 49, 50, 52, 54, 58, 60, 64, 85$$

With only 16 data measurements remaining, the 10% trimmed mean is

$$\overline{x}_{tr(10)} = \frac{1}{16}\sum_{i=1}^{16} x_i = \frac{1}{16}(29 + 30 + 31 + 37 + 39 + 40 + 45 + 47$$
$$+49 + 50 + 52 + 54 + 58 + 60 + 64 + 85) = \frac{770}{16} = 48.1 \text{ months.}$$

Notice that the trimmed mean is now much closer to the uncensored sample median of 48.0 months. This result might indicate to the pump manufacturer that those pumps with lifetimes less than two years were actually defective, and did not represent the true quality of the product.

6.5.4 Sample Variance

Often an experimenter encounters a situation in which data about random variables have been accumulated, yet the true probability distribution function $f(x)$ is unknown. There are several options that might be used to determine an informative measure of the reasonableness of a sample set. The *population* variance and *sample* variance are dispersion indices that deal with the variability of actual data. If the true mean $\mu(x)$ of a distribution is known, then the population variance is denoted $\sigma^2(x)$, and the population standard deviation is $\sigma(x)$, where,

$$\sigma^2(x) = \frac{1}{N}\sum_{i=1}^{N}(x_i - \mu(x))^2. \tag{6.25}$$

However, the actual value of $\mu(x)$ is rarely known. Instead, the experimentally observed average, $\overline{x}$, is usually used as an estimate of $\mu(x)$. Typically, the *sample variance*, denoted s^2, is used to estimate the variance in the data distribution, where

$$\boxed{s^2 = \frac{1}{N-1}\sum_{i=1}^{N}(x_i - \overline{x})^2} \quad . \tag{6.26}$$

The sample standard deviation, denoted by s, is the positive square root of the sample variance. That $N-1$ is used in the denominator instead of N, used in the definition of the population variance, is because all of the N x_i are used to calculate $\overline{x}$, so that only $N-1$ of the x_i are independent of $\overline{x}$. In common parlance, "one degree of freedom" is lost by using $\overline{x}$ to approximate $\mu(x)$ [Box et al. 1978]. Another way of understanding this issue is to recall the result of Eq. (6.22). If $N-1$ of the x_i's are known, the final x_i is already determined because the summation of $(x_i - \overline{x})$ must equal zero. Hence, there are only $N-1$ degrees of freedom that can be used to determine the sample variance.

Example 6.7: A series of 30 radiation measurements are performed on a check source, each measurement 6 seconds long, to calibrate a detection system. Given the following counts as recorded for each measurement, determine the sample mean, the sample variance, the sample standard deviation and plot the data distribution function.

Solution:

Measurement data:

$$29, 30, 26, 33, 32, 31, 19, 35, 29, 31, 38, 25, 23, 33, 24,$$
$$28, 37, 26, 29, 41, 30, 27, 23, 34, 40, 27, 21, 30, 29, 31.$$

From Eq. (6.22), the experimental mean is found to be

$$\overline{x} = \frac{1}{N}\sum_{i=1}^{N} x_i = \frac{891}{30} = 29.7.$$

The sample variance is found from Eq. (6.26)

$$s^2 = \frac{1}{N-1}\sum_{i=1}^{N}(x_i - \overline{x})^2 = \frac{1}{30-1}\sum_{i=1}^{30}(x_i - 29.7)^2 = \frac{816.3}{29} = 28.15.$$

The sample standard deviation is

$$s = \sqrt{28.15} = 5.31.$$

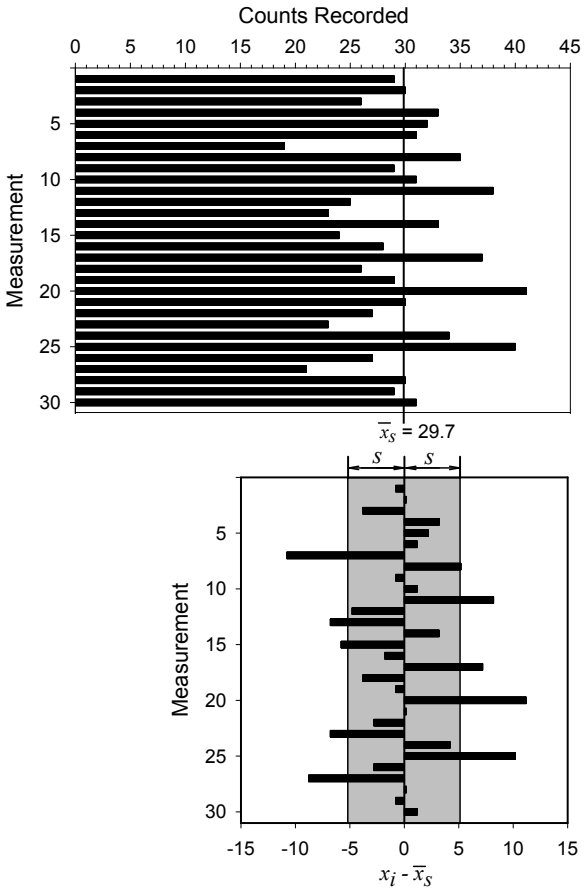

Figure 6.3. The distribution of counts in each of the 30 measurements and the difference, positive and negative, from the mean value ($\overline{x} = 29.7$). Also shown is a comparison with the sample standard deviation ($s = 5.31$).

The sum of the differences, shown in Fig. 6.3, is zero. However, the sample variance and sample standard deviation are non-zero. The sample standard deviation is shown in Fig. 6.3 as compared to the difference $x_i - \overline{x}$ for the 30 measurements.

The data distribution function, $f_{\mathcal{D}}(x_i)$, is determined with Eq. (6.17), where each frequency of observed counts is divided by 30. For instance, four measurements resulted in the observation of $x_i = 29$ counts, yielding

$$f_{\mathcal{D}}(x_i = 29) = \frac{4}{30} = 0.13\overline{3}.$$

The resulting histogram for the 30 measurements is plotted in Fig. 6.4. Finally, it should be noted that as more data are accumulated, the data distribution function begins to take on the appearance of the theoretical PDF, in this case, a Gaussian distribution.

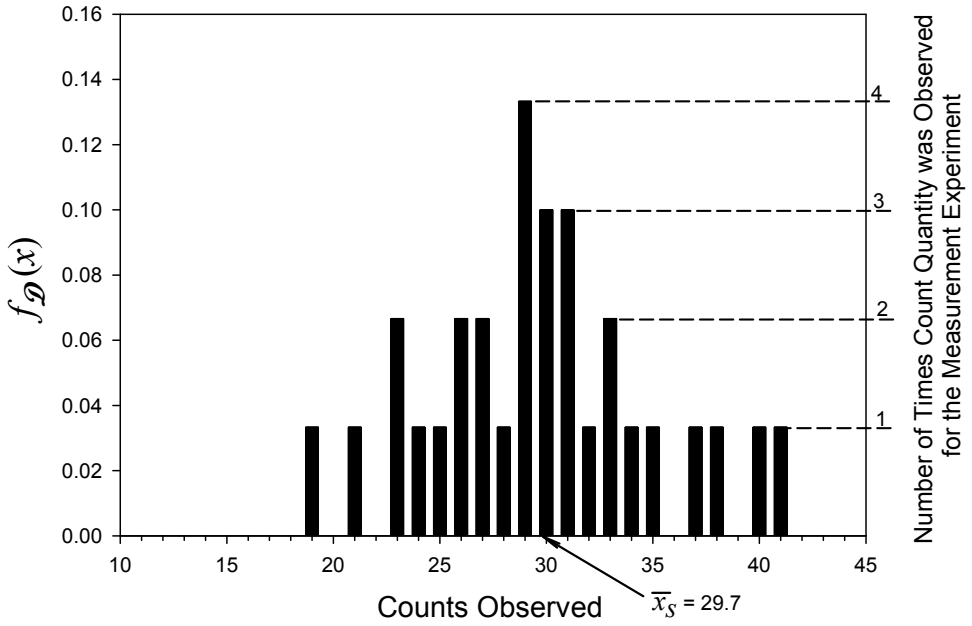

Figure 6.4. The distribution of counts in each of the 30 measurements projected as a data distribution function. The data distribution function describes the experimentally determined probability of observing a randomly chosen number of counts per measurement.

6.6 Binomial Distribution

There are experiments in which only two outcomes are possible, hence the name binomial, which translates as meaning "two terms". Examples of binomial statistical experiments include tossing a coin for "heads" or "tails", picking marbles of two different colors from a box, uncovering shells with or without a prize underneath, and selecting whether or not today is your birthday. If such an experiment, regardless of type, is conducted over N number of trials, then the possibilities of observing either one or the other result can be listed. Typically one of the possible outcomes is listed as a "success" (S) and the other a "failure" (F). For instance, consider a coin toss experiment in which exactly three trials are conducted. In such a case, if the outcome is a "heads" it is listed as a success, and an outcome of "tails" is listed as a failure. For any independent set of 3 trials, there are only 8 possible outcomes, as listed in Table 6.3.

Table 6.3. Possible outcomes of a binomial experiment with $N = 3$.

Outcome	Number of successes	Probability
SSS	3	p^3
SSF	2	$p^2(1-p)$
SFS	2	$p^2(1-p)$
FSS	2	$p^2(1-p)$
SFF	1	$p(1-p)^2$
FFS	1	$p(1-p)^2$
FSF	1	$p(1-p)^2$
FFF	0	$(1-p)^3$

The probability of observing a success is denoted p. Because there are only two possible outcomes from any single trial, the probability of observing a failure must be $(1-p)$. Also listed in Table 6.3 are the probabilities of achieving any of the possible combinations. For instance, the probability of achieving a success 3 times in a row is $ppp = p^3$. The probability of observing an outcome for x number of times from N trials can be determined by dividing the number of times the desired outcome can appear by the total number of possible outcomes. Because only one outcome results in three successes, the probability of throwing three heads in a row out of three trials is $1/2^3 = 0.125$. Unfortunately, for a large number of trials N,

listing all possible outcomes becomes an explosively difficult method to use. For example, there are 1024 possible outcome combinations for 10 independent trials.

Fortunately, a Swiss mathematician Jacques Bernoulli (a.k.a. James or Jacob) worked out a general solution to binomial experiments,[3] often referred to as *Bernoulli trials*, hence eliminating the need to list all possible experimental outcomes. Let p denote the probability of observing a success for a particular event. Then the probability that the event is not observed in any trial is $q = 1-p$. In any trial one must either observe the event or not observe the event. Thus, $p + q = 1 = (p + q)^N$. A binomial expansion then gives

Figure 6.5. Jacques Bernoulli (1654–1705).

$$(p+q)^N = p^N + Np^{(N-1)}q + \frac{N(N-1)}{2!}p^{N-2}q^2 + \frac{N(N-1)(N-2)}{3!}p^{N-3}q^3 + ... + q^N = 1. \quad (6.27)$$

Substitution of $(1-p)$ for q yields,

$$(p+q)^N = p^N + Np^{(N-1)}(1-p) + \frac{N(N-1)}{2!}p^{N-2}(1-p)^2 + \frac{N(N-1)(N-2)}{3!}p^{N-3}(1-p)^3 + ... + (1-p)^N = 1, \quad (6.28)$$

which can be rewritten as,

$$(p+q)^N = f(N) + f(N-1) + f(N-2) + ... + f(0) = 1. \quad (6.29)$$

Here the PDF $f(x)$ is the probability of observing the event x (an integer) number of times in N trials. Each individual term in Eqs. (6.28) and (6.29) can be denoted as

$$\boxed{\mathcal{B}(x|p,N) \equiv f_{\mathcal{B}}(x) = \frac{N!}{(N-x)!x!}\,p^x(1-p)^{N-x}, \quad x = 0, 1, 2, \ldots, N.} \quad (6.30)$$

In this discrete PDF (see Sec. 6.2.2), known as the *binomial* distribution, the random variable x assumes non-negative integer values, i.e., $x_1 = 0, x_2 = 1, \ldots$.

The binomial distribution is the governing distribution whenever the following experimental conditions are fulfilled:

1. The experiment consists of a fixed number of N trials, where N is specified before the experiment begins.

2. Each trial is identical in condition, and each trial can result in one of two possible outcomes. Generally, the outcome is denoted as a success S or a failure F.

[3] Late in the 17th century, Jacques Bernoulli (see Fig. 6.5) derived the binomial PDF and, of even greater importance, the law of large numbers. These results were eventually published posthumously in 1713 by his nephew, Nicolaus Bernoulli, in *Ars Conjectandi* ("The Art of Conjecture").

3. The trials are independent, and the outcome of each trial does not affect the outcomes of other trials.

4. The probability of a success p is the same from trial to trial.

For instance, if a test involves the probability of removing specific balls from a box (for instance, black or white in a mixture of both), for each ball removed from the box the actual probability for the next test has changed because a ball has been removed. For large sample sets, the resulting change in p may be small enough to be of no consequence; however, the experimenter must review the possibility of whether or not replacement does matter. Generally, an experiment can be approximated as being binomial provided that the sample size, N, is less than 5% of the population size. For instance, with a box of 10,000 marbles, extracting 500 or less marbles during the experiment can be approximated as a binomial experiment.[4]

For any given binomial experiment, the average number of successes observed is

$$\mu(x) = \sum_{x=0}^{N} x\mathcal{B}(x|p,N)) = \sum_{x=0}^{N} \frac{xN!}{(N-x)!x!}\, p^x(1-p)^{N-x}. \tag{6.31}$$

Let $y = x-1$ and $M = N-1$; then $x = y+1$ and $N = M+1$, and it is easy to show $N-x = M-y$. Thus

$$\begin{aligned}\mu(x) &= \sum_{y=0}^{M} \frac{(y+1)(M+1)!}{(M-y)!(y+1)!}\, p^{y+1}(1-p)^{M-y} = \sum_{y=0}^{M} \frac{(M+1)(M)!}{y!(M-y)!}\, p\, p^y(1-p)^{M-y} \\ &= (M+1)p\sum_{y=0}^{M} \frac{(M)!}{y!(M-y)!}\, p^y(1-p)^{M-y} = Np\sum_{y=0}^{M} f(y|p,M)\end{aligned}$$

Because the summation of a discrete PDF over all possible outcomes is unity, the above simplifies to

$$\mu(x) = Np. \tag{6.32}$$

In a similar manner, the variance of the binomial distribution is found to be

$$\sigma^2(x) = pN(1-p). \tag{6.33}$$

Example 6.8: A simple experiment, with which most readers are familiar, is that of tossing a fair coin. Intuitively it is known that the probability of observing a "head" or a "tail" is 50%. Suppose the observation of a heads is determined to be a success. What is the probability that out of 10 tosses exactly 7 successes are observed? What is the average number of successes expected from 10 coin tosses?

Solution:

For the parameters $p = 0.500$, $x = 7$, and $N = 10$, the probability of throwing exactly 7 heads out of 10 trials is

$$\mathcal{B}(x|0.5,10) = \frac{N!}{(N-x)!x!}\, p^x(1-p)^{N-x} = \frac{10!}{(10-7)!7!}\,(0.5)^7(1-0.5)^{10-7} = \frac{10!}{3!7!}(0.5)^7(0.5)^3 = 0.117.$$

[4] Note that, while the binomial distribution is a good approximation for large sample populations, its use for small populations without replacement can result in unacceptable error. For such small populations, the *hypergeometric distribution* must be used [Devore 1991]. Because this distribution is rarely used for radiation counting, the hypergeometric distribution is not covered here.

There is, thus, an 11.7% probability that exactly 7 out of 10 tosses result in the observation of heads. The expected number of heads observed from 10 coin tosses is $\mu = pN = (10)(0.5) = 5$. The variance is $\sigma^2 = pN(1-p) = (0.5)(10)(0.5) = 2.50$. Finally, the standard deviation $\sigma = \sqrt{2.50} = 1.58$. Thus, for 10 coin tosses, the expected number of heads that are observed is 5.00 ± 1.58.

The expected number of successes from a binomial distribution for various values of p are shown in Table 6.4 for the condition in which $N = 10$. The binomial distribution becomes symmetric for $p = 0.5$, such as with the coin toss example. The summed probabilities equal unity in each case, meaning that out of 10 trials, at least one of the observations in the column marked x are observed. The condition in which $p = .5$ with $N = 10$, as with the coin toss example, is plotted in Fig. 6.6. For the case of $N = 10$ trials the probabilities of different outcomes for fixed values of p are listed in Table 6.4.

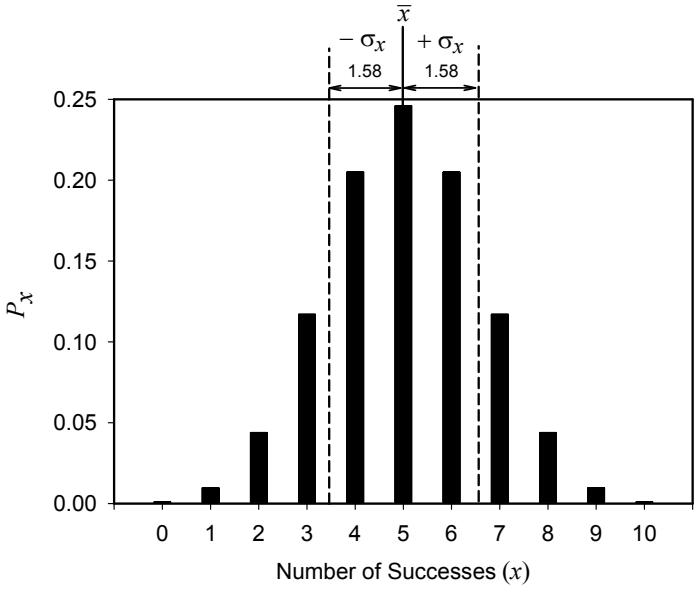

Figure 6.6. The binomial distribution for the coin toss example, in which $N = 10$, showing the probabilities of throwing exact numbers of heads (successes).

6.6.1 Radioactive Decay and the Binomial Distribution

Radionuclides are governed by binomial statistics because a radionuclide either decays in a time interval t or it does not. Consider a radioactive sample initially containing N_o identical radionuclides with a decay constant λ. The probability a radionuclide does not decay in time t is $(1-p) = e^{-\lambda t}$, so the probability it does decay is $p = (1 - e^{-\lambda t})$. From Eq. (6.30) the probability $f_{\mathcal{B}}(x)$ that x atoms decay in time T is

$$f_{\mathcal{B}}(x) = \frac{N_o!}{(N_o - x)!x!}(1 - e^{-\lambda T})^x (e^{-\lambda T})^{N_o - x} \qquad x = 0, 1, 2, \ldots, N_o. \tag{6.34}$$

From Eq. (6.32) the average number decaying in time T is

$$\mu(x) = N_o(1 - e^{-\lambda T}) \tag{6.35}$$

and the variance is

$$\sigma^2(x) = N_o(1 - e^{-\lambda T})e^{-\lambda T} = \mu(x)e^{-\lambda T}. \tag{6.36}$$

Table 6.4. Probabilities for the number of successes for a binomial distribution with $N = 10$ and $p = 0.1$, 0.3, 0.5, 0.7 and 0.9.

	$f_{\mathcal{B}}(x)$				
x	$p = 0.1$	$p = 0.3$	$p = 0.5$	$p = 0.7$	$p = 0.9$
0	0.348678	0.028248	0.000977	5.90×10^{-6}	10^{-10}
1	0.387420	0.121061	0.009766	0.000138	9×10^{-9}
2	0.193710	0.233474	0.043945	0.001447	3.65×10^{-7}
3	0.057396	0.266828	0.117188	0.009002	8.75×10^{-6}
4	0.011160	0.200121	0.205078	0.0036757	0.000138
5	0.001488	0.102919	0.246094	0.102919	0.001488
6	0.000138	0.036757	0.205078	0.200121	0.011160
7	8.75×10^{-6}	0.009002	0.117188	0.266828	0.057396
8	3.65×10^{-7}	0.001447	0.043945	0.233474	0.193710
9	9×10^{-9}	0.000138	0.009766	0.121061	0.387420
10	10^{-10}	5.90×10^{-6}	0.000977	0.028248	0.348678

If $\lambda T \ll 1$, i.e., the measurement time is very much less than the half-life of the radionuclide, $\sigma(x) = \sqrt{\mu(x)}$.

Let c be the probability that a decay produces a count in a radiation detection system. Then the probability a count is observed in time T is $p_c = c(1 - e^{-\lambda T}) \simeq c\lambda T$ if $\lambda T \ll 1$. Thus, the probability of obtaining x counts in time T is

$$f_{\mathcal{B}}(x) = \frac{N_o!}{(N_o - x)!x!}(c\lambda T)^x(1 - c\lambda T)^{N_o - x}, \qquad x = 0, 1, 2, \ldots, N_o. \tag{6.37}$$

Although, this approximation for $f_{\mathcal{B}}(x)$ and the exact result of Eq. (6.34) describe the statistics of radioactive decay, these descriptions have little utility. Because N_o is typically very large (10^5–10^{15}), the terms involving N_o typically are uncalculably huge or ridiculously small. Another difficulty with using the binomial distribution to describe radioactive decays occurs if a radioactive sample has multiple radioactive species. In this case, the probability of obtaining x decays in time T is no longer described by a binomial distribution. However, both of these problems are avoided by using the Poisson distribution discussed next.

6.7 Poisson Distribution

Suppose that an experimenter is observing a radiation source anticipating the emission of a radiation quantum. The source contains m different radioactive species with M_i atoms and a decay constant λ_i for the ith species. Assume there is negligible decay in the observation time T, i.e., $\lambda_i T \ll 1$, so that the M_i do not change appreciably. The observing time T is segmented into N smaller intervals of the same length Δt; hence, $T = N\Delta t$. From Eq. (6.34) the probability that no atoms of species i decays in Δt is

$$f_{\mathcal{B}}(0) = \frac{M_i!}{(M_i - 0)!0!}(1 - e^{-\lambda_i \Delta t})^0(e^{-\lambda_i \Delta t})^{(M_i - 0)} = e^{-\lambda_i M_i \Delta t}. \tag{6.38}$$

The probability none of the radionuclides decay in Δt is, thus, $\prod_{i=1}^{m} \exp(-\lambda_i M_i \Delta t)$ and the probability one (or more) radionuclides decay is

$$p_{\text{decay}} = 1 - \prod_{i=1}^{m} e^{-\lambda_i M_i \Delta t} = 1 - e^{-(\lambda_1 M_1 + \ldots + \lambda_m M_m)\Delta t}. \tag{6.39}$$

As $N \to \infty$, $\Delta t \to 0$ and

$$p_{\text{decay}} \simeq \left(\sum_{i=1}^{m} \lambda_i M_i \right) \Delta t, \tag{6.40}$$

which also vanishes as $N \to \infty$ with the probability of two or more decays vanishing faster than the probability of a single decay in Δt. Now define c_i as the probability of recording a count per decay of radionuclide species i,[5] so the probability of recording a count in a small Δt is

$$p = \left(\sum_{i=1}^{m} c_i \lambda_i M_i \right) \Delta t, \tag{6.41}$$

Again as $N \to \infty$, both $\Delta t \to 0$ and $p \to 0$; but the product Np remains finite, i.e., Eq. (6.41) with $\Delta t = T/N$ yields

$$Np = N \left(\sum_{i=1}^{m} c_i \lambda_i M_i \right) \frac{T}{N} = \left(\sum_{i=1}^{m} c_i \lambda_i M_i \right) T \equiv \mu. \tag{6.42}$$

Thus, in the limit of large N, with $p = \mu/N$ the binomial distribution of Eq. (6.30) becomes

$$f_{\mathcal{B}}(x) = \lim_{N\to\infty} \frac{N!}{(N-x)!x!} \left(\frac{\mu}{N}\right)^x \left(1 - \frac{\mu}{N}\right)^{N-x}, \quad x = 0, 1, 2, ..., N \tag{6.43}$$

When N is large, the evaluation of the binomial distribution of Eq. (6.43) becomes computationally difficult because the various factorials in the binomial coefficient become enormous. But Eq. (6.43) can be considerably simplified as follows:

$$\begin{aligned} \lim_{N\to\infty} f_{\mathcal{B}}(x) &= \lim_{N\to\infty} \frac{N(N-1)\cdots(N-x+1)}{N \quad (N) \quad \cdots \quad (N)} \frac{\mu^x}{x!} \left(1 - \frac{\mu}{N}\right)^N \left(1 - \frac{\mu}{N}\right)^{-x} \\ &= \lim_{N\to\infty} \frac{\left(1 - \frac{1}{N}\right) \cdots \left(1 - \frac{x-1}{N}\right)}{\left(1 - \frac{\mu}{N}\right)^x} \frac{\mu^x}{x!} \left(1 - \frac{\mu}{N}\right)^N. \end{aligned} \tag{6.44}$$

As $N \to \infty$, the terms $(1 - i/N)$ and $(1 - \mu/N)$ approach unity. Also from the properties of the base of the natural logarithms e, it is known that

$$\lim_{N\to\infty} \left(1 - \frac{\mu}{N}\right)^N = e^{-\mu}. \tag{6.45}$$

Hence Eq. (6.44), in the limit as $N \to \infty$, yields

$$\boxed{\mathcal{P}(x|\mu) \equiv f_{\mathcal{P}}(x) = \frac{\mu^x}{x!} e^{-\mu}, \quad x = 0, 1, 2, \ldots} \quad . \tag{6.46}$$

[5] Here it assumed that an ideal counting system is being used so that c_i is a constant and unaffected by realities such as dead time.

This PDF with a single parameter μ, is referred to as the Poisson (pronounced /pwä-´sōn/) probability distribution function.[6] Here it is learned that the Poisson distribution can be used provided that the probability of observing any single event is small (by comparison to N), or $p \ll 1$. Unlike the binomial PDF, the Poisson PDF describes the radioactive decay of both a single radioactive species or a sample containing multiple different radionuclides.

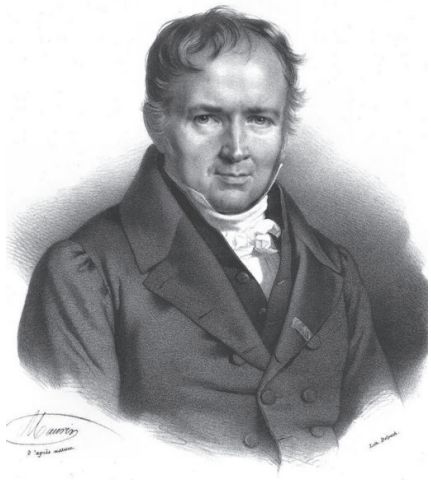

Figure 6.7. Siméon-Denis Poisson (1781–1840).

Certain properties of the Poisson distribution should be noted. Because it is a probability distribution function, it must be normalized, i.e.,

$$\sum_{x=0}^{\infty} \frac{(pN)^x}{x!} e^{-pN} = 1. \tag{6.47}$$

For a large number of trials, the average or expected number of successes would be $Np = \mu$. This result can be derived more formally as follows:

$$\langle x \rangle = \sum_{x=0}^{\infty} x \frac{\mu^x}{x!} e^{-\mu} = \sum_{x=1}^{\infty} \frac{\mu^x}{(x-1)!} e^{-\mu} = \mu \sum_{y=0}^{\infty} \frac{\mu^y}{y!} e^{-\mu} = \mu. \tag{6.48}$$

In a similar fashion, the variance of the Poisson distribution is found to be

$$\sigma^2(x) = \mu. \tag{6.49}$$

This is a very important property of Poisson statistics, namely that the variance is equal to its mean, i.e., $\sigma^2 = \mu$. Because the Poisson distribution is the limiting distribution for the binomial distribution, this result is in agreement with the limiting value of the binomial variance for large N, p small, and $Np = \mu$. From Eq. (6.33) one has

$$\sigma_{\mathcal{B}}^2 = Np(1-p) = \mu(1-p) = \lim_{p \to 0} \mu(1-p) = \sigma_{\mathcal{P}}^2. \tag{6.50}$$

Example 6.9: During harvest season, a farmer learns that approximately 1% of the corn in his field has insects that could damage the ears. If he pulls exactly 200 corn ears from his field to inspect them, what is the probability that he finds exactly 3 ears of corn with insects?

Solution:

The PDF governing the number of infected ears found in N tries is described by the binomial PDF because either an ear has insects or it does not. A comparison between the binomial and Poisson methods will be conducted. For the binomial PDF, with $p = 0.01$, $x = 3$, and $N = 200$, the expected probability that three corn ears have insects for a sample set of 200 is

$$f_{\mathcal{B}}(x=3) = \frac{N!}{(N-x)!x!} p^x (1-p)^{N-x} = \frac{200!}{97!\,3!} (0.1)^3 (1-0.1)^{97} = 0.18135$$

Also, the average number of ears that will have insects out of a sample of 200 ears is

$$\mu_{\mathcal{B}} = pN = (0.01)(200) = 2,$$

[6] Siméon-Denis Poisson (see Fig. 6.7) published the distribution function, now named after him, in *Recherches sur la probabilité des jugements en matière criminelle et en matière civile (1837)*, an analysis of probability regarding the French criminal justice system, where the Poisson distribution appears for the first and only time in his publications.

with a standard deviation of $\sigma_{\mathcal{B}} = pN(1-p) = \sqrt{(0.01)(200)(1-0.01)} = \pm 1.407$.

The approximation of the binomial PDF by a Poisson PDF yields the expected probability that exactly three ears of corns are infested as

$$f_{\mathcal{P}}(x=3) = \frac{(pN)^x}{x!}e^{-pN} = \frac{[(0.01)(200)]^3}{3!}e^{-(0.01)(200)} = 0.18045.$$

Also, the average number of ears and the standard deviation that have insects out of a sample of 200 ears is

$$\mu_{\mathcal{P}} = pN = (0.01)(200) = 2 \qquad \text{and} \qquad \sigma_{\mathcal{P}} = pN = \sqrt{(0.01)(200)} = \pm 1.414.$$

Notice how well the Poisson result agrees with the true result of the binomial PDF. Fig. 6.8 shows the resulting Poisson distribution for $x = 0, \ldots, 8$.

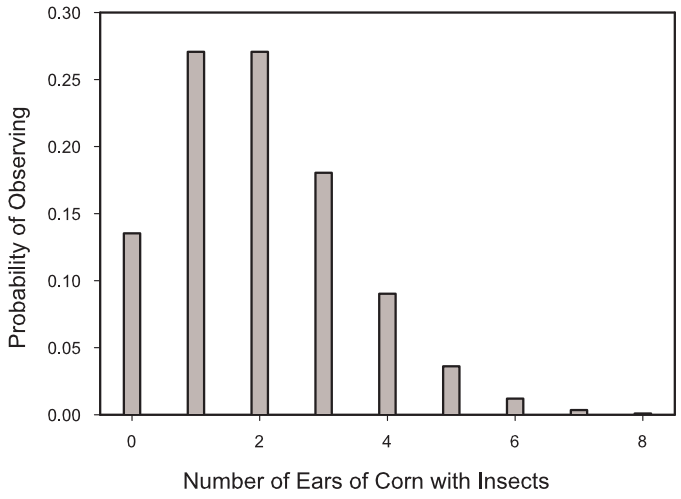

Figure 6.8. The Poisson distribution for Example 6.9, showing the expected probabilities of finding insects in specific numbers of corn ears from a sample set of 200.

Example 6.10: A radioactive sample has a half-life of 10 years. The sample mass has $N = 10^9$ identical radioactive atoms at time $t = 0$. What is the probability that exactly 120 atoms decay within a one-minute observation period of the sample beginning at $t = 0$?

Solution:

Here $\lambda = \ln(2)/10$ yrs $= 1.3188 \times 10^{-7}$ min^{-1}, $x = 120$ and $N = 10^9$. The expected number of decays in one minute is

$$p = \lambda \Delta t = (1.3188 \times 10^{-7}\text{min}^{-1})(1 \text{ min}) = 1.3188 \times 10^{-7}.$$

The average number of decays observed within a one-minute observation period is

$$\mu_{\mathcal{P}} = pN = (1.3188 \times 10^{-7})(10^9) = 131.88 \text{ decays}.$$

Here Poisson statistics must be used because in this case binomial statistics produce fatal overflow problems when attempting to evaluate $f_{\mathcal{B}}(x = 120)$.

$$f_{\mathcal{P}}(x=120) = \frac{(pN)^x}{x!}e^{-pN} = \frac{131.88^{120}}{120!}e^{-131.88} = 0.02096,$$

so there is about a 2% probability that exactly 120 decays are observed in a one-minute period. Notice that the probability distribution shown in Fig. 6.9 is nearly symmetric about the mean value. Indeed, as the probability of observing an event decreases to small values, and the average value for observing the event increases (a large sample set), the Poisson PDF converges on a symmetric distribution about the mean.

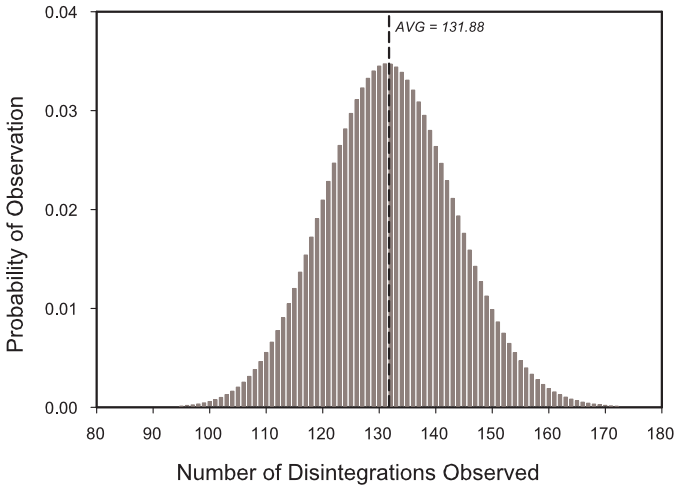

Figure 6.9. The Poisson distribution for Example 6.10, showing the probabilities of observing an exact number of disintegrations per minute from a radioactive sample initially composed of 10^9 radioactive atoms.

6.8 Gaussian or Normal Distribution

For large sample sets and high averages, both the binomial and Poisson distributions are cumbersome to implement numerically. A more manageable probability distribution function is the *Gaussian* PDF, also called the *normal* PDF. With this PDF the probability of observing an event within some dx is[7]

$$\mathcal{N}(x|\mu,\sigma)\,dx = \frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]dx. \tag{6.51}$$

Here $\mathcal{N}(x|\mu,\sigma) \equiv f_{\mathcal{N}}(x)$ is the PDF that has the following properties: (1) It is properly normalized, i.e.,

$$\int_{-\infty}^{\infty} f_{\mathcal{N}}(x)\,dx = \int_{-\infty}^{\infty}\frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]dx = 1. \tag{6.52}$$

(2) The average value of x is

$$\int_{-\infty}^{\infty} x f_{\mathcal{N}}(x)\,dx = \int_{-\infty}^{\infty}\frac{x}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]dx = \mu. \tag{6.53}$$

[7] Independently, Adrain in 1808 and Gauss (see Fig. 6.10) a year later developed the formula for the normal distribution and showed that experimental errors were fit well by this distribution. However, almost thirty years earlier this distribution had been discovered by by Laplace in 1778 as he derived the extremely important central limit theorem.

(3) The variance of the Gaussian distribution is

$$\int_{-\infty}^{\infty}(x-\mu)^2 f_{\mathcal{N}}(x)\,dx = \int_{-\infty}^{\infty}\frac{(x-\mu)^2}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]dx = \sigma^2(x) = \mathrm{var}(x). \tag{6.54}$$

Figure 6.10. Carl Friedrich Gauss (1777–1855).

The normal distribution is ubiquitous in nature. The famous "bell-shape" curve keeps popping up everywhere in every discipline. That the normal distribution is so prevalent is explained by the very general and powerful *central limit theorem* (CLT). In words, this theorem states that if N samples z_i are drawn from *any* PDF with mean $\mu(z)$ and variance $\sigma^2(z)$, then the arithmetic average $\overline{z}$ is asymptotically distributed, for large N, as a normal distribution with mean μ and standard deviation $\sigma(z)/\sqrt{N}$. The astonishing feature about the CLT is that nothing is said about the distribution function used to generate the N samples of z, from which the random variable $\overline{z}$ is formed. No matter what the distribution is, provided it has a finite variance, the sample mean $\overline{z}$ has an approximately normal distribution for large samples. The restriction to distributions with finite variance is of little practical consequence because most useful PDFs have a well-defined mean and variance.[8]

In radiation counting, the measured counts are governed by the binomial distribution and well approximated by the Poisson. Because of the CLT, it is not surprising that samples from a Poisson PDF assume a Gaussian distribution for sufficiently large N. A normal distribution in which $\sigma = \mu = \sqrt{pN}$ is, in fact, a very good approximation to the Poison PDF with mean μ, especially for large μ. Shown in Fig. 6.11 is a comparison of the Poisson distribution and the normal distribution for a mean value of 25. Thus, it is seen that the normal distribution is a good approximation for μ as small as 25. Although the Poisson distribution is a discrete PDF and the Gaussian distribution is a continuous PDF, the similarity between the two is unmistakable.

The basic characteristics of the continuous Gaussian distribution are shown in Fig. 6.12, where it has been renormalized by multiplying $f_{\mathcal{N}}(x)$ by $(\sqrt{2\pi})\sigma$. Data from such a distribution are routinely reported as $\overline{x} \pm \sigma$ where $\overline{x}$ is the average number of measured counts during a specified time period and σ is the *standard deviation* of $\overline{x}$. When an error is reported as one standard deviation (or "one sigma") it is called the *standard error*.

Another important feature of the continuous Gaussian distribution is the *full width at half maximum* (FWHM), which is the width of the distribution along the abscissa where it has half the maximum value of the distribution along the ordinate. For instance, the renormalized distribution of Fig. 6.12 has a maximum value of 1, hence the FWHM is the change in x between the points at which the distribution equals 0.5. The relationship between σ and the FWHM is found by evaluating $f_{\mathcal{N}}(x') = 0.5 f_{\mathcal{N}}(\mu)$, where as seen in Fig. 6.12, $|\mu - x'| = 0.5$ FWHM. To find the FWHM write $f_{\mathcal{N}}(x') = 0.5 f_{\mathcal{N}}(\mu)$ explicitly as

$$\frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(0.5\ \ \mathrm{FWHM})^2}{2\sigma^2}\right] = \frac{1}{2}\frac{1}{\sqrt{2\pi}\sigma}.$$

[8] One exception is the Cauchy or Lorentzian PDF, which has no mean or variance,

$$f_{\mathcal{C}}(x) = \frac{1}{\pi}\frac{\beta}{(x-a)^2+\beta^2}, \quad -\infty < \alpha < \infty, \quad \beta > 0, \quad -\infty < x < \infty.$$

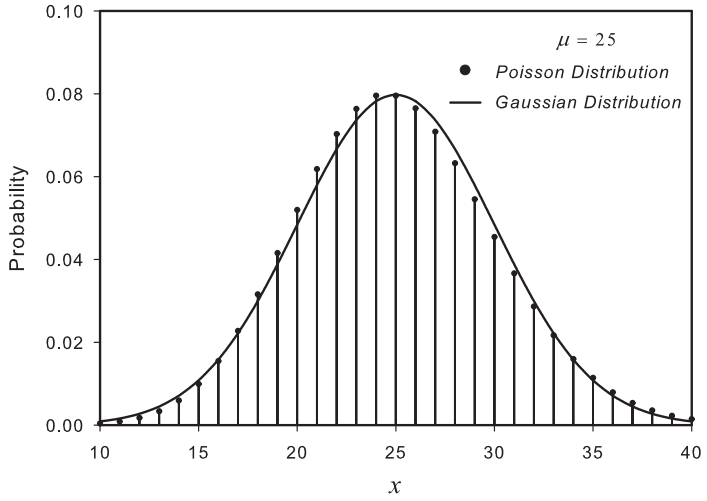

Figure 6.11. A comparison of the Poisson PDF $f_{\mathcal{P}}(x_i)$ and the Gaussian PDF $f_{\mathcal{N}}(x)$ for a mean value of 25. The Poisson PDF is slightly asymmetric, whereas the Gaussian PDF is symmetric about the mean. Yet, the Gaussian distribution is a good approximation for the Poisson PDF, hence is commonly used as a substitute for the Poisson PDF in radiation counting.

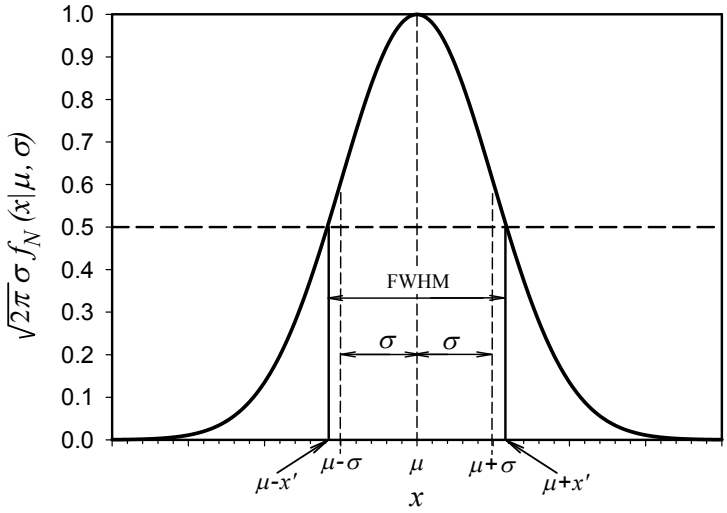

Figure 6.12. The Gaussian, or normal, distribution function that has been multiplied by $\sqrt{2\pi}\sigma$.

Take the log of both sides and solve for FWHM to obtain

$$\boxed{\text{FWHM} = 2\sqrt{2\ln(2)}\sigma \simeq 2.355\sigma.} \tag{6.55}$$

6.8.1 Standard Normal Distribution

The normal distribution of Eq. (6.51) can be changed into a more symmetric one. Let $z = (x - \mu)/\sigma$ so that Eq. (6.51) becomes

$$f_{\mathcal{N}}(z) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] \equiv f_{\mathcal{N}}(z|0,1). \tag{6.56}$$

The mean of this standard normal is

$$\mu = \int_{-\infty}^{\infty} z f_{\mathcal{N}}(z) dz = \int_{-\infty}^{\infty} \frac{z}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz = 0, \tag{6.57}$$

and the variance is

$$\sigma^2(z) = \int_{-\infty}^{\infty} z^2 f_{\mathcal{N}}(z) dz = \int_{-\infty}^{\infty} \frac{z^2}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz = 1. \tag{6.58}$$

Here it is found that the average is 0, meaning that the distribution is centered at $z = 0$, and the variance and standard deviations are both equal to unity. This particular form of the Gaussian distribution is referred to as the *standard normal probability distribution* and sometimes is denoted by $f_{\mathcal{N}}(z) \equiv \mathcal{N}(z|0,1)$.

A normal distribution $\mathcal{N}(x|\mu,\sigma)$ with any μ or σ is transformed to the standard normal $\mathcal{N}(z|0,1)$ by letting $z = (x - \mu)/\sigma$. By converting a normal distribution to the standard normal PDF the probability distribution becomes "standardized," the results of which can be found in a number of different mathematical tables for various values of z. Hence, by converting the Gaussian distribution to the standard normal distribution, the probabilities can be easily determined for any values of μ and σ. The standard normal PDF is shown in Fig. 6.13.

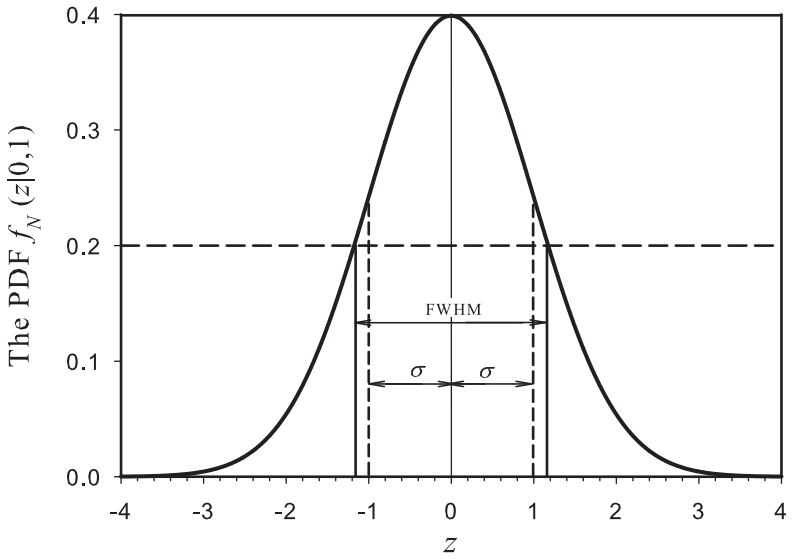

Figure 6.13. The standard normal distribution $f_{\mathcal{N}}(z|0,1)$ is centered at $z = 0$ with both σ^2 and σ equal to 1. The x-axis labels are the number of standard deviations from the mean ($z = 0$).

Example 6.11: A factory produces ball bearings with an average radius of $\mu = 6$ mm and with a standard deviation of $\sigma = 0.04$ mm. The diameters of the ball bearings must not be any less than 5.9 mm nor larger than 6.1 mm in order to fit into the sleeves for which they were designed. Out of a daily manufacture run of 20,000 ball bearings, how many ball bearings must be rejected?

Solution:

Good ball bearings fall between the diameters of 6 mm ± 0.1 mm, hence, the rejected ball bearings have radii in the intervals $(0, 5.9)$ mm and $(6.1, \infty)$. Here it is assumed that a normal PDF describes the distribution of radii. Although negative radii are unphysical, the area under the Gaussian tail of $(-\infty, 0)$ is negligibly small and totally ignorable here. Thus

$$\text{Prob}\{x < 5.9\text{mm}\} + \text{Prob}\{x > 6.1\text{mm}\} =$$

$$\int_{-\infty}^{5.9} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{(x-6)^2}{2(0.04)^2}\right] dx + \int_{6.1}^{\infty} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{(x-6)^2}{2(0.04)^2}\right] dx$$

To evaluate these two integrals, convert the normal PDF to the standard normal PDF by substituting

$$z = \frac{x-\mu}{\sigma} = \frac{x-6}{0.04}$$

so that the acceptance limits become

$$z_{low} = \frac{5.9-6}{0.04} = -2.5 \qquad \text{and} \qquad z_{high} = \frac{6.1-6}{0.04} = 2.5.$$

Because the Gaussian distribution is symmetric about the mean, it is necessary to calculate the probability of finding ball bearings within only one of these intervals, and afterwards simply doubling the answer. Thus, to find probability in the interval $(2.5, \infty)$ integrate the standard normal PDF between $-\infty$ and 2.5 and subtract the results from 1 as shown in Fig. 6.14.

$$\begin{aligned}\text{Prob}\{x < 5.9\text{mm}\} + \text{Prob}\{x > 6.1\text{mm}\} &= 2\left[\int_{2.5}^{\infty} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz\right] \\ &= 2\left[1 - \int_{-\infty}^{2.5} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz\right].\end{aligned}$$

The value of the last integral is easily found from a table of the standard normal PDF, where it is found

$$\int_{-\infty}^{2.5} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz = 0.99379.$$

Hence the probability a ball bearing is rejected is

$$\text{Prob}\{x < 5.9\text{mm}\} + \text{Prob}\{x > 6.1\text{mm}\} = 2\,[1 - 0.99379] = 0.01242.$$

It is, thus, expected that $(20,000)(0.01241) = 248.4$ ball bearings must be rejected each day.

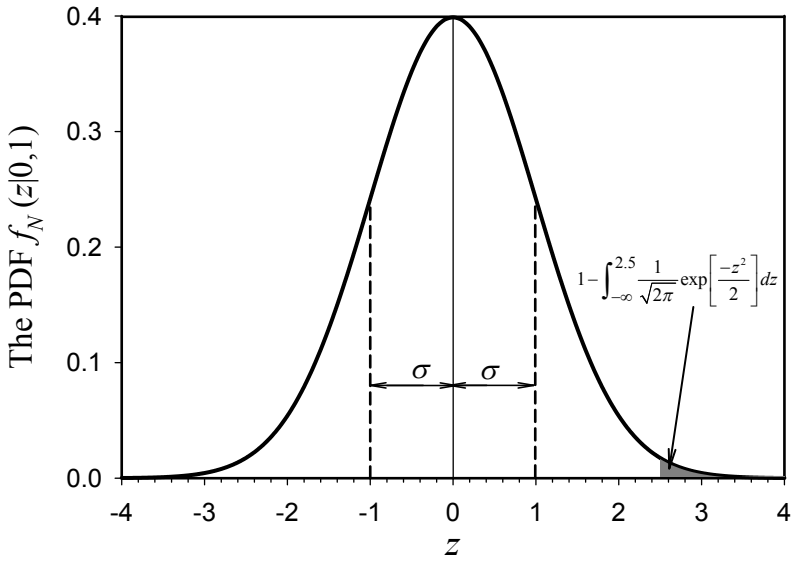

Figure 6.14. The standard normal PDF of Example 6.11, showing the probability region between 2.5 and ∞.

6.8.2 Cumulative Normal Distribution and the Error Function

The cumulative normal distribution has a special importance for a variety of mathematical applications. It is defined as

$$F_{\mathcal{N}}(y) = \int_{-\infty}^{y} \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx. \tag{6.59}$$

Notice that the $F_{\mathcal{N}}(y)$ is the probability of observing an event between $-\infty$ and some specified value y. This cumulative normal distribution can be converted to the cumulative standard normal distribution by using again the substitution $z = (x-\mu)/\sigma$ to give

$$F_{\mathcal{N}}(u) = \int_{-\infty}^{u} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz. \tag{6.60}$$

The above integration of the standard normal distribution is shown in Fig. 6.15.

A function closely related to the CDF of the standard normal distribution is the *error function*, defined as

$$\operatorname{erf}(u) = \int_{0}^{u} \frac{2}{\sqrt{\pi}} \exp\left[-z^2\right] dz. \tag{6.61}$$

Because the standard normal PDF is symmetric about the origin, the relationship between the error function and the cumulative standard normal distribution is, for $u > 0$,

$$F_{\mathcal{N}}(u) = \frac{1}{2} + \int_{0}^{u} \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{u}{\sqrt{2}}\right)\right]. \tag{6.62}$$

For any positive value of the product $u_\sigma \equiv u\,\sigma$, $\operatorname{erf}(u_\sigma/\sqrt{2}\sigma)$ is the probability that the error of a single measurement lies between $-u_\sigma$ and $+u_\sigma$. Because $\sigma = 1$ for the standard normal distribution, the probability

interval between $\pm\sigma$ is $\text{erf}(1/\sqrt{2}) = 0.683$. This is the same probability of observing x from $\mathcal{N}(x|\mu,\sigma)$ in the interval $[\mu-\sigma, \mu+\sigma]$. A comparison of the functions $F_{\mathcal{N}}(u)$ and $\text{erf}(u)$ is shown in Fig. 6.16.

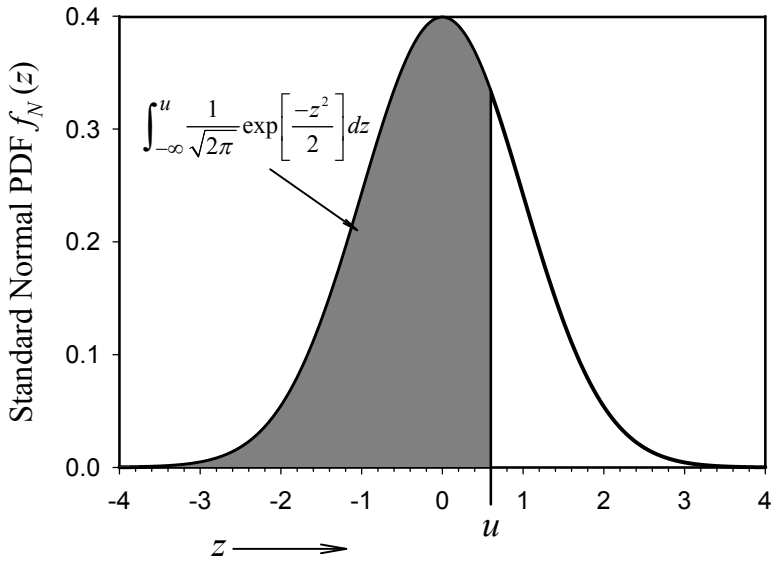

Figure 6.15. The cumulative standard normal distribution showing the probability region up to the value of u (shaded area).

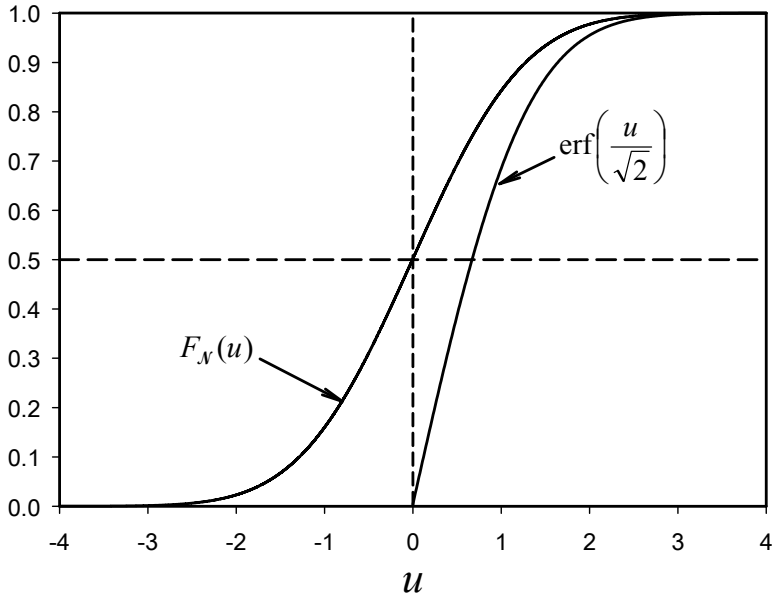

Figure 6.16. A comparison of the cumulative standard normal distribution $F_{\mathcal{N}}(u)$ of Eq. (6.59) and the error function $\text{erf}(u/\sqrt{2})$ given by Eq. (6.61).

Example 6.12: Use the error function to calculate the probability of observing x in the interval $[\mu - m\sigma, \mu + m\sigma]$ for $m = 0.5$, $m = 1.5$, and $m = 2.5$.

Solution:
The probability is

$$\text{Prob}\{\mu - m\sigma \le x \le \mu + m\sigma\} = \text{erf}\left(\frac{\text{u}_\sigma}{\sqrt{2}\sigma}\right) = \text{erf}\left(\frac{\text{u}\cdot\sigma}{\sqrt{2}\sigma}\right) = \text{erf}\left(\frac{\text{u}}{\sqrt{2}}\right).$$

Here u equals 1.5, 2.5 and 2.5. From error function tables,

$$\text{Prob}\{\mu - 0.5\sigma \le x \le \mu + 5\sigma\} = \text{erf}\left(\frac{0.5}{\sqrt{2}}\right) = \text{erf}(0.354) = 0.383$$
$$\text{Prob}\{\mu - 1.5\sigma \le x \le \mu + 1.5\sigma\} = \text{erf}\left(\frac{1.5}{\sqrt{2}}\right) = \text{erf}(1.061) = 0.866$$
$$\text{Prob}\{\mu - 2.5\sigma \le x \le \mu + 2.5\sigma\} = \text{erf}\left(\frac{2.5}{\sqrt{2}}\right) = \text{erf}(1.768) = 0.988.$$

6.8.3 Discrete Gaussian Distribution

The previous sections about the normal PDF have described continuous functions. However, for radiation counting, either the presence of a radiation disintegration (or count) is observed or it is not. In other words, a fraction of an event can never be observed. The Poisson PDF is a discrete distribution that is a better model for describing radiation counting statistics; however, it is numerically difficult to use for large numbers of counts. Thus, one is forced to use the normal PDF. Because only discrete integers of counts can be observed, it, therefore, becomes necessary to use the *discrete* Gaussian distribution to describe sample populations.

The discrete Gaussian distribution is defined, measured and analyzed only at integer values x_i of counts, although the mean μ is not necessarily an integer. This discrete distribution is normalized, i.e.,

$$\sum_{i=1}^{\infty} f_{\mathcal{N}}(x_i) = 1, \tag{6.63}$$

where, because the normal PDF approximating the Poisson has $\sigma^2 = \mu$,

$$f_{\mathcal{N}}(x_i) = \frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x_i-\mu)^2}{2\sigma^2}\right] = \frac{1}{\sqrt{2\pi\mu}}\exp\left[-\frac{(x_i-\mu)^2}{2\mu}\right]. \tag{6.64}$$

It is actually the discrete form of the Gaussian distribution that is observed for radiation counting experiments. The observations of counts must be either null or positive discrete numbers, yet the mean, standard deviation, and variance are determined from the accumulated data and may take on any value between 0 and ∞, because they are not necessarily integers.

Suppose an experimenter has a radioactive source used for calibration, such as ^{137}Cs. During a single measurement over some time interval, the experimenter observes 42 counts. Because there is only one measurement, the observed number of counts in the measurement also serves as the mean; hence as a first estimate $\sigma^2 = \mu = 42$. Ignore background counts for the moment, so from this single measurement, the distribution is expected to follow a Gaussian PDF as shown in Fig. 6.17.

The distribution of Fig. 6.17 shows the expected probabilities $f_{\mathcal{N}}(x_i)$ of observing various numbers of counts, based on an average of 42 counts. The summed values of the probabilities $\sum_{i=1}^{\infty} f_{\mathcal{N}}(x_i) = 1$. Should the experimenter take a second identical measurement, according to the results in Fig. 6.17, there is a 6.16% probability of once again observing 42 counts, meaning that there is a 93.84% probability that 42 counts will not be observed. Should the experimenter take another measurement, it would most likely be some other number than 42, and combining the two results would produce a new estimate of the mean $\mu \simeq \overline{x}$.

Suppose the experimenter continues to take measurements under identical conditions, tallying the number of times, or probability, each time a particular number of counts in a measurement is observed. The data average, from Eq. (6.22), would change with each measurement. After numerous measurements (perhaps a hundred or so), the experimenter should notice that the experimentally observed distribution approaches that described by Eq. (6.64) with the observed *new* average $\mu \simeq \overline{x}$, defined by Eq. (6.22), and with $\sigma^2 \simeq s^2$ defined by Eq. (6.26).

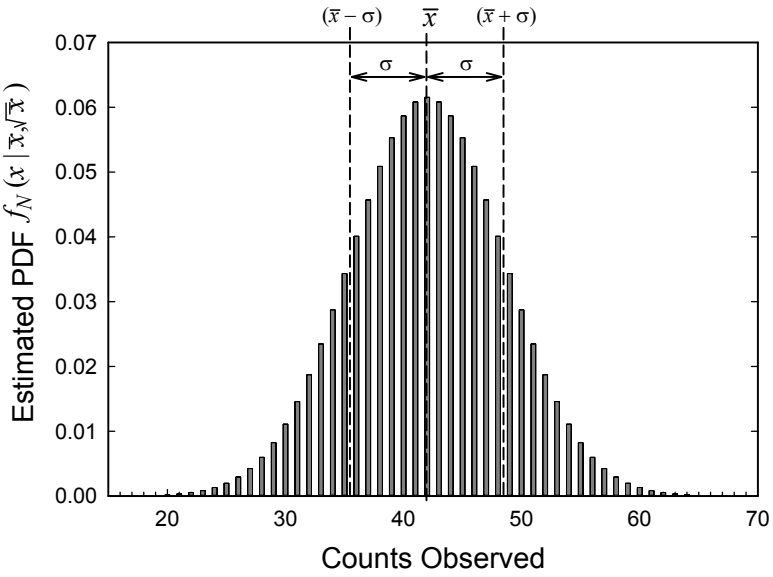

Figure 6.17. The discrete Gaussian (normal) distribution determined for a single observed measurement with 42 counts.

6.8.4 The Normal Distribution in Radiation Measurements

For a single measurement in which x counts are observed, the mean value is estimated as x with an estimated standard deviation of $\sigma = \sqrt{x}$; hence the reported value is $x \pm \sigma$. If a Gaussian distribution can approximate the data, then σ has a specific meaning, namely, there is a 68.3% probability that the next observed measurement has a value that falls within the range $x \pm \sigma$. Table 6.5 lists the relationship between the number of radiation induced counts recorded and the percent standard deviation. Thus to obtain a standard error of 1% or less requires recording at least 10,000 gross counts.

For a single radiation measurement, the counts observed are a good first estimate of the number of counts that would be observed in a second

Table 6.5. Standard deviation (%) of count data measured with a radiation detector operating in pulse mode.

Observed Counts	Standard Deviation (1-σ error)
100	10%
400	5%
1100	3%
2500	2%
10000	1%

independent measurement. If the counts observed are greater than approximately 25, a normal PDF can be used to model the expected results. Hence, with x being the gross number of counts observed in the single measurement, the mean and standard deviation are, respectively,

$$\overline{x} = x \qquad \text{and} \qquad \sigma(\overline{x}) = \sqrt{x}. \tag{6.65}$$

This result would then be reported as "counts $= x \pm \sqrt{x}$." Often it is preferred that the standard deviation σ be reported in terms of a relative to mean (fraction of the mean) or as a percent of the average, respectively given by,

$$\sigma_{\text{rel}} = \frac{\sqrt{x}}{x} = \frac{1}{\sqrt{x}} \qquad \text{and} \qquad \sigma_{\%} = 100\frac{\sqrt{x}}{x} = \frac{100}{\sqrt{x}}. \tag{6.66}$$

Typically, the measurement is reported as "counts $= x \pm \sigma_{\text{rel}}$" or "counts $= x \pm \sigma_{\%}$."

Example 6.13:

A radiation measurement is conducted in which the gross counts observed are 258. How should the counts be reported in terms of absolute, fractional and percent standard errors?

Solution:

With the above results one has

$$\text{counts} = x \pm \sqrt{x} = 258 \pm \sqrt{258} = 258 \pm 16.1 \qquad \text{absolute.}$$

$$\text{counts} = x \pm \frac{1}{\sqrt{x}} = 258 \pm \frac{1}{\sqrt{258}} = 258 \pm 0.0622 \qquad \text{relative.}$$

$$\text{counts} = x \pm 100\frac{1}{\sqrt{x}} = 258 \pm 100\frac{1}{\sqrt{258}} = 258 \pm 6.22\% \qquad \text{percentage.}$$

Uncertainties are not always reported as one standard deviation. Sometimes a larger uncertainty is reported in order to increase the probability that the mean is included within the range between $x - k\sigma$ and $x + k\sigma$. As shown in Table 6.6, if the error is reported as one standard deviation, the probability is 68.3%. However for an error range of $x - 1.65\sigma$ to $x + 1.65\sigma$ the probability increases to 90%. This new interval would be reported as the 90% *confidence interval*. However, the convention is to report errors as one standard deviation. For anything other than one standard deviation, one should specify the number of standard deviations or the confidence interval.

Table 6.6. Probability intervals relative to the number of standard deviations based upon the Gaussian distribution.

No. of standard deviations $k\sigma$	Probability event observed in $\pm k\sigma$
0.683σ	0.500
1.000σ	0.683
1.645σ	0.900
1.960σ	0.950
2.000σ	0.955
2.576σ	0.990
3.000σ	0.997
3.291σ	0.999
4.000σ	0.99994
5.000σ	0.999999

Lastly, the shape of full-energy peaks observed from gamma-ray *spectra* are typically Gaussian. Figure 6.18 shows a common gamma-ray spectrum from a ^{22}Na source, which emits 511-keV annihilation photons from positron emissions, and 1.28-MeV gamma rays. On comparing Fig. 6.18 to Fig. 6.12, one can observe that the photon energy peaks are Gaussian in shape. The Gaussian shaped peaks arise from statistical fluctuations in the number of free signal carriers (charge carriers) excited per monoenergetic photon interaction event.[9] Typically the resolution of the gamma-ray

[9] The details regarding signal formation in gamma-ray spectrometers are addressed in the chapters on scintillation and semiconductor detectors.

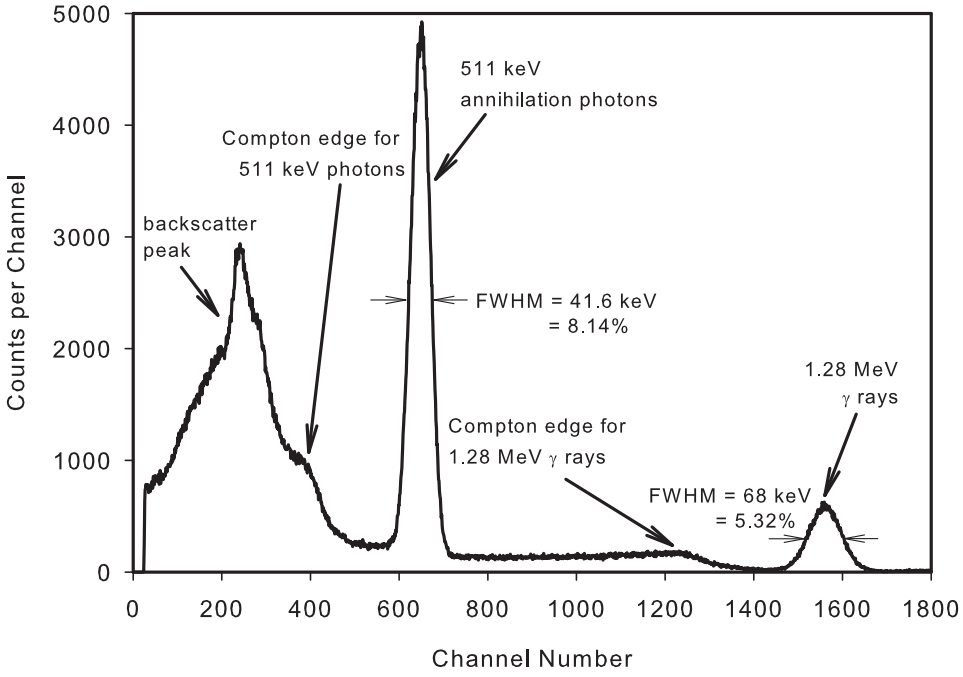

Figure 6.18. Differential pulse height distribution of the gamma rays emitted by the radioactive decay of ^{22}Na as measured by a NaI(Tl) scintillation detector. ^{22}Na is a positron and gamma-ray emitter, hence shown are the 511-keV full-energy peaks from positron annihilation and the 1.28-MeV γ ray emissions. In addition to the two full-energy peaks, several other features are also apparent. The end points of continua for Compton scattered photons are shown, referred to as "Compton edges", one for the 511-keV annihilation photons and one for the 1.28-MeV γ rays. The backscatter peak arises from ^{22}Na emissions scattering in the material surrounding the detector, and then entering and interacting in the NaI detector.

peak from the detector is quoted as a function of the full peak width at half the maximum value (FWHM), which for a Gaussian distribution is 2.355σ, where σ is in units of energy. In terms of percent, the energy resolution is found by dividing 235.5σ by the gamma-ray energy. A detailed discussion on these matters follows in the chapter on spectroscopy.

6.9 Error Propagation

A measurement, generally, may have several sources of error, all of which may be of such importance that they cannot be ignored. It becomes necessary to understand how each random variable affects the measurement error and, moreover, how such measurement error can be calculated from the values of the observed variables [Bevington and Robinson 1992; Taylor 1997]. The usual method to estimate the error of a function of the measured variables is to propagate the errors in each variable.

For a function described by $f(\mathbf{x}) \equiv f(x_1, x_2, x_3, ..., x_N)$, where the $\mathbf{x} = \{x_1, x_2, ..., x_N\}$ are random variables, the variables are usually measured quantities used to determine some average value of the random variable f. For instance, it is common practice to perform a *background* measurement, with no radiation source present, after performing a measurement on a suspected radiation source. The counts observed in the background measurement are subtracted from the counts observed from the radiation source measurement.

However, both measurements have an uncertainty or standard error associated with them. What then is the error for the difference between the counts in these two measurements?

To estimate the standard deviation of f in terms of the standard deviations $\sigma(x_i)$ of the x_i, it is necessary to "propagate" these errors. The usual way to develop such an *error propagation formula* is to begin by expanding $f(\mathbf{x})$ in a Taylor series about the mean values of the x_i, namely about the $\boldsymbol{\mu} = \{\mu_1, \mu_2, \ldots, \mu_N\}$. Such an expansion can be written as[10]

$$f(x_1, x_2, \ldots, x_N) = \sum_{i_1=0}^{\infty}\sum_{i_2=0}^{\infty}\cdots\sum_{i_N=0}^{\infty}\frac{\partial^{i_1}}{\partial x_1^{i_1}}\frac{\partial^{i_2}}{\partial x_2^{i_2}}\cdots\frac{\partial^{i_N}}{\partial x_N^{i_N}}\frac{f(\mathbf{x})}{i_1!, i_2!, \ldots, i_N!}\bigg|_{\mathbf{x}=\boldsymbol{\mu}}$$
$$\times(x_1-\mu_1)^{i_1}(x_2-\mu_2)^{i_2}\ldots(x_N-\mu_N)^{i_N}. \tag{6.67}$$

Now assume that higher order terms are negligibly small so that only the first two terms are retained. With this assumption the Taylor series reduces to

$$f(\mathbf{x}) \simeq f(\boldsymbol{\mu}) + \sum_{i=1}^{N}(x_i-\mu_i)\frac{\partial f(\boldsymbol{\mu})}{\partial x_i}, \tag{6.68}$$

where the notation

$$\frac{\partial f(\boldsymbol{\mu})}{\partial x_i} \equiv \frac{\partial f(\mathbf{x})}{\partial x_i}\bigg|_{\mathbf{x}=\boldsymbol{\mu}},$$

is used. Let $a_0 = f(\mu_1, \mu_2, ..., \mu_N)$ and $a_i = \partial f/\partial x_i|_{\mathbf{x}=\boldsymbol{\mu}}$. The average or *expected* value of $f(\mathbf{x})$ is calculated from Eq. (6.68) as

$$E(f) \equiv \langle f\rangle = \left\langle a_0 + \sum_{i=1}^{N}(x_i-\mu_i)a_i\right\rangle = \langle a_0\rangle + \sum_{i=1}^{N}\langle a_i x_i - a_i\mu_i\rangle$$
$$= a_0 + \sum_{i=1}^{N}\langle a_i x_i - a_i\mu_i\rangle = a_0 + \sum_{i=1}^{N}a_i(\mu_i-\mu_i) = a_0.$$

Thus, it is seen that $\langle f\rangle = f(\boldsymbol{\mu})$.

Now, what of the error? The variance of F is determined as follows:

$$\sigma^2(f) \equiv \langle(f(\mathbf{x})-f(\boldsymbol{\mu}))^2\rangle \simeq \left\langle\left\{\left(a_0+\sum_{i=1}^{N}(x_i-\mu_i)a_i\right)-a_0\right\}^2\right\rangle = \left\langle\left(\sum_{i=1}^{N}(x_i-\mu_i)a_i\right)^2\right\rangle$$
$$= \left\langle\sum_{i=1}^{N}a_i^2(x_i-\mu_i)^2 + \sum_{i=1}^{N}\sum_{\substack{j=1\\ j\neq i}}^{N}a_i a_j(x_i-\mu_i)(x_j-\mu_j)\right\rangle$$
$$= \sum_{i=1}^{N}a_i^2\langle(x_i-\mu_i)^2\rangle + 2\sum_{i=1}^{N}\sum_{\substack{j=1\\ j<i}}^{N}a_i a_j\langle(x_i-\mu_i)(x_j-\mu_j)\rangle$$
$$= \sum_{i=1}^{N}\left(\frac{\partial f(\boldsymbol{\mu})}{\partial x_i}\right)^2\sigma_i^2 + 2\sum_{i=1}^{N}\sum_{\substack{j=1\\ j<i}}^{N}\frac{\partial f(\boldsymbol{\mu})}{\partial x_i}\frac{\partial f(\boldsymbol{\mu})}{\partial x_j}\sigma_{ij}^2. \tag{6.69}$$

[10] For a Taylor series to exist, it is necessary for f to be continuous and possess derivatives of all orders.

Here σ_{ij} is the covariance defined as

$$\mathrm{cov}(x_i, x_j) \equiv \sigma_{ij}^2 = \langle (x_i - \mu_i)(x_j - \mu_j) \rangle. \tag{6.70}$$

Equivalently, the covariance is given by

$$\mathrm{cov}(x_i, x_j) = \langle x_i x_j \rangle - \mu_i \mu_j. \tag{6.71}$$

Although determination of the covariance is important in cases where the variables are correlated, the result is dependent upon the units of measure. Hence, the same covariance can vary widely by simply changing the units from, for example, mm to cm. To remedy the issue, a scaling factor is used to produce a more meaningful result, referred to as the *correlation coefficient*,

$$\rho_{ij} \equiv \frac{\mathrm{cov}(x_i, x_j)}{\sigma_i \sigma_j}, \tag{6.72}$$

where $\sigma_i \equiv \sigma(x_i)$ and $\sigma_j \equiv \sigma(x_j)$. Substitution of Eq. (6.71) into Eq. (6.72) yields,

$$\rho_{ij} = \frac{\langle x_i x_j \rangle - \mu_i \mu_j}{\sigma_i \sigma_j}. \tag{6.73}$$

and Eq. (6.69) becomes

$$\sigma^2(f) = \sum_{i=1}^{N} \left(\frac{\partial f(\boldsymbol{\mu})}{\partial x_i} \right)^2 \sigma_i^2) + 2 \sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} \frac{\partial f(\boldsymbol{\mu})}{\partial x_i} \frac{\partial f(\boldsymbol{\mu})}{\partial x_j} \rho_{ij} \sigma^2(\hat{x}_i) \sigma^2(\hat{x}_j). \tag{6.74}$$

But how is one to use this formula since the μ_i are generally not known? It is usual to use the measured values $\hat{x}_i$ as an estimate of μ_i. In many situations, such as radiation measurements, it is often assumed, usually justifiably, that the experimentally observed random variables are independent so the covariances are zero. With these two simplifications, Eq. (6.74) reduces to the following error propagation formula:

$$\boxed{\sigma^2(f) = \sum_{i=1}^{N} \left(\frac{\partial f(\mathbf{x})}{\partial x_i} \right)^2 \Bigg|_{x_i = \hat{x}_i} \sigma^2(\hat{x}_i).} \tag{6.75}$$

If the x_i are radiation counts that can be described by Gaussian distributions, then $\sigma^2(x_i) \simeq \sigma^2(\hat{x}_i) = \hat{x}_i$.

The "error propagation formula" of Eq. (6.75) can be used provided that

1. the function can be expressed as a Taylor expansion in which the first two terms adequately approximate the function, and
2. the variables are truly independent of each other so that the covariance between the variables is zero (or, at least, negligibly small).

The second requirement can be usually verified by understanding the details of the physics and the measurement systems used to obtain the measurements $\hat{x}_i$. However, the first requirement is generally more difficult to verify, especially if f is highly non-linear or even if f depends very sensitively on one or more of the $\hat{x}_i$.

There are a few common situations frequently encountered in radiation counting where the error propagation formula is used. These are discussed in the following subsections. For clarity, in the following examples of error propagation a "measurement" refers to a single experiment in which a number of radiation "counts" is observed over a preset period of time.

6.9.1 A Measurement is Scaled by a Constant

There are measurements in which the end result must be scaled by a constant. For instance, consider the case

$$f(x) = Ax,$$

where A is a constant and x is the number of counts in the measurement. With the error propagation formula, Eq. (6.75), and because $\sigma^2(\hat{x}) = \hat{x}$ for a single radiation measurement, one obtains

$$\sigma^2(f) = \sum_{i=1}^{1} \left(\frac{\partial f(x_i)}{\partial \hat{x}_i} \right)^2 \sigma^2(\hat{x}_i) = \left(\frac{\partial (Ax)}{\partial x} \right)^2 \Bigg|_{x=\hat{x}} \sigma^2(\hat{x}) = A^2 \sigma^2(\hat{x}). \tag{6.76}$$

Thus, the standard deviation of a random variable multiplied by a constant is

$$\boxed{\sigma(f) = A\sigma(\hat{x}).} \tag{6.77}$$

Hence, it is found that the standard error of the initial measurement is simply scaled by the constant.

Example 6.14: Suppose an experimenter wished to scale the counts obtained in a radiation measurement. A good example is when the counts were taken for a non-standard time period, and the experimenter wishes to scale the counts to a standardized period. For instance, if the measurement lasted 6 minutes and $\hat{x} = 3078$ counts were observed. What number of counts and standard error should the experimenter report if the measurement times had been 60 minutes?

Solution:

The scaling factor A would be 10 in order to change the time from 6 to 60 minutes. Thus the 60-minute measurement would produce

$$f(\hat{x}) = A\,\hat{x} = (10)(3078 \text{ counts}) = 30780 \text{ counts},$$

where $\hat{x}$ is the total gross counts observed in the 6-minute measurement. From the error propagation formula

$$\sigma(f) = A\sigma(\hat{x}) = (10)\sqrt{3078} = 554.8 \text{ counts}.$$

The expected counts and standard error for a 60-minute measurement time are then reported as

$$N_{\text{counts}} = 30780 \text{ counts } \pm \text{ } 554.80 \text{ counts}.$$

Had the experimenter actually counted for one hour and recorded 30780 counts, the standard error would have been $\pm\sqrt{30780} = \pm 175.4$. It is, thus, important to note that the scaled standard error is larger than it would have been had the experimenter actually performed a one-hour measurement. This outcome reinforces the fact that the total number of observed counts determines the statistical error, and not the count rate. Whether the experimenter performed the measurement for one minute or one hour, the average count rate remains the same. Yet, accumulating more observed counts in a measurement reduces the overall error in the measurement.

6.9.2 Random Variables are Added or Subtracted

There are circumstances in which two independent variables must be added or subtracted. Consider a function

$$f(x) = a_1 x_1 \pm a_2 x_2 \pm ... \pm a_N x_N,$$

where x_1 through x_N are independent random variables and the a_i are arbitrary constants. With the error propagation formula of Eq. (6.75) and measured values $\hat{x}_i$, the estimate of the variance of f is

$$\sigma^2(f) = \sum_{i=1}^{N} \left(\frac{\partial f(\hat{x}_i)}{\partial \hat{x}_i} \right)^2 \sigma^2(\hat{x}_i) = \sum_{i=1}^{N} \left(\frac{\partial (\pm a_i \hat{x}_i)}{\partial \hat{x}_i} \right)^2 \sigma^2(\hat{x}_i) = \sum_{i=1}^{N} (\pm a_i)^2 \sigma^2(\hat{x}_i) = \sum_{i=1}^{N} a_i^2 \sigma^2(\hat{x}_i).$$

Therefore, the standard deviation of random variables either added or subtracted is the sum square of the absolute variances, i.e.,

$$\boxed{\sigma^2(f) = \sum_{i=1}^{N} a_i^2 \sigma^2(\hat{x}_i).} \tag{6.78}$$

Example 6.15: In most radiation counting environments, there is an ever present background radiation field that can interfere with radiation measurements. To correct for this background, a measurement is first taken with the suspected radiation source present, and then a second measurement is taken with the suspected radiation source removed. If the measurement duration times are the *same* for both measurements, then neither needs be scaled for different measurement times. The results of the second measurement, referred to as a *background* measurement, is subtracted from the first measurement that recorded the summed counts from *both* the suspected radiation source and the background radiation. It is necessary to report the error for the net counts N_{net} observed. Consider the case

$$f(\mathbf{x}) = f(B, G) = G - B,$$

where G is the initial radiation measurement of gross counts and B is the background measurement. The background measurement B is subtracted from the gross measurement G to determine the net measurement of counts from only the radiation source. However, both G and B have error associated with their measurements, and both contribute to the error in N_{net}. Suppose that radiation measurements of a source and background yield $G = 2032$ counts and $B = 256$ counts. What are the net number of counts?

Solution:

The average net counts are $N_{\text{net}} = G - B = 2032 \text{ cts} - 256 \text{ cts} = 1776 \text{ cts}$. Because $\partial f/\partial G = \partial f/\partial B = 1$, the error propagation formula of Eq. (6.75) yields

$$\sigma(N_{\text{net}}) = \sqrt{\sum_{i=1}^{2} \sigma_i^2} = \sqrt{\sigma^2(G) + \sigma^2(B)} = \sqrt{G + B} = \sqrt{2032 + 256} = 47.83 \text{ cts}.$$

The net counts and standard error are then reported as

$$N_{\text{net}} = 1776 \text{ cts} \pm 47.83 \text{ cts}.$$

6.9.3 Random Variables are Multiplied or Divided

Under some situations, random variables must be either multiplied or divided. First consider the multiplication case, in which

$$f(x) = ax_1x_2\ldots x_N = a\prod_{i=1}^{N} x_i,$$

where the x_i are independent random variables with measured value $\hat{x}_i$ and a is some constant. Because $\sigma^2(\overline{x}) = \overline{x}$, the error propagation formula, Eq. (6.75), gives

$$\begin{aligned}\sigma^2(f) &= \sum_{i=1}^{N}\left(\frac{\partial f}{\partial x_i}\right)^2\sigma_i^2 = \left(\frac{\partial}{\partial x_1}(ax_1x_2...x_N)\right)^2\sigma_1^2 + \ldots + \left(\frac{\partial}{\partial x_N}(ax_1x_2...x_N)\right)^2\sigma_N^2 \\ &= \left[a\prod_{\substack{i=1\\ i\neq 1}}^{N} x_i\right]^2\sigma_1^2 + \ldots + \left[a\prod_{\substack{i=1\\ i\neq N}}^{N} x_i\right]^2\sigma_N^2 = \sum_{j=1}^{N}\left[\left(a\prod_{\substack{i=1\\ i\neq j}}^{N} x_i\right)^2\sigma_j^2\right].\end{aligned}$$

Now divide both sides by $f^2(x)$ to get the sum square of the relative variances,

$$\left(\frac{\sigma(f)}{f(x_1,\ldots,x_N)}\right)^2 = \sum_{i=1}^{N}\left(\frac{\sigma_i^2}{x_i}\right)^2. \tag{6.79}$$

Now consider the division case, in which a product of random variables is divided by another product of random variables,

$$f(x) = \frac{g(x)}{h(x)} \equiv \frac{ax_{g1}x_{g2}\ldots x_{gN}}{x_{h1}x_{h2}\ldots x_{hM}}, \tag{6.80}$$

where x_{gi} and x_{hj} are independent random variables. From Eq. (6.79),

$$\frac{\sigma^2(g)}{g^2(x)} = \sum_{i=1}^{N}\frac{\sigma^2(x_{gi})}{x_{gi}^2} = \sum_{i=1}^{N}\frac{\sigma_{gi}^2}{x_{gi}^2} \qquad \text{and} \qquad \frac{\sigma^2(h)}{h^2(x)} = \sum_{j=1}^{M}\frac{\sigma^2(x_{hj})}{x_{hj}^2} = \sum_{j=1}^{M}\frac{\sigma_{hj}^2}{x_{hj}^2}. \tag{6.81}$$

Application of the error propagation formula of Eq. (6.75) to Eq. (6.80) yields,

$$\sigma^2(f) = \left(\frac{\partial f}{\partial g(x)}\right)^2\sigma^2(g) + \left(\frac{\partial f}{\partial h(x)}\right)^2\sigma^2(h) = \left(\frac{1}{h(x)}\right)^2\sigma^2(g) + \left(-\frac{g(x)}{h^2(x)}\right)^2\sigma^2(h). \tag{6.82}$$

Divide both sides by $f^2(x)$ to obtain

$$\frac{\sigma^2(f)}{f^2(x)} = \left(\frac{\sigma(g)}{g(x)}\right)^2 + \left(\frac{\sigma(h)}{h(x)}\right)^2, \tag{6.83}$$

and substitution of the terms from Eqs. (6.81) yields

$$\frac{\sigma^2(f)}{f^2(x)} = \sum_{i=1}^{N}\frac{\sigma_{gi}^2}{x_{gi}^2} + \sum_{j=1}^{M}\frac{\sigma_{hj}^2}{x_{hj}^2}. \tag{6.84}$$

This is essentially the same result as Eq. (6.79). For multiplied or divided random variables, it is thus concluded that the general expression for the variance, based on measured values of the random variable, i.e., $x_i \rightarrow \hat{x}_i$, is

$$\boxed{\sigma^2(f) = f^2(\hat{x}_1, \ldots, \hat{x}_N) \left(\sum_{i=1}^{N} \left[\frac{\sigma(\hat{x}_i)}{\hat{x}_i} \right]^2 \right)} \quad . \tag{6.85}$$

Example 6.16: Suppose that the activity of a small unknown source is to be determined. One popular method to do this is to compare it to a similar small source of known activity. For example, a calibrated source is measured for a specified time. Afterwards, an uncalibrated source of the same type is placed in the identical location and measured for the same amount of time. A background measurement is then taken for the identical time period. What is the activity and standard error of the uncalibrated source given the following data?

Calibrated source activity (A_c): 0.9 μCi
Calibrated source measurement (G_c): 11280 counts
Unknown source measurement (G_u): 14560 counts
Background measurement (B): 120 counts

Solution:

The average value of the unknown activity is

$$f(x) \equiv A_u = A_c \frac{G_u - B}{G_c - B}$$

where G_u is the uncalibrated source measurement, G_c is the calibrated source measurement, B is the background measurement, A_c is the activity of the known source and A_u is the activity of the unknown source.

$$A_u = A_c \frac{G_u - B}{G_c - B} = 0.9 \ \mu\text{Ci} \ \frac{14560 \text{ cts} - 120 \text{ cts}}{11280 \text{ cts} - 120 \text{ cts}} = 1.165 \ \mu\text{Ci}.$$

The error propagation formula is used to find the standard error. For a first approximation, assume that the background has a negligible effect on the standard error of A_u. Because the variance of a single measurement is the observed number of counts, the error propagation formula yields

$$\begin{aligned} \sigma(A_u) &\simeq \left[A_u^2 \left(\left[\frac{\sigma(x_u)}{x_u} \right]^2 + \left[\frac{\sigma(x_c)}{x_c} \right]^2 \right) \right]^{1/2} = \left[A_u^2 \left(\frac{x_u}{x_u^2} + \frac{x_c}{x_c^2} \right) \right]^{1/2} \\ &= \left[A_u^2 \left(\frac{1}{x_u} + \frac{1}{x_c} \right) \right]^{1/2} = \left[(1.165 \ \mu\text{Ci})^2 \left(\frac{1}{14560 \text{ cts}} + \frac{1}{11280 \text{ cts}} \right) \right]^{1/2} \\ &= 0.0146 \ \mu\text{Ci} \end{aligned}$$

The measured activity and standard error are then reported as

$$A_u = 1.165 \ \mu\text{Ci} \ \pm \ 0.0146 \ \mu\text{Ci}.$$

6.9.4 Random Variables in Exponents or Logarithms

The emission rate of a radiative source decreases exponentially, and it is common to encounter situations in which the uncertainty of exponentials and logarithms of random variables must be determined. Consider the case

$$f(x) = e^{ax}, \tag{6.86}$$

where x is a random variable and a is a constant.[11] From the error propagation formula, Eq. (6.75), one has

$$\sigma^2(f) = \sum_{i=1}^{1} \left(\frac{\partial}{\partial \hat{x}_i} f(\hat{x}_i) \right)^2 \sigma^2(\hat{x}_i) = \left(\frac{\partial}{\partial \hat{x}} e^{a\hat{x}} \right)^2 \sigma^2(\hat{x}) = \left(a e^{a\hat{x}} \right)^2 \sigma^2(\hat{x}). \tag{6.87}$$

Therefore, the standard deviation for an exponential function is

$$\boxed{\sigma(f) = a \exp[a\hat{x}]\sigma(\hat{x}).} \tag{6.88}$$

For logarithmic functions,

$$f(x) = \ln(ax),$$

where x is a random variable and a is a constant. With the error propagation formula, Eq. (6.75), one has

$$\sigma^2(f) = \sum_{i=1}^{1} \left(\frac{\partial}{\partial \hat{x}_i} f(\hat{x}_i) \right)^2 \sigma^2(\hat{x}_i) = \left(\frac{\partial}{\partial \hat{x}} \ln(a\hat{x}) \right)^2 \sigma^2(\hat{x}) = \hat{x}^{-2} \sigma^2(\hat{x}).$$

Therefore, the standard deviation for a logarithmic function is

$$\boxed{\sigma(f) = \sigma(\hat{x})/\hat{x}.} \tag{6.89}$$

Example 6.17: The total attenuation coefficient can be estimated with a simple, counting experiment. A radiation measurement G_1 is made from a source with no attenuator present, and a second measurement G_2, of equal duration, is repeated with an attenuator of known thickness t placed between the source and detector. Because radiation is exponentially attenuated, the two measurements are related by

$$G_2 = G_1 e^{-xt}$$

where $\overline{x}$ is the attenuation coefficient. Solving for $\overline{x}$, one obtains

$$x = \frac{1}{t} \ln\left(\frac{G_1}{G_2} \right) = \frac{1}{t} \left[\ln(G_1) - \ln(G_2) \right].$$

Suppose the following values are observed: $t = 1.5$ mm, $\sigma(t) = 0.05$ mm, $G_1 = 1500$ cts, and $G_2 = 1235$ cts. Estimate the attenuation coefficient.

---

[11] Caution should be exercised here, mainly because the exponential function is highly non-linear. As a result, the first two terms of the Taylor expansion may not adequately describe $f(x)$. The reader is advised to refer to Section 6.9.7.

Solution:

The linear attenuation coefficient is thus estimated as

$$\hat{x} = \frac{1}{1.5}\left[\ln(1500) - \ln(1235)\right] = 0.1296 \text{ mm}^{-1}.$$

The variance is found from the error propagation formula as

$$\begin{aligned}
\sigma^2(\hat{x}) &= \left(\frac{\partial}{\partial t}\frac{1}{t}\left[\ln(G_1) - \ln(G_2)\right]\right)^2 \sigma^2(t) \\
&\quad + \left(\frac{\partial}{\partial G_1}\frac{1}{t}\left[\ln(G_1) - \ln(G_2 t)\right]\right)^2 \sigma^2(G_1) + \left(\frac{\partial}{\partial G_2}\frac{1}{t}\left[\ln(G_1) - \ln(G_2)\right]\right)^2 \sigma^2(G_2) \\
&= \left(-\frac{1}{t^2}\left[\ln(G_1) - \ln(G_2)\right]\right)^2 \sigma^2(t) + \left(\frac{1}{G_1 t}\right)^2 \sigma^2(G_1) + \left(-\frac{1}{G_2 t}\right)^2 \sigma^2(G_2) \\
&= \left(-(1.5)^{-2}\left[\ln(1500) - \ln(1235)\right]\right)^2 (0.05)^2 + \left(\frac{1}{(1500)(1.5)}\right)^2 (1500) + \left(-\frac{1}{(1235)(1.5)}\right)^2 (1235) \\
&= 6.75 \times 10^{-4} \text{ mm}^{-2}.
\end{aligned}$$

The standard error for the measured linear attenuation coefficient is $\sigma_{\hat{x}} = \sqrt{6.75 \times 10^{-4}} = 2.6 \times 10^{-2}$ mm^{-1}. Hence, linear attenuation coefficient is reported to be $x = 0.1296 \pm 0.026$ mm^{-1}.

6.9.5 A Series of Radiation Measurements

Quite often a series of radiation counts is conducted rather than a single measurement. For instance, the variance about the average in a series might reveal the "goodness" of the data.[12] Here it is assumed that a consecutive series of counts $\hat{x}_i$ is taken in which the conditions for each measurement are identical (counting time, source position, etc.). What then is the total standard error in the sum of all the measurements? The sum of the independent random variables x_i, itself another random variable, is

$$f(x_1, \ldots, x_N) \equiv x_{\text{sum}} = x_1 + x_2 + \ldots + x_N = \sum_{i=1}^{N} x_i$$

With the error propagation formula of Eq. (6.75) and the measured values $\hat{x}_i$, the variance of the sum is

$$\sigma^2_{\text{sum}} = \sum_{i=1}^{N} \left(\frac{\partial}{\partial \hat{x}_i} x_i\right)^2 \sigma^2(\hat{x}_i) = (1)^2\sigma^2(\hat{x}_1) + (1)^2\sigma^2(\hat{x}_2) + \ldots + (1)^2\sigma^2(\hat{x}_N) = \hat{x}_1 + \hat{x}_2 + \ldots + \hat{x}_N = \hat{x}_{\text{sum}}.$$

This is an important result because it shows that the variance of the sum is dependent upon only the total number of radiation counts observed and not the number of measurements taken! Hence, the total value of x_{sum} determines the error, whether it is from a single measurement or a series of many measurements. In other words, there is no appreciable difference in the error observed from a single long measurement accumulated over some time t, or a series of N measurements in which each individual measurement is taken for a time t/N.

[12] The goodness of data refers to the correlation between the expected data fluctuations and the observed data fluctuations. This concept is covered in Section 6.10.

What then is the error in the average of the N counts? Again, it is assumed that the conditions for each measurement are identical. The average of the counts is

$$\overline{x} = \frac{1}{N}(x_1 + x_2 + ... + x_N) = \sum_{i=1}^{N} \frac{x_i}{N}.$$

Again use the error propagation formula to determine the variance of this average,

$$\sigma^2(\overline{x}) = \sum_{i=1}^{N} \left(\frac{\partial}{\partial \hat{x}_i} \frac{x_i}{N} \right)^2 \sigma^2(\hat{x}_i) = \frac{1}{N^2} \sum_{i=1} \sigma^2(\hat{x}_i) = \frac{1}{N^2} \sum_{i=1}^{N} \hat{x}_i = \frac{\overline{x}}{N}.$$

Thus, the standard deviation of an average of a set of measurements is

$$\boxed{\sigma(\overline{x}) = \sqrt{\frac{\overline{x}}{N}} = \frac{1}{N} \left[\sum_{i=1}^{N} \hat{x}_i \right]^{1/2}.} \tag{6.90}$$

When $N = 1$, Eq. (6.90) reduces to Eq. (6.65). For N replicate measurements, the error in the average observed count is reduced by $\sqrt{N}$. This result assumes, of course, that the measurements are independent and that no changes occur in the radiation field or with the detector's response during the time that the N data points are recorded. If another series of N measurements were to be taken, a new average value for $\overline{x}$ would be found; yet there would be a 68.3% chance that the new average would fall within the interval ranging from $\overline{x} - \sigma_{\overline{x}}$ and $\overline{x} + \sigma_{\overline{x}}$ from the first series of measurements. The average number of counts observed per measurement and standard error for N measurements is

$$\overline{x} \pm \sigma(\overline{x}) = \overline{x} \pm \sqrt{\frac{\overline{x}}{N}}. \tag{6.91}$$

Example 6.18: An experimenter makes five identical and independent radiation measurements, each two minutes, and records the counts 1207, 1167, 1235, 1193, and 1243. What is the average expected number of counts per minute and the standard error?

Solution:

The average counts observed per measurement is

$$\overline{G} = \sum_{i=1}^{N} \frac{G_i}{N} = \frac{1}{5}(1207 + 1167 + 1235 + 1193 + 1243) = 1209 \text{ counts}.$$

From Eq. (6.90),

$$\sigma(\overline{x}) = \sqrt{\frac{\overline{G}}{N}} = \sqrt{\frac{1209}{5}} = 15.55 \text{ counts}.$$

Division by 2 yields the average expected counts per minute and error as 604.5 ± 7.77 cpm.

6.9.6 Measurements Over Different Time Intervals

Statistical error in radiation counting is determined by the total number of counts observed during a measurement or series of measurements. However, there may be cases in which the measurements are not all taken over the same period of time. What then is the error? It is incorrect to simply use the error of a *count rate*. Instead, the experimenter must first determine the error of the total counts observed and convert that result into a count rate. To illustrate this, consider an experimenter who takes four different measurements over four different measurement times producing the results shown in Table 6.7. All four measurements represent the same count rate, but the error in each is tremendously different.

Table 6.7. Comparison of errors for measurements with different measurement times but with the same count rate.

Observed counts G	Count time t	Standard error σ	Standard error %	Count rate g
100	10 s	± 10	10%	10 cps
1000	100 s	± 31.6	3.16%	10 cps
10000	1000 s	± 100	1%	10 cps
100000	10000 s	± 316	0.316%	10 cps

The count rate for the ith measurement is given by $g_i = G_i/t_i$. The average count rate for N independent measurements of the same radiation source is

$$\overline{f}(\mathbf{x}) \equiv \overline{g}(G_1, \ldots, G_n, t_1, \ldots, t_n) = \sum_{i=1}^{N} G_i \Big/ \sum_{i=1}^{N} t_i. \tag{6.92}$$

To determine the error in the average count rate, write each count rate measurement in terms of total counts observed per unit time. Assume that the error in the measurement time is negligible so that $\sigma_{t_i} \simeq 0$. Then with the error propagation formula, the variance in the count rate is[13]

$$\sigma^2_{\overline{g}} = \sum_{j=1}^{N} \left(\frac{\partial}{\partial G_i} \sum_{i=1}^{N} G_i \Big/ \sum_{i=1}^{N} t_i \right)^2 \sigma^2(G_j) = \sum_{i=1}^{N} \sigma^2(G_i) \Big/ \left(\sum_{i=1}^{N} t_i \right)^2 = \sum_{i=1}^{N} G_i \Big/ \left(\sum_{i=1}^{N} t_i \right)^2. \tag{6.93}$$

Now suppose that $f(\mathbf{x})$ involves M different radiation source configurations and that multiple measurements are made for each source configuration. Further, suppose $f(\mathbf{x})$ takes sums and differences of measurements for the different source configurations. For example, measurements are often taken with a radioisotopic source present and with the source removed to obtain background counts. Then the background count rate is subtracted from the source count rate to obtain the *net* or background-corrected source count rate. In general one seeks the average

$$\overline{f}(\mathbf{x}) = \sum_{m=1}^{M} (\pm) \overline{g}_m(G_{m1}, \ldots, G_{mN_m}, t_{m1}, \ldots, t_{mN_m}), = \sum_{m=1}^{M} \left[(\pm) \sum_{i=1}^{N_m} G_{mi} \Big/ \sum_{i=1}^{N_m} t_{mi} \right]. \tag{6.94}$$

Here N_m is the number of different measurements taken with the mth source configuration and G_{mi} and t_{mi} are the counts and count time for the ith measurement. From the error propagation formula, the variance of this average is found to be

$$\sigma^2_{\overline{f}} = \sum_{m=1}^{M} \left[\sum_{i=1}^{N_m} G_{mi} \Big/ \left(\sum_{i=1}^{N_m} t_{mi} \right)^2 \right], \tag{6.95}$$

from which the standard deviation $\sigma_{\overline{f}}$ is readily found.

[13] Alternatively, if N is greater than 10 or so, the sample variance $s^2(\overline{g}) = \frac{1}{\sqrt{N-1}} \sum_{i=1}^{N} (g_i - \overline{g})^2$ can be used to estimate $\sigma^2_{\overline{g}}$.

Example 6.19: A scientist takes a 15-minute background measurement, resulting in $B_1 = 241$. The scientist then takes two radiation measurements of the sample, each over 10 minute periods, and observes $G_1 = 1993$ and $G_2 = 1957$. During a third measurement, he is called to meeting, and stops the third measurement at 6 minutes, recording $G_3 = 1165$ counts. Before leaving, he removes the source and starts a background measurement. When the scientist returns, the background measurement has continued for 67 minutes, yielding $B_2 = 1043$ counts. What is the average net count rate and standard error?

Solution:
The net count rate is found by subtracting the background count rate from the gross count rate. From Eq. (6.94), the net average count rate is

$$\overline{n} = \left[\sum_{i=1}^{N_G} G_i \Big/ \sum_{i=1}^{N_G} t_{Gi}\right] - \left[\sum_{i=1}^{N_B} B_i \Big/ \sum_{i=1}^{N_B} t_{Bi}\right], \quad \text{where } N_G = 3, N_B = 2,$$

$$= \left(\frac{1993 \text{ cts} + 1957 \text{ cts} + 1165 \text{ cts}}{10 \text{ min} + 10 \text{ min} + 6 \text{ min}}\right) - \left(\frac{241 \text{ cts} + 1043 \text{ cts}}{15 \text{ min} + 67 \text{ min}}\right) = 180.1 \text{ cpm}.$$

From Eq. (6.95), the variance is

$$\sigma_{\overline{n}}^2 = \left[\sum_{i=1}^{N_G} G_i \Big/ \left(\sum_{i=1}^{N_G} t_{Gi}\right)^2\right] + \left[\sum_{i=1}^{N_B} B_i \Big/ \left(\sum_{i=1}^{N_B} t_{Bi}\right)^2\right], \quad \text{where } N_G = 3, N_B = 2,$$

$$= \frac{1993 \text{ cts} + 1957 \text{ cts} + 1165 \text{ cts}}{(10 \text{ min} + 10 \text{ min} + 6 \text{ min})^2} + \frac{241 \text{ cts} + 1043 \text{ cts}}{(15 \text{ min} + 67 \text{ min})^2} = 7.758 \text{ min}^{-2}$$

The standard error is found to be $\sigma_{\overline{m}} = \sqrt{7.758} = 2.785 \text{ min}^{-1}$. The net count rate and error are then reported as 180.1 ± 2.79 cpm.

Equal Counting Times

If the count times are identical for the N_m measurements in each source configuration, i.e., $t_{m1} = t_{m2} = \ldots = t_{mN_m} \equiv t_m$, then Eq. (6.92) reduces to,

$$\overline{n} = \sum_{m=1}^{M} \left((\pm)\frac{1}{N_m}\sum_{i=1}^{N_m} \frac{G_{mi}}{t_m}\right) = \sum_{m=1}^{M} \left((\pm)\frac{1}{N_m}\sum_{i=1}^{N_m} g_{mi}\right) = \sum_{m=1}^{M} \left((\pm)\frac{1}{N_m t_m}\sum_{i=1}^{N_m} G_{mi}\right). \tag{6.96}$$

and the variance reduces to

$$\sigma_{\overline{n}}^2 = \sum_{m=1}^{M} \left[\sum_{i=1}^{N_m} G_{mi} \Big/ \left(\sum_{i=1}^{N_m} t_m\right)^2\right] = \sum_{m=1}^{M} \left[\sum_{i=1}^{N_m} G_{mi} \Big/ (N_m t_m)^2\right] = \sum_{m=1}^{M} \left[\frac{1}{N_m^2 t_m}\sum_{i=1}^{N_m} g_{mi}\right]. \tag{6.97}$$

Example 6.20: A researcher takes a single radiation measurement on a sample in a low background counting environment and observes $G = 2310$ counts in a one-minute counting period. Afterwards, the researcher conducts a single one-hour long background measurement and observes $B = 213$ counts. What is the net count rate and standard error?

Solution:
The net count rate is found by subtracting the background count rate from the gross count rate. From Eq. (6.96), the net average count rate is,

$$\overline{n} = \frac{1}{N_G}\sum_{i=1}^{N_G}\frac{G_i}{t_G} - \frac{1}{N_B}\sum_{i=1}^{N_B}\frac{B_i}{t_B}, \text{ where } N_G = 1, N_B = 1,$$

$$= \frac{G}{t_G} - \frac{B}{t_B} = \left(\frac{2310 \text{ cts}}{1 \text{ min}} - \frac{213 \text{ cts}}{60 \text{ min}}\right) = 2306.15 \text{ cpm}.$$

From Eq. (6.97), the standard error is

$$\sigma_{\overline{n}} = \left(\frac{G}{t_G^2}+\frac{B}{t_B^2}\right)^{1/2} = \left(\frac{g}{t_g}+\frac{b}{t_b}\right)^{1/2} = \left(\frac{2310 \text{ cts}}{(1 \text{ min})^2} + \frac{213 \text{ cts}}{(60 \text{ min})^2}\right)^{1/2} = 48.06 \text{ cpm}.$$

The count rate and error are reported to be 2306.15 ± 48.06 cpm.

Example 6.21: Before measuring a radioactive sample, a technician takes a 30-minute background measurement, resulting in $B_1 = 513$. The technician then takes four radiation measurements of the sample, each over 5-minute measurement periods, and observes $G_1 = 2310, G_2 = 2219, G_3 = 2387$, and $G_4 = 2264$ counts. Afterwards, the technician conducts another 30-minute long background measurement and observes $B_2 = 478$ counts. What is the average net count rate and its standard error?

Solution:
The net count rate is found by subtracting the background count rate from the gross count rate. From Eq. (6.96), net average count rate is (with $N_G = 4$ and $N_B = 2$)

$$\overline{n} = \frac{1}{N_G}\sum_{i=1}^{N_G}\frac{G_i}{t_G} - \frac{1}{N_B}\sum_{i=1}^{N_B}\frac{B_i}{t_B}, = \frac{1}{4}\left(\frac{9180 \text{ cts}}{5 \text{ min}}\right) - \frac{1}{2}\left(\frac{991 \text{ cts}}{30 \text{ min}}\right) = 442.48 \text{ cpm}.$$

From Eq. (6.97), the standard error is

$$\sigma_n = \left\{\frac{1}{N_G^2}\sum_{i=1}^{N_G}\frac{G_i}{t_G^2} + \frac{1}{N_B^2}\sum_{i=1}^{N_B}\frac{B_i}{t_B^2}\right\}^{1/2}, \text{ where } N_G = 4, N_B = 2,$$

$$= \left\{\frac{1}{16}\left(\frac{9180 \text{ cts}}{25 \text{ min}^2}\right) + \frac{1}{4}\left(\frac{991 \text{ cts}}{900 \text{ min}^2}\right)\right\}^{1/2} = 4.82 \text{ cpm}.$$

The count rate and error are reported to be 442.48 ± 4.82 cpm.

6.9.7 Caution about Error Propagation

The error propagation formula of Eq. (6.75) is based on the assumption that the first two terms in the Taylor series expansion for a function $f(x_1, x_2, ..., x_N)$, evaluated at measured values $\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_N$, adequately describes its variation with the x_i. The first two terms of the Taylor series expansion describe a linear variation with the x_i, and for radiation counting the function is evaluated about the mean of the data distribution. Hence, for highly non-linear functions, such as high order polynomials and exponential functions, Eq. (6.75) may not provide an adequate description. This discrepancy between the actual function and an estimate from the truncated Taylor series expansion is especially of concern for arguments that are far from the mean values ($\overline{x}_i$).

Further, data are assumed to be independent and uncorrelated in Eq. (6.75). But there are situations where this assumption is simply incorrect. For example, often a series of data is analyzed with linear regression to determine a specific characteristic (or characteristics) of the underlying distribution. Examples include the determination of a radioactive decay constant or a photon attenuation coefficient of a material. From the *least squares* fit of the data, a slope and intercept are determined, and the data values actually *are* correlated when determining these parameters. Under such situations, the covariance of the data may be an important component of the standard error, hence it is advisable to actually use Eq. (6.74) in such cases.

6.10 Data Interpretation

In any statistical analysis where prediction or interpretation is drawn from a probability distribution function lies the possibility of misinterpreting the data. For instance, in radiation counting, there is a possibility of declaring a sample radioactive when in fact it is not, or the possibility of measuring a radioactive source, but declaring it non-radioactive. Such concerns are especially important if the count rate from the suspected radioactive source is comparable to that from background radiation. Consider a sample suspected of being radioactive, with the hypothesis that the sample is not radioactive. This is termed the *null hypothesis*, denoted by H_0. The other possibility is, of course, that the sample actually is radioactive, is termed the *alternative hypothesis*, denoted H_a. If an experimenter measures the activity of the sample, then two following possible errors in the interpretation of the data can occur [Devore 1991].

Type I error consists of rejecting the null hypothesis in favor of the alternative hypothesis H_a when in fact H_0 is true, meaning in this case declaring the sample radioactive when in fact it is not, termed a *false positive*.

Type II error consists of accepting the null hypothesis H_0 when it is incorrect, meaning the sample is declared non-radioactive when it actually is radioactive, termed a *false negative*.

Such errors are difficult to identify, yet the probability of making either a Type I or Type II error can be determined. The method used for determining these probabilities is referred to as "hypothesis testing."[14] The test procedure is usually defined by some measure called a *test statistic* or a *rejection region*. The test statistic defines a quantity, whether it be the average value or some other statistic, with which the observed data are to be interpreted. The rejection region is a range of values in which a new hypothesis is accepted over the previous hypothesis. For radiation counting, one might use the average counts observed from a calibration with the background radiation as a test statistic and the region greater than $\overline{x} + 2\sigma$ as the rejection region. Hence, samples producing counts greater than $\overline{x} + 2\sigma$ are declared radioactive, and samples producing counts below $\overline{x} + 2\sigma$ are deemed non-radioactive. Or, it may be hypothesized that a single measurement is a good first estimate of the average number of counts expected per measurement, and the rejection region is defined as some function of the standard deviation.

[14] Although hypothesis testing is often used in probability and statistics, it is widely considered to be a branch of *decision theory*.

Figure 6.19 shows the standard normal distribution in which the regions outside of $z \pm 1.96\sigma$ are designated rejection regions. The remaining values of z are in the acceptance region. Given any hypothesis about the distribution of Fig. 6.19, for instance the mean value, a measurement falling outside of $\overline{z} \pm 1.96\sigma$ implies that the hypothesis be rejected. The form shown in Fig. 6.19 is referred to as a *two-tailed test* because regions on both sides of the mean value are designated as rejection regions. There are some circumstances in which extreme values on only one side of the distribution is of interest. Such a test is referred to as a *one-tailed test*.

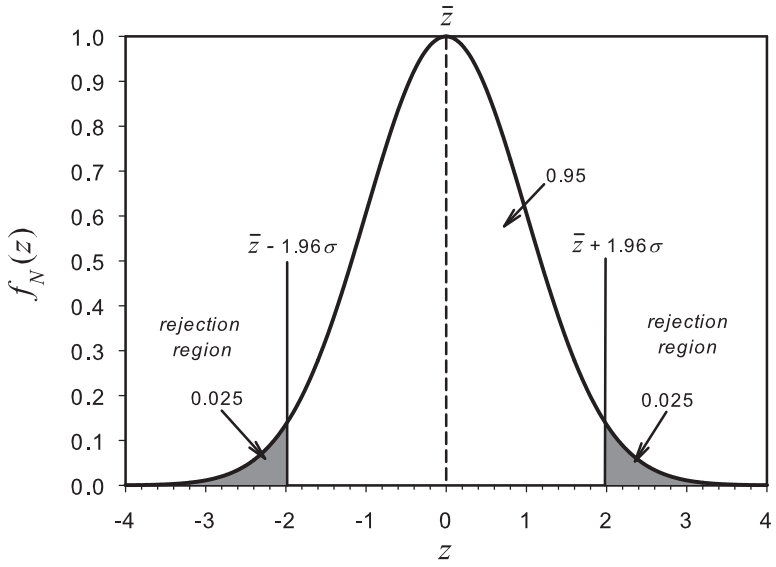

Figure 6.19. The standard normal distribution showing the rejection region and the acceptance region. The sum of the shaded regions represents 5% of the normal distribution, and the light region represents 95% of the distribution. There is a 95% chance that the next measurement results in z falling within the acceptance region and only a 5% chance that the next measurement results in z falling in either of the shaded regions.

Example 6.22: Suppose a single radiation measurement is performed in which $\hat{x} = 194$ counts are observed. Such counts follow a Gaussian distribution. The hypothesis H_0 is declared that 194 is the mean value with the standard deviation $\sigma = \sqrt{\hat{x}} = 13.93$. Hence, the mean value is the test statistic. It is also asserted that the hypothesis is rejected should the next independent measurement produce a count outside of $\pm 1.96\sigma$ (the rejection region—see the shaded area in Fig. 6.20). The rejection region is 5% of the area under the Gaussian PDF, whereas the acceptance region is 95% of the area.

Should the next measurement produce a count that falls in the shaded area of Fig. 6.20, then the hypothesis H_0 is rejected at a 0.05 level of significance. For instance, if another measurement produced 121 counts, then at the 0.05 level, the hypothesis that 194 is the mean value of the underlying Gaussian distribution would be rejected. What this also means is, because 5% of the PDF lies outside of $\pm 1.96\sigma$, then there is a 5% probability that the experimenter can make a Type I error by declaring the mean is *not* 194 when it actually is!

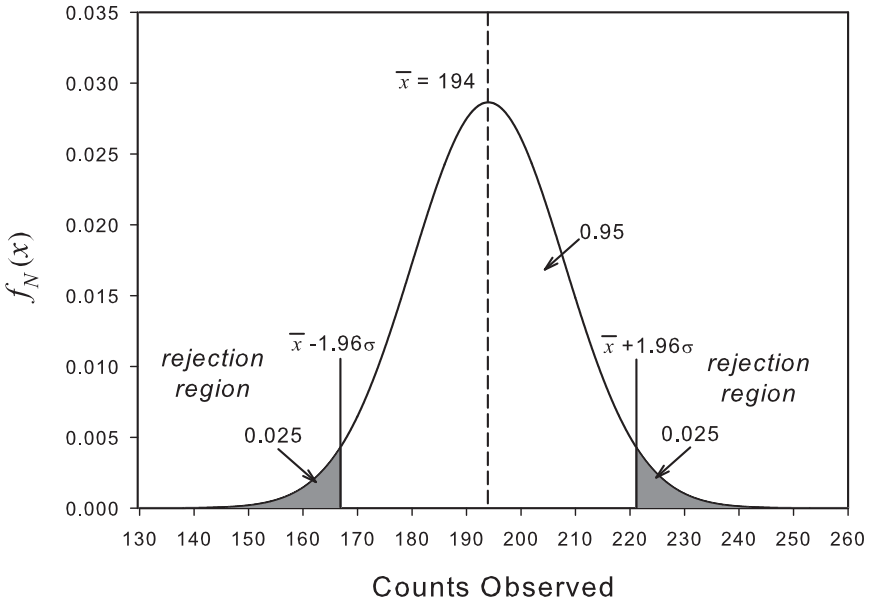

Figure 6.20. The Gaussian distribution $f_{\mathcal{N}}(x|\bar{x},\bar{x})$ as predicted for the case in which it is assumed that $\overline{x} = \sqrt{\sigma} = 194$. The sum of the shaded regions represent 5% of the Gaussian PDF, and the light region represents 95% of the PDF.

6.10.1 Radiation Detection Limits

Sometimes a suspected radioactive sample produces counts similar to those of a background count for the same counting time. How is it possible to determine if the sample is actually radioactive or not? Clearly such a case involves Types I and II errors.

As shown in Fig. 6.21, the Gaussian background and radioactive sample distributions of counts can overlap. In this plot the expected background counts are subtracted from both the background and sample count distribution, i.e., the Gaussian distributions are plotted as a function of the net counts. Because the two distributions overlap it is possible an experimenter can declare a sample radioactive, when it is not (Type I error), or declare the sample "clean" when it is actually radioactive (Type II error).

The net sample counts are defined the gross sample counts G less the background counts B, i.e., $N_s = G - B$. The standard deviation of the background is σ_B, and the standard deviation of the total counts from the sample is σ_G. If the sample is *not* radioactive ($N_s \simeq 0$), then it is expected that $G - B \simeq B - B \simeq 0$. Under such a condition, the standard deviation is

$$\sigma(N_{\rm net}) \equiv \sigma_0 = \sqrt{\sigma_B^2 + \sigma_B^2} = \sqrt{2\sigma_B^2} = \sqrt{2B}. \tag{6.98}$$

But should the sample produces net counts comparable to that of the background ($N_s \simeq B$ or $G \simeq 2B$), the standard deviation is approximately,

$$\sigma(N_{\rm net}) \simeq \sqrt{G + B} = \sqrt{2B + B} = \sqrt{3B}. \tag{6.99}$$

The concepts of Type I and Type II error are important for radiation counting in the presence of significant background radiation. Typically the limiting ability to detect non-background radiation is given by the *minimum detectable activity* (MDA), which defines the minimal amount of radiation that can be detected given a specific confidence limit defined by the rejection region and radiation background [Currie 1968; Rucker 1995].[15]

Related to the MDA is the *critical detection limit* (CDL), which defines the limit by which counts from a sample can be reported with a preset rejection region. Hence, any measurement resulting in counts below the CDL is not worth reporting, based on a one-tailed test at the low end of the sample measurement count distribution. The CDL is defined by the confidence limit defined by some fixed multiple of the standard deviation of the sample distribution.

Shown in Fig. 6.22 are two net count distributions for background and sample measurements in which the tails of the distributions overlap. It should be remembered that the background influences the MDA, and the MDA is determined by the error that an experimenter deems as tolerable. Hence, given some predetermined test and rejection regions, the adjacent shaded regions α and β can be defined, in which α represents the probability of making a Type I error and β represents the probability of making a Type II error. The decision to state that a sample is not radioactive is defined by $1-\alpha$, in which $\alpha = k_\alpha \sigma_0$, is a fraction of the high-end tail of the Gaussian background distribution, where values of $k\sigma$ are listed in Table 6.6. For instance, it is quite common to choose $k_\alpha = 1.645$ so that $\alpha = 0.05$ and that $1-\alpha = 1-1.645\sigma_B = 0.95$. Because the background net count distribution is centered about zero, the CDL (denoted as L_C) is

$$\boxed{L_C = k_\alpha \sigma_0 = k_\alpha \sqrt{2B}.} \tag{6.100}$$

Hence, a sample measurement producing net counts below the CDL is declared non-radioactive. The MDA must be larger than CDL and can be defined in terms of the CDL by setting the MDA equal to the CDL plus some confidence interval with an overlapping rejection region defined in Fig. 6.22 as β. Hence, the MDA, denoted by L_D, is

$$L_D = L_C + k_\beta \sigma_N = k_\alpha \sigma_0 + k_\beta \sigma_{N_s}. \tag{6.101}$$

Typically, β is chosen to be 0.05, hence $k_\beta = k_\alpha = 1.645$.

Two limiting cases in which the sample yields low counts are now considered. In the first case, assume that the background and net sample count rates are similar.

CASE 1: $(N_s \simeq B)$.

$$\begin{aligned} L_D &= k_\alpha \sigma_B + k_\beta \sigma_N = k_\alpha \sqrt{2B} + k_\beta \sqrt{G+B} = k_\alpha \sqrt{2B} + k_\beta \sqrt{3B} \\ &= 1.645(\sqrt{2}\sigma_B + \sqrt{3}\sigma_B) = 5.176\sigma_B. \end{aligned} \tag{6.102}$$

Suppose, however, the net sample counts are quite a bit smaller than those of the background radiation. With the same criteria for k_β and k_α, the following is stated,

CASE 2: $(N \ll B)$. The MDA can be rewritten as

$$L_D = L_C + k_\beta \sigma_N = L_C + k_\beta \sqrt{L_D + \sigma_0^2}, \tag{6.103}$$

which, when combined with Eq. (6.100), and solved for L_D yields

$$L_D = L_C + \frac{k_\beta^2}{2}\left[1 + \sqrt{1 + \frac{4L_C}{k_\beta^2} + \frac{4L_C^2}{k_\alpha^2 k_\beta^2}}\right]. \tag{6.104}$$

[15] The use of the word "activity" in the MDA is unfortunate because the MDA does not refer to the true activity of a sample (number of decays per unit time), but rather to the number of counts produced above background.

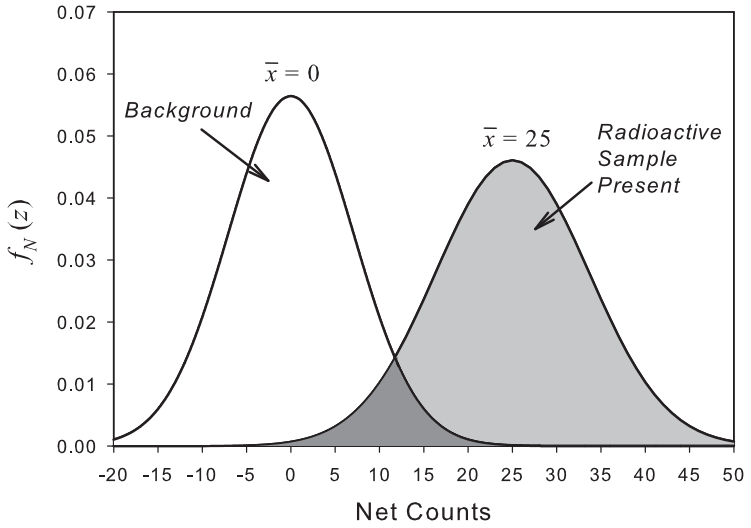

Figure 6.21. Overlapping Gaussian distributions for a case in which a radioactive sample produces comparable counts as does the background radiation. Here the background counts have been subtracted from both distributions and are thus plotted as a function of the net counts, i.e., background subtracted counts or net counts. In this hypothetical case, the background $B = 25$ so that an average net measurement for a non-radioactive sample is 0 counts. The low-level radioactive sample has $N_s = 25$ counts. Notice the significant overlap between the two distributions, hence leaving considerable room for misinterpretation of the radioactive nature of the sample.

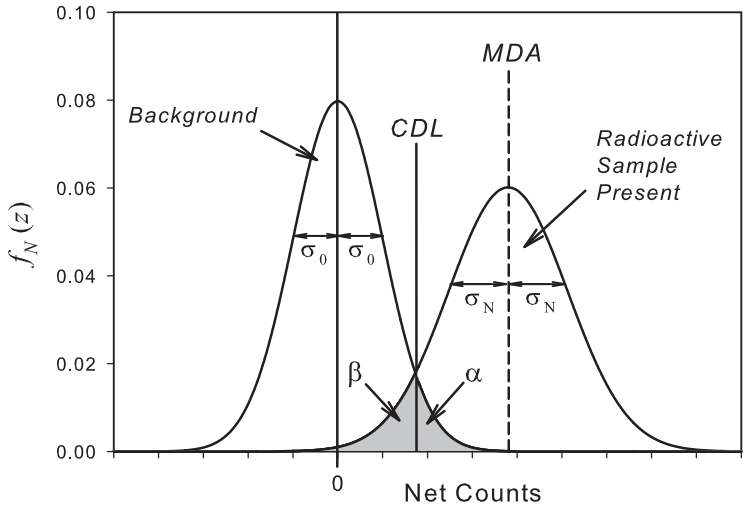

Figure 6.22. Overlapping Gaussian distributions for a case in which a radioactive sample produces a net count comparable to that of the background radiation. The area of the shaded region α is the probability of a Type I error, and the area of the shaded region β is the probability of a Type II error.

If $k_\alpha = k_\beta = k$, then the above reduces to [Currie 1968],

$$\boxed{L_D = k^2 + 2L_C,} \tag{6.105}$$

a commonly used test for low level radiation. Hence, a sample measurement with net counts above the MDA is declared radioactive with 95% confidence.

Example 6.23: A nuclear engineering student discovers an advertisement for "radioactive marbles" on the internet and decides to purchase a few for his collection of atomic memorabilia. Upon receiving the yellowish-green marbles, the student decides to take a measurement to determine if the marbles really are radioactive. A 95% confidence level is decided upon for both Types I and II error, so that $k = k_\alpha = k_\beta = 1.645$. The following data are collected: $G = 217$ counts, $B = 194$ counts, and $N_s = 217 - 194 = 23$ counts. Then

$$\begin{aligned} L_D &= k^2 + 2L_C = k^2 + 2k\sqrt{2B} \\ &= (1.645)^2 + 1.645(2)\sqrt{2}\sqrt{194} = 2.706 + 4.65(13.93) = 67.3. \end{aligned}$$

This result indicates that at least 67.3 net counts should be observed from the sample to reduce the probability of a Type II error to only 5%. With the MDA at 67.3, but $N_s = 23$, the student suspects that the marbles are not radioactive. The CDL is found to be

$$L_C = k_\alpha \sigma_0 = k_\alpha \sqrt{2B} = (1.645)\sqrt{2}(13.93) = 32.4.$$

Since $N_s < L_C$, the result is considered "not worth reporting," and the student determines with 95% confidence that the marbles are not radioactive. (Next time, buy the red Fiesta Ware!)

In recent years, the standard that defined the use of MDA and CDL was updated to address perceived deficiencies [Strom, 2001; ANSI 13.30, 2011]. Measurements and analysis indicate that Eq. (6.100) routinely overestimates the fraction of false positive events [Strom, 2001], becoming large as α is reduced ($\alpha \leq 0.05$). The inaccuracy stems from the fact that a Gaussian distribution is assumed for these low count rates, when in fact the actual average and variance for the observed counts are not well defined.

An alternative, but equivalent, expression for Eq. (6.100) that incorporates varying count rates is [Nicholson 1963],

$$L_C(R_n, \alpha) = k_\alpha \sqrt{\frac{B}{t_B}\left(\frac{1}{t_B} + \frac{1}{t_G}\right)}, \tag{6.106}$$

where t_B is the background count time and t_G is the gross count time, and L_C is given as a count rate. Eq. (6.106) is a function of the net count rate R_n and α, whereas Eq. (6.100) is a function of the observed net counts and α. One suggested method of correction is to substitute $(B+1)$ for B in the analysis [Strom 2001], which implies that the actual average background count observed (or predicted with a Gaussian model) is higher than the measured average. The correction is based on the "belief" that the observations can be described by a uniform Bayesian probability distribution function where the expected value of the observed background counts is $B + 1$. Substitution for B yields,

$$L_C(R_n, \alpha) = k_\alpha \sqrt{\frac{(B+1)}{t_B}\left(\frac{1}{t_B} + \frac{1}{t_G}\right)}, \tag{6.107}$$

where L_C is given as a count rate. Although Eq. (6.107) reduces the frequency of false positives from Eq. (6.100), the estimated false positive rate is still higher than the actual rate.

Alternative treatments for L_C are listed and briefly described in the literature [Strom 2001]. The study compares eight different decision rules in which it was concluded that all of the methods introduce bias into the predicted false positive rate, with Eq. (6.100) yielding the highest false positive rate. Eq. (6.107) adequately suppresses the false positive rate; however, alternative methods appear to yield even lower false positive rates, but apparently risk an increase in false negatives for low counting rates.

6.10.2 Chi-Square Test for "Goodness" of Data

Data accumulated by a counting system may yield results that are affected by systematic errors. For instance, electronic noise may be a source of significant problems, especially if the lower level discriminator (LLD) is set too low. It is often important that an experimenter test the counting system for such possible issues before beginning a radiation measurement experiment.

In Section 6.8 it was shown that counting statistics can be modeled with a Gaussian PDF with mean μ and variance $\sigma^2 = \mu$, provided that the probability p of observing a decay is small and the sample mean $\overline{x}$ is larger than approximately 25. Therefore, given a set of measurements $\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_N$, it should be possible to compare in some way the population variance σ^2 to the sample variance s^2 of Eq. (6.26). One approach is to calculate the χ^2 *statistic* defined as[16]

$$\chi^2 \equiv \frac{\sum_{i=1}^{N}(x_i - \mu)^2}{\sigma^2(x)}, \tag{6.108}$$

where x_i is the ith random sample from $\mathcal{N}(x|\mu, \sigma)$. Here χ^2 is a random variable and is distributed according to the χ^2 PDF [Mood et al. 1974]

$$f(\chi^2|\nu) = \frac{1}{2^{\nu/2}\Gamma(\nu/2)}(\chi^2)^{(\nu/2)-1}e^{-\chi^2/2}, \quad x > 0, \tag{6.109}$$

with $\nu = N$ degrees of freedom. This PDF is illustrated in Fig. 6.23 for $\nu = 1, 2, 3, 4$, and 5. From this figure this distribution is seen to be asymmetrical about the mean, although the χ^2 distribution becomes increasingly symmetric as ν becomes large.

How might χ^2 help one to decide if a counting system is operating properly? If one were to estimate μ by $\overline{x}$ and use the measured $\hat{x}_i$ in place of the x_i then, with Eq. (6.26), χ^2 would be estimated as

$$\hat{\chi}^2 \equiv \frac{\sum_{i=1}^{N}(\hat{x}_i - \overline{x})^2}{\sigma^2} = \frac{(N-1)s^2}{\sigma^2}. \tag{6.110}$$

Divide by $(N-1)$ to obtain the so-called *reduced* chi-square statistic $\chi^2_\nu = s^2/\sigma^2$. Thus, if the data are a good fit to the Gaussian model, then χ^2_ν should be close to unity. If, however, s^2 is greatly different from σ^2, then χ^2_ν would be either very small or much greater than unity, an indication that something is probably amiss with the counting system. Calculation of the reduced χ^2_ν is a very easy and quick way to check a counting system.

Although the above reduced chi-squared procedure is a quick and easy method, it does not yield any quantification of the confidence one has about how well the data fit the Gaussian model. The chi-squared test for "goodness" of data, begins by calculating a *measured* or critical χ^2 value from Eq. (6.108), with the

[16] The square on χ^2 is to remind one that this statistic can never be negative.

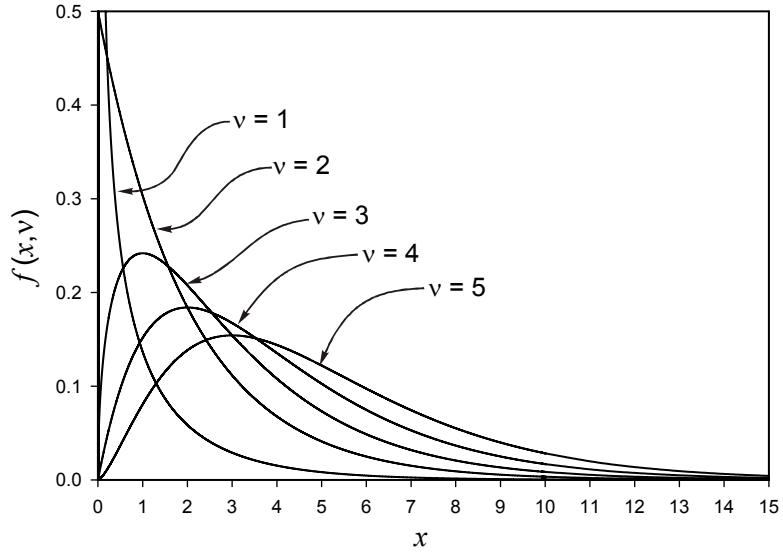

Figure 6.23. The χ^2 probability distribution function for $\nu = 1, 2, 3, 4$, and 5.

observed data, i.e., $\mu \simeq \overline{x}$ and $\sigma^2 \simeq \overline{x}$, as

$$\widehat{\chi}^2 = \frac{1}{\overline{x}} \sum_{i=1}^{N} (\hat{x}_i - \overline{x})^2. \tag{6.111}$$

This statistic is also distributed as the χ^2 PDF but now with $N - 1$ degrees of freedom because μ has been approximated by $\overline{x}$ (see Section 6.5.4).

The probability α of observing a χ^2 greater than χ^2_α is

$$\alpha(\nu) = \int_{\chi^2_\alpha}^{\infty} \frac{1}{2^{\nu/2}\Gamma(\nu/2)} (\chi^2)^{(\nu/2)-1} e^{-\chi^2/2}\, d\chi^2. \tag{6.112}$$

For example, shown in Fig. 6.24 is the χ^2 distribution for $\nu = 20$, in which the shaded region defines the probability of observing a $\widehat{\chi}^2$ value between the limits $\chi^2_\alpha = 27$ and ∞.

Given any χ^2_α and ν, the probability $\alpha(\nu)$ of obtaining a value of $\widehat{\chi}^2$ greater that χ^2_α can be found by numerical evaluation of Eq. (6.112). Conversely, $(1 - \alpha(\nu))$ is the probability of obtaining a $\widehat{\chi}^2$ less than χ^2_α. Figure 6.25 shows values of α for $\nu = 1, 2, 3, 4$, and 5 as a function of the critical value χ^2_α. Shown in Table 6.8 are the values χ^2_α, with the associated probabilities α, for ν ranging from 1 to 30. Thus, the chi-square goodness-of-fit test consists of calculating $\widehat{\chi}^2$ from the measured data. Then from Table 6.8 find the probabilities of obtaining a value larger or smaller than $\widehat{\chi}^2$. If either of these probabilities is much greater or much less than 0.5, then the data are suspect.

Typically, an experimenter should choose a confidence interval to determine whether or not the observed data are unusual. For instance, if a $\widehat{\chi}^2$ value for a set of N measurements yields an α of 0.05, then there is only a 5% probability of observing a higher value should a new data set of N measurements be acquired. Similarly, should the $\widehat{\chi}^2$ value yield α of 0.95, there is a 95% probability that the next set of N measurements produces a higher value. In either case, the result is at the extremes of the χ^2 distribution, a strong indication

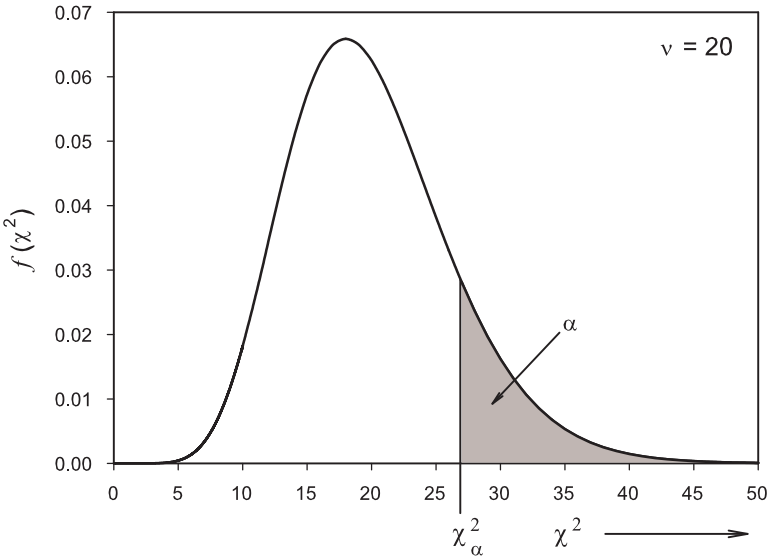

Figure 6.24. The χ^2 probability distribution function for $\nu = 20$, showing a critical value of $\chi^2_\alpha = 27$, where α is the shaded region.

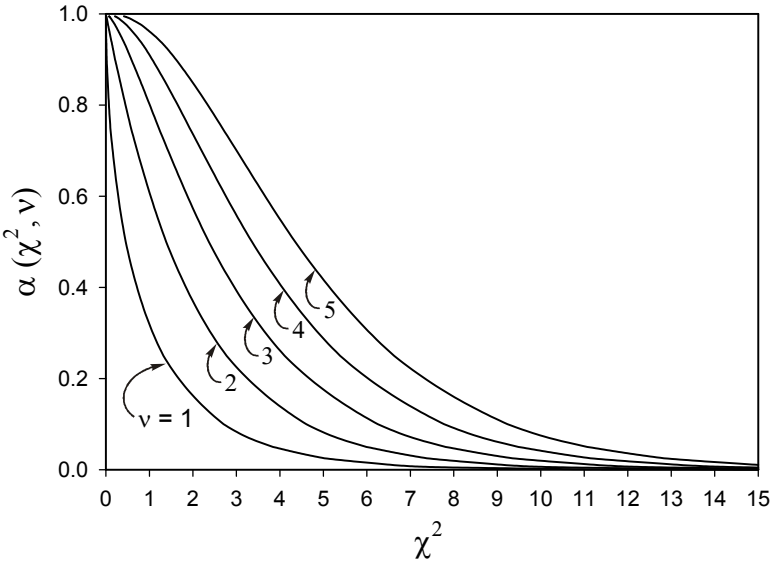

Figure 6.25. The values of α for $\nu = 1, 2, 3, 4$, and 5 as a function of various critical values of χ^2.

that the data are not following the expected Gaussian model. An acceptable confidence interval should be decided upon by the experimenter that minimizes either Type I or Type II error, depending on which is more important in the data analysis.

Example 6.24: An experimenter takes a series of five measurements with a counting system to test the goodness of the data and obtains the following counts: 302, 311, 297, 307, and 299. Find the value of $\widehat{\chi^2}$ and determine the probability of observing a value greater than (or less than) $\widehat{\chi}^2$.

Solution:

From Eq. (6.111),

$$\widehat{\chi}^2 = \frac{\sum_{i=1}^{N} (\overline{x} - x_i)^2}{\overline{x}} = \frac{1.44 + 60.84 + 38.44 + 14.44 + 17.64}{303.2} = 0.438.$$

From Table 6.8 with $\nu = 5 - 1 = 4$, the value of $\widehat{\chi}^2 = 0.438$ falls between 0.297 and 0.484 under the probability columns (α) of 0.99 and 0.975, respectively. Application of linear interpolation between these χ^2_α values, α is found to be 0.9787. This result means that a new series of measurements would have a 97.87% chance of having a $\widehat{\chi}^2$ value greater than 0.438 (or a 2.13% of observing a value less than 0.438). The experimenter should be suspicious of the data!

What do these results mean? Because the distribution yields a low value for χ^2, the variance about the mean is much smaller than should be observed for samples from a Gaussian distribution. Had the $\widehat{\chi}^2$ value been relatively large, for instance near 14 for the case with $\nu = 4$, then the variance about the mean is much larger than should be observed for a Gaussian distribution. Finally, a $\widehat{\chi}^2$ value yielding $\alpha \approx 0.5$ describes the expected variance for a Gaussian distribution.

The χ^2 test is an important tool. If the value of the probability α falls far from 0.5, then something may be wrong with the detector, the electronics, or the counting system arrangement. Possible sources of the problem include:

1. The lower level discriminator (LLD) is set too low, hence the electronic noise is being measured as a significant addition to the real radiation counts.
2. Pickup from ground loops and other electronic noise.
3. Poor preparation of the radioactive sample.
4. Faulty equipment or malfunctioning equipment.

Finally, the experimenter must decide if the result of the chi-squared test is simply a matter of statistics. Because the χ^2 distribution has a range [0,∞], all positive values of $\widehat{\chi}^2$ are possible. Hence, the observation of a single $\widehat{\chi}^2$ value yielding an extreme value of α is not alarming, and might be considered an outlier. However, if several subsequent tests also produce $\widehat{\chi}^2$ values with extreme values of α, then it is almost certain that a problem exists with the counting system.

6.10.3 Presentation of Data

Presentation of counting data should also give the estimated one-sigma errors. In plots of counting data *error bars* are typically used to show the experimental error associated with each data marker. The length of the error bars are scaled to properly depict the values of $\pm\sigma$. If the error is too small to be properly represented by error bars, then the data are represented only by the data markers. In some cases, error bars should be shown along both the ordinate and abscissa of a Cartesian graph.

Theoretical plots, empirical plots and curve fitting routines are depicted by a continuous smooth curve *without data points*. With plotting software, an experimenter may be tempted to use data points and a

dot-to-dot line linking the calculated or theoretical values; but this is simply incorrect. In plotting data a clear distinction must always be made between experimental data points and a theoretical comparison (or curve fit to the data).

Shown in Fig. 6.26 is a *counting curve* for a proportional gas-filled radiation counter[17] versus the high voltage applied to operate the detector. The curve shows the counts observed and the standard error ($\pm\sigma$) for each measurement. In this example, the uncertainties in the applied voltage were deemed to be smaller than the data markers and, hence, horizontal error bars are omitted. Also in the graph a *curve fitted* line is drawn freehand through the data. Such a curve does not represent a theoretical or empirical equation. Equivalently, bicubic splines, for example, can be used to produce a *smooth* curve through the data [Press et al. 1992]. However, such a line is not necessary, but is usually provided to show the trend of the data for presentation purposes. Notice that the trend line is not drawn through each data point, but rather is a smooth representation, showing an estimated average of the data. Error bars are present on data markers in which the value of $\pm\sigma$ exceeds the marker size.

Fig. 6.27 depicts data and a theoretical comparison for an experiment in which different thicknesses of a Cu attenuator are placed between a detector and a ^{137}Cs source. As the Cu thickness is increased, the gamma rays passing through the Cu sheet and entering the detector are exponentially reduced. The example shows the theoretical variation with Cu thickness, for a specific detector and source strength, to be 300 counts when no attenuator is present. Also shown are the theoretical limits $\pm\sigma$ for the attenuated counts based on Gaussian counting statistics. The actual data observed are presented as data markers with error bars defined by $\pm\sigma$ for each data point. Finally two Gaussian distributions show how data samples at two Cu thicknesses should be distributed.

Fig. 6.27 also reveals another important aspect of data presentation, namely it is statistically expected that only 68.3% of the error bars should actually come into contact with the true mean value. In other words, for data following a Gaussian PDF, 31.7% of the data markers and accompanying error bars should not contact either the theoretical or sample mean! Hence, it is simply incorrect to connect all experimental data points together by lines drawn between each pair of data markers.

6.10.4 Concluding Remarks

Radiation emissions are stochastic (non-deterministic) such that the observation of a radioactive decay event cannot be predicted exactly; rather only probability statements can be made of observing an event within a specified period of time. A true mean value (population mean) of the radioactive decay rate can be calculated from the decay constant of the radionuclide, and the probability of observing a radioactive decay is bounded by the variance about that mean. However, experimenters, who do not know the decay constant, must use measured values to obtain the sample mean and sample variance. Almost always there is a difference between the true and sample means, and a difference between the population sample variances. These differences generally become smaller as more data are accumulated.

Three basic statistical models are developed that can describe radioactive decay and counting statistics with the Gaussian (or normal) distribution most often used for radiation counting. Many examples are included to assist in understanding the use of these models. The reader is warned that the models apply only to stochastic processes, and do not account for systematic and sampling errors. Systematic errors may be introduced by biases unknown to the experimenter, such as malfunctioning equipment. The χ-square test can often expose that such biases exist. Sampling errors arise from performing measurements on a sample population different from the one desired. For example, a radioactive sample containing two types of radionuclides or a background count with the radioactive sample not sufficiently far away from the detector would cause sampling errors.

[17] Proportional counters, a type of gas-filled detector, are covered in Chapter 10.

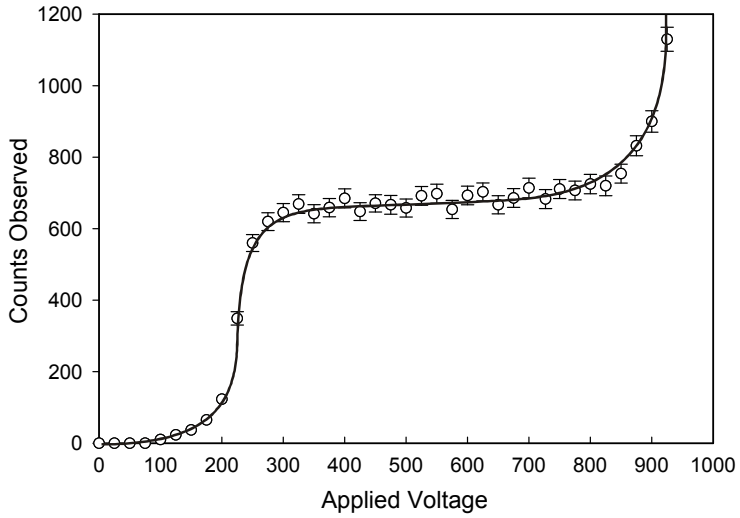

Figure 6.26. Example of data points with error bars, showing a counting curve for a gas-filled proportional counter and a smooth curve fit through the data.

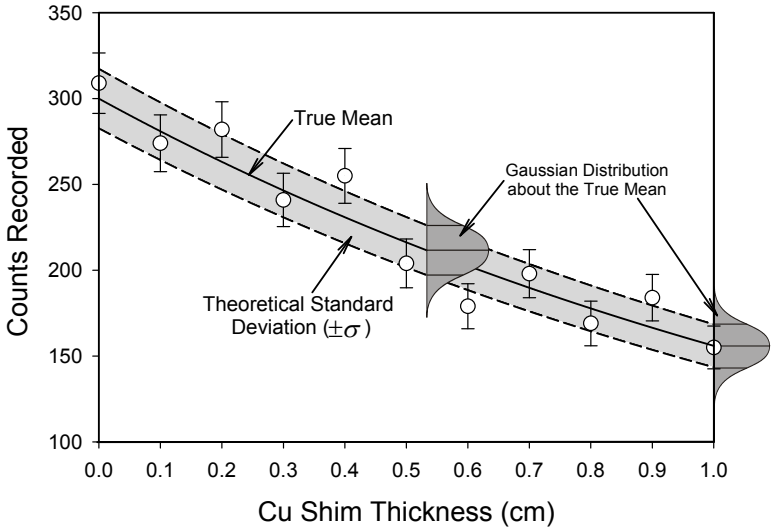

Figure 6.27. Example of data points with error bars, showing the true mean and standard deviation, along with experimental standard deviations for each data point.

The purpose of this chapter is to provide the necessary tools for an experimenter to perform basic radiation measurements. Throughout this book other more specialized statistical models used in radiation detection are introduced. There are also a huge number of other statistical models used in other branches of science and engineering that are not discussed here. For details on these other probability and statistical models for engineering and science, and their proper application, the reader is directed to the reference list at the end of the chapter.

PROBLEMS

1. What is the probability of tossing heads 10 times out of 15 with a "fair" coin?

2. "Introduction to Engineering Concepts 101" is a huge class with 375 students enrolled. Use Poisson statistics to determine the probability that exactly 3 students in the class have a birthday today. Plot the probability distribution function for 0 through 10 students having birthdays.

3. An amateur archer practices once every afternoon, shooting 100 arrows and, generally, hits the target. One time out of 15, the archer hits the bull's eye. After shooting 100 arrows, what is the average number of bull's eyes achieved, and what is the standard deviation? What is the probability that the archer strikes exactly 10 bull's eyes after 100 tries?

4. A set of radiation measurements is made with the following results:

$$54, 89, 64, 102, 90, 78, 56, 74, 88, 42,$$
$$70, 94, 50, 82, 100, 64, 72, 78, 58, 76$$

Find the sample mean, variance and standard deviation.

5. Ten radiation measurements are conducted from which a standard error is determined. If an eleventh measurement is conducted under identical conditions, by what amount does the standard deviation change?

6. ACME Roadrunner Company manufactures alternators with a one-year guarantee. Random sampling of alternators yielded the following number of months to failure for 22 alternators:

$$37, 25, 44, 51, 26, 41, 18, 29, 58, 34, 43$$
$$31, 11, 27, 40, 39, 52, 23, 36, 38, 45, 55$$

Determine the experimental mean, median and variance of the data distribution. Find the 10% trimmed mean and compare it to the median. Use a Gaussian PDF to estimate what percentage of alternators fail and must be returned for a warranty replacement?

7. Show that Eq. (6.95) reduces to

$$\sigma_n = \frac{1}{N}\sqrt{\sum_{i=1}^{N}\left(\frac{G_i}{t_{Gi}^2}+\frac{B_i}{t_{Bi}^2}\right)}$$

if the number of measurements performed N is the same for both gross and background counts, with all t_G equal and all t_B equal.

8. A measurement is conducted with 662 keV gamma rays from a ^{137}Cs source. A detection system records an average counting rate of 125 cpm. A background measurement records an average count rate of 15 cpm. If a 30-minute background measurement is performed, how long must the ^{137}Cs source measurement be in order to reduce the standard error of the net counts below 1%?

9. A radiation measurement is conducted in which a total gross number of counts is 2109, taken over 1 minute. A 10-minute background measurement is taken, resulting in 312 counts. What is the net count rate and standard deviation (in counts and in percent)?

10. The following set of measurements, each for a six-second duration, resulted in the following number of counts:

$$70, 64, 49, 58, 57, 52, 59, 53, 53, 58, 63, 61, 62, 68, 67, 51, 56, 54, 51, 66$$
$$66, 68, 71, 67, 51, 64, 73, 58, 69, 62, 56, 60, 57, 53, 57, 52, 55, 65, 61, 58$$
$$56, 61, 55, 70, 65, 68, 73, 57, 62, 58, 55, 63, 54, 58, 57, 64, 58, 66, 54, 49$$
$$68, 54, 62, 58, 79, 74, 53, 63, 58, 51, 56, 60, 56, 57, 62, 62, 59, 50, 63, 57$$
$$72, 45, 57, 47, 48, 62, 59, 53, 40, 77, 79, 48, 51, 69, 65, 60, 58, 71, 64, 48$$

(a) Calculate the sample mean, sample variance and the sample standard deviation. (b) Plot the data distribution function and indicate the mean and standard deviation. (c) Use the sample mean to plot the expected Gaussian PDF on the same graph. (d) Compare the experimental and theoretical distributions by examining the variances and standard deviations.

11. A measurement is conducted with a 356-keV gamma-ray source that produces 1267 counts in a period of 5 minutes. A 2-mm thick sheet of material is placed between the source and the detector and the detector records 874 counts in 5 minutes? What is the attenuation coefficient and its standard error for the material?

12. The following measurements were taken over five-minute periods each:

$$1288, 1443, 1377, 1341$$

and the following background measurements were taken over ten-minute periods each:

$$351, 436, 379, 414$$

Calculate the net counting rate per minute and the associated percent error.

13. A measurement was taken over a period of five minutes, resulting in 1417 counts. The background was measured for one hour, resulting in 315 counts.

1. What is the average counting rate per minute and its percent standard error?
2. What is the estimated number of counts and its percent standard error for a one-hour measurement?
3. Use the average cpm to find the percent standard error if the measurement was conducted for one hour as opposed to five minutes. How does this result compare to the five-minute measurement?

14. Prove that the covariance $\langle (x_i - \overline{x}_i)(x_j - \overline{x}_j) \rangle$ can be approximated by $\langle x_i x_j \rangle - \overline{x}_i \overline{x}_j$. [Hint: Start by expanding $(x_i - \overline{x}_i)(x_j - \overline{x}_j)$].

15. The half-life of a radiation source is sought. The first measurement, taken over a period of 1 minute, yielded 2350 counts. Ten minutes later, a second measurement was started, again over a 1-minute period, and yielded 1780 counts. What is the half-life of the source and the standard error in the measured half-life?

16. Perform the χ^2 test on the data of Example 6.7. If a new set of measurements is taken under identical conditions, what is the probability that the new $\widehat{\chi}^2$ value is greater? What is your determination of the "goodness" of the data?

17. Use the reduced chi-squared statistic to examine the "goodness" of the data in Example 6.7.

18. Derive Eq. (6.104) using the results of Eq. (6.100) and Eq. (6.101). Show that if $k_\alpha = k_\beta$, then Eq. (6.104) reduces to Eq. (6.105).

19. An unmarked sample was found on the bottom shelf, way in the back, of the neutron activation analysis (NAA) lab. It is unknown how old this sample is, and unfortunately, whether or not it is still radioactive. The background recorded by a counting system in the NAA lab is 35 cpm. For a one-minute measurement, what is the CDL required to produce with 95% confidence that the sample is not radioactive? What is the MDA required for 95% confidence that the sample is still radioactive? Repeat your analysis for a 60-minute measurement.

20. You are a final contestant on the *Let's Make a Deal!* show, and must pick one of three doors, behind which only one door has the grand prize, and behind the other two doors there is a pallet of dog food. After making your initial selection, one of the doors that you did not choose is opened to reveal a pallet of dog food, hence either the door you picked or the remaining closed door has the grand prize. You are then given the opportunity to change your choice to the other closed door. Should you make the change? Determine the statistics of winning if you change as opposed to keeping your original choice.

Chapter 7

Source and Detector Effects in Radiation Measurements

An experiment is a question which science poses to Nature, and a measurement is the recording of Nature's answer.

Max Planck

The purpose of making radiation measurements is usually to infer information about the source of the radiation. In particular, a detector response, such as a count rate, is often used to estimate the strength or intensity of the radiation particles emitted by a source. Typically, the emission rate of a specified type of radiation is sought. Although the detector count rate is *approximately* proportional to the emission rate of the radiation from the source, there are many correction factors (some small, some large) that must be made to the observed count rate to obtain an accurate estimate of the source strength. For example, not all emitted radiation is emitted in a direction that intersects the detector volume. Likewise radiation emitted toward the detector can be scattered by the surrounding medium into directions pointing away from the detector. Thus, to accurately infer information about source strengths it is important to understand how the source strength is related to the detector's response. The several effects that must be accounted for are the topics of this chapter.

To limit the scope of this chapter, the sources of radiation considered in this chapter are assumed to be radioactive sources which emit radiation isotropically. Other sources of radiation such as cosmic rays, accelerator sources, radiation from reactor beam ports, x-ray machines, etc., have their own special phenomena that must be considered to infer accurate source strengths.

7.1 Detector Efficiency

Upon the detection of radiation, a proper calculation of the source activity, or radiation field, requires an understanding of the detector response in the local environment. The ability of a detector to respond to radiation is often reported as "efficiency", yet there are multiple definitions for detector efficiency, which include *absolute* efficiency, *relative* efficiency, and *intrinsic* efficiency [McGregor and Shultis 2011].

Absolute efficiency ϵ_A is defined as the ratio of the measured number of counts recorded by the detector to the total number of emissions from the radiation source during a time Δt, or, equivalently, the ratio of the count rate R_{det} to the source emission rate,

$$\epsilon_A = \frac{R_{det}}{AB\prod_{i=1}^{n} C_i}, \tag{7.1}$$

where A is the source activity, B is the branching ratio or the probability, per radioactive decay, of emission of the radiation of interest and C_i are various correction factors that apply to the measurement. A significant characteristic of absolute efficiency measurements is that they are sensitive to changes in the source/detector

geometry. Hence, reporting the absolute efficiency is of little value unless the experimental arrangement is described with adequate specificity to permit accurate reproduction of the measurement. The absolute efficiency depends critically on the detector's performance characteristics and on the geometrical positioning of the detector with respect to the radiation source. There are conditions under which absolute efficiency is a standard for reporting a detector's performance. For instance, the measurement method to report absolute efficiency for high-purity Ge (HPGe) detectors (see Chapter 20) is outlined under ANSI/IEEE 325-1996, which describes a standardized distance, orientation and radiation energy. However, for general use, the characterization of a detector by its absolute efficiency may be difficult to repeat.

Relative efficiency ϵ_R is the absolute efficiency of a test detector compared directly with another reference detector of known absolute efficiency ϵ_A^{ref} under identical conditions, i.e.,

$$\epsilon_R = \frac{\epsilon_A}{\epsilon_A^{ref}} = \frac{R_{det}}{AB\epsilon_A^{ref}\prod_{i=1}^{n} C_i}. \tag{7.2}$$

Typically, the reference detector is an established standard. For instance, using the HPGe example once again, the ANSI/IEEE 325-1996 standard prescribes that the HPGe detector be compared directly to the performance of a 3-in. × 3-in. right-cylindrical NaI:Tl detector (see Chapter 13), where the established absolute efficiency for the NaI:Tl detector is 1.2×10^{-3} [Fairstein et al. 1996]. Commercial vendors commonly quote relative efficiencies for various detectors; hence, it is important that the user understand the characterization method used to determine the efficiency.

Intrinsic efficiency ϵ_I is the ratio of the detector response (counts or count rate) to the particle emission or emission rate further divided by the solid angle Ω subtended by the detector with respect to the (point) source divided by the 4π solid angle of radiation emission, i.e.,

$$\epsilon_I = \frac{4\pi\epsilon_A}{\Omega} = \frac{4\pi R_{det}}{AB\Omega\prod_{i=1}^{n} C_i}. \tag{7.3}$$

Here Ω is proportional to the probability that emitted radiation intersect the detector's entrance aperture. For the case that the radiation source is not a point source, $\Omega/4\pi$ is replaced by a correction factor P_F which is again the probability the emitted radiation is in a direction toward the detector aperture. The intrinsic efficiency is often reported in an attempt to reduce the dependence upon system geometry, by considering only the radiation that is emitted toward the detector. Intrinsic efficiency, can, in principle, be used to scale the expected absolute efficiency for various alternate source/detector geometries.

Although the use of intrinsic efficiency mitigates the geometric dependence on efficiency measurements, it does not completely eliminate this dependence. Other effects such as the source preparation, detector characteristics, and the medium between the source and detector can also affect the measured results. These various effects that alter the measured efficiency can be classified into the following three broad categories.

Source Effects: The source preparation and encapsulation can alter the energy and number of radiation particles arriving at the detector aperture.

Detector Effects: The operational characteristics of a detector can alter the measured energy and number of radiation particles recorded by the detector.

Geometric Effects: The geometry of the source, detector and their configuration with respect to each other affect the energy and number of radiation particles arriving at the detector aperture.

These topics and how to correct for them are discussed in the remainder of this chapter.

7.2 Source Effects

Preparation of the source material and its encapsulation has an effect on the emission rate of radiation from the source assembly. Both alpha and beta particles sources can suffer significant backscatter from the source backing, or can also have considerable energy attenuation if the source material or source encapsulation is too thick. Likewise, the material (such as air) between the source and detector and the detector window reduce the number and energy of particles reaching the sensitive volume of the detector. Measurement of gamma rays and neutrons may produce significant room scatter if the shielding around the detector is inadequate. However, even with shielding to prevent room scatter, scattering from the shielding material itself produces scattered particles than can still reach the detector. Correction for all of these effects in order to determine accurately the source strength from a measured detector response is a formidable task. However, with proper source and detector designs, the needed correction factors can be made small (a few percent) so that approximate estimates of them can suffice.

Consider an idealized source/detector geometry shown in Fig. 7.1 in which the source material, the source substrate or backing, the source encapsulation cover and the detector window consist of parallel planes. As shown, there are many possibilities for source radiation to be prevented from reaching the active volume of the detector and also possibilities for which emitted radiation that would miss the detector can be redirected into the detector. To address all of the possibilities would require a detailed radiation transport calculation. In this section the two most important source effects are considered, namely (1) self-absorption of the radiation by the source and (2) the backscattering of radiation from the source substrate. These effects are addressed using simple and, thus, approximate analyses and are based on several key assumptions such as straight-line radiation trajectories, exponential or finite range attenuation, no source cover, a radionuclide source with isotropic emission, and a detector response that is insensitive to the energy and angle of incidence of the entering radiation. First a few key parameters are defined and then results for different types of radiation are given.

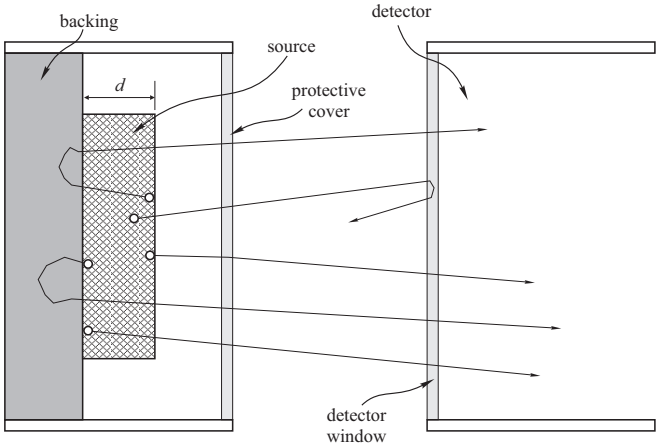

Figure 7.1. Observed counts and count rates can be affected by source and detector effects, including backscattering off of the detector window, backscattering off of the source backing, and attenuation through the source material, source window, medium between the detector and source, or detector window.

Source Self-Absorption Effect

Define the self-absorption factor for a source layer of thickness d

$$f_a(d) \equiv \frac{\text{no. particles exiting the source}}{\text{no. particles exiting without self-absorption}}, \tag{7.4}$$

where only particles emitted towards the front surface (i.e., the surface adjacent to the detector are considered). This factor is the probability $P_a^{esc}(d)$ that a particle born uniformly in the source volume escapes through the front surface. Division of the measured source strength S_{meas}, inferred from the detector count rate, by f_a gives a source strength corrected for source self-absorption that is larger than S_{meas} because f_a is always less than unity.

As $d \to 0$ the self-absorption factor $f_a(d) \to 1$, i.e., there is no self-absorption and all source particles escape the source layer. It should be noted that both the energy and angular distributions of the escaping

particles are, generally, different than those particles emitted by the radionuclide. Also the self-absorption factor cannot be measured experimentally since all sources must be composed of matter and, thus, be capable of interacting with the radiation.

Source Backscatter Effect

Radiation particles emitted by the source in directions away from the detector can reach the source backing, of thickness T, in which they can scatter and some are subsequently reflected back towards the detector. To correct S_{meas} for this backscatter effect, a backscatter factor $f_b(T)$ is defined as

$$f_b(T) \equiv \frac{\text{no. particles recorded with source backing}}{\text{no. particles recorded without source backing}}. \tag{7.5}$$

To evaluate $f_b(T)$ it is assumed there is negligible source self-absorption so that half of the source particles S leave towards the detector and half impinge on the source backing. Because the recorded count rate is proportional to the rate at which particles leave the source in the direction of the detector, the backscatter factor is given by

$$f_b(T) = \frac{0.5S + 0.5S\ \eta_b(T)}{0.5S} = 1 + \eta_b(T), \tag{7.6}$$

where η_b is the *reflection coefficient* and is the probability a particle entering the substrate is reflected back to the surface.

This coefficient increases from 0 to a saturation value η_b as the thickness of the source backing increases from 0 (no backscattering) to a value beyond which negligible particles are reflected. For particles with a finite range R_{eff} saturation reflection is achieved when $T = R_{eff}/2$ since no particles can reach a greater depth and return to the backing surface. In practice, $T \simeq 0.3R_{eff}$ achieves saturation reflection. For particles that are exponentially attenuated with an attenuation coefficient μ, $T \simeq 1/\mu$ results in near saturation. The reflection coefficient usually is a measured quantity, although with modern Monte Carlo transport techniques it can be calculated.

7.2.1 Alpha Particles

The preparation of the radioisotope that emits alpha particles can affect the observed count rate and spectroscopic energy resolution. If the radioisotope is deposited as a thick layer, the alpha particles lose energy as they travel through the source material. The energy loss depends on the alpha-particle trajectory and where in the source material the particle was emitted. Likewise particles emitted towards the material upon which the radioisotope was deposited can make multiple Coulombic scatters and be reflected back towards the detector. This backscatter component can cause an overestimation of the source activity by increasing the count rate over that expected from a source with no backing.

In some cases, alpha-particle sources have a protective covering to reduce risk of contamination from radioisotope leakage. These thin windows, as well as the detector window, can cause alpha particles to scatter away from the detector, thereby causing an underestimation in the source activity. Further, thin windows can absorb energy from the particles, thereby reducing the range and measured energy while increasing the uncertainty for spectroscopy measurements. To minimize the effect of the detector window a thin form of boPET[1] is typically used for alpha-particle source windows and detector windows, thereby, reducing both the effects of energy loss and backscattering. These multiple measurement problems are illustrated in Fig. 7.1. Finally, if there is a medium, such as air, between the source and the detector window further degradation of the energy of the alpha particles occurs.

[1] Biaxially oriented polyethylene terephthalate (boPET) is a stretched polyester film commonly known by trade names such as Mylar. Applied as detector windows, these films are generally between 3 to 6 microns thick (or 0.4 to 0.8 mg cm^{-2}), and being primarily composed hydrogen, carbon and oxygen ($C_{10}H_8O_4$), alpha-particle backscattering is minimal.

Attenuation

Consider the arrangement, shown in Fig. 7.2, in which an alpha particle source of thickness d, plated upon a planar backing, is placed inside the chamber of a gas-filled detector, such that half of the emissions are initially emitted towards the gas, the other half being emitted in the direction of the backing. Under ideal conditions, half of the emissions should be detected.[2] However, particles emerging at oblique angles from the normal (perpendicular) trajectory may pass through so much material that they lose too much energy for detection.

Recall that alpha particles have discrete ranges in matter, denoted here as $R_o \simeq R_{\text{CSDA}}$, about which there is a minimal amount of straggle. As alpha particles are emitted in the source material, they lose energy before emerging into the detector. At some critical angle θ the alpha particle has just enough energy to still be detected as it emerges from the source material, a condition that is dependent on the alpha-particle trajectory and the detector electronic lower level discriminator (LLD) threshold ($E_\alpha \geq E_{LLD}$). This effective range R_{eff} is the maximum distance that the alpha particle can travel through the source material before $E_\alpha < E_{LLD}$, i.e.,

$$R_{eff} = R_o - R_z, \tag{7.7}$$

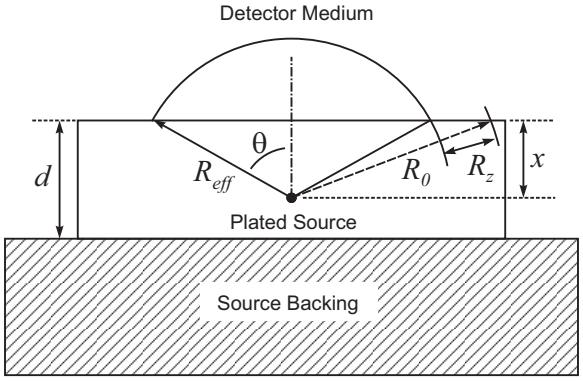

Figure 7.2. Depicted are the average total range R_o and the average effective range R_{eff} of alpha-particle emissions from a plated source of thickness d born at location x.

where R_z is the *residual range*, the range in the source material that an alpha particle with energy E_{LLD} would have.

Consider an alpha particle emitted at depth x in the source material. Because the emission is isotropic, the probability it reaches the source surface with sufficient energy to be detected is $p_{esc}(x) = \Delta\Omega(x)/4\pi$, where $\Delta\Omega(x)$ is the solid angle subtended by the disk on the surface defined by the cone with the half-angle θ in Fig. 7.2. A differential solid angle in spherical coordinates (see Section 7.4) is $d\Omega = \sin\theta\, d\theta\, d\psi$ where θ is the polar angle and ψ is the azimuthal angle. Hence

$$\Delta\Omega(x) = \int d\Omega = \int_0^{2\pi} d\psi \int_0^{\theta} \sin\theta\, d\theta = 2\pi(1-\cos\theta) = 2\pi\left(1 - \frac{x}{R_{eff}}\right). \tag{7.8}$$

Note that if $x \geq R_{eff}$, $p_{esc}(x) = 0$ because either no particles can escape the source material or escaping particles have energies below E_{LLD} and cannot be detected. Then the probability P_a an alpha particle born uniformly within the source material escapes attenuation from the source material is given by

$$P_a^{esc} = \int_0^{\min(d,R_{eff})} \{\text{probability an alpha particle is emitted in } dx \text{ about } x\} \times \{p_{esc}(x)\}. \tag{7.9}$$

Because the radioisotope is distributed uniformly in the source material, the probability an alpha particle is emitted in dx about x is dx/d so that

$$P_a^{esc} = \int_0^{\min(d,R_{eff})} \left\{\frac{dx}{d}\right\}\left\{\frac{\Delta\Omega(x)}{4\pi}\right\} = \frac{1}{2d}\int_0^{\min(d,R_{eff})} \left(1 - \frac{x}{R_{eff}}\right) dx. \tag{7.10}$$

[2] Such a detector is often referred to as a 2π detector, because the source emits particles into the detector chamber over a solid angle of 2π steradians.

Evaluation of the integral yields

$$P_a^{esc} = \begin{cases} \frac{1}{2}\left[1 - \frac{d}{2R_{eff}}\right], & \text{if } d < R_{eff} \\ \frac{R_{eff}}{4d}, & d \geq R_{eff} \end{cases} . \tag{7.11}$$

In the above analysis it was assumed that the source material composition is known so that the ranges R_o and R_{eff} are known. Unfortunately, the chemical form of the source material is seldom known because source manufacturers often regard this information as proprietary.

Attenuation of alpha particles through the intermediate medium between the detector and source, typically air, causes energy loss and range reduction. Alpha particle detectors must be placed close enough to the source such that the particles can enter the detector medium with sufficient energy to be detected. In the prior case of the 2π detector, the alpha-particle source is placed inside the detector cavity. However, operation of common survey meters and thin-window detectors does not permit such a placement, and the sensitive detector volume must be placed within the range of the alpha particles. Further, the thin window of the device must be taken into account as part of the total range reduction.

The total energy attenuation becomes a function of the source thickness, the medium distance between the detector and source, and the detector entrance window thickness. Often it is the "mass thickness" of a material that is quoted for range (see Fig. 7.3), defined as the product of the alpha-particle range and the mass density of the attenuating material, i.e., $R_{\text{mass}} = \rho R_o$ g cm^{-2}.

Backscattering

Consider the backscatter events shown in Fig. 7.1. From the general expression for Rutherford backscattering [Kaplan 1962], it is unlikely that an alpha particle backscatters towards the detector from a nucleus in the source backing material in a single scattering event. Instead, it is multiple small-angle scatters that can cause the alpha particle, originally on a trajectory towards the source backing, to eventually emerge from the source towards the detector. The overall consequence of alpha-particle backscattering is to produce a higher count rate than that without backscattering. Hence a backscattering correction factor should be estimated and used when reporting the measured source activity.

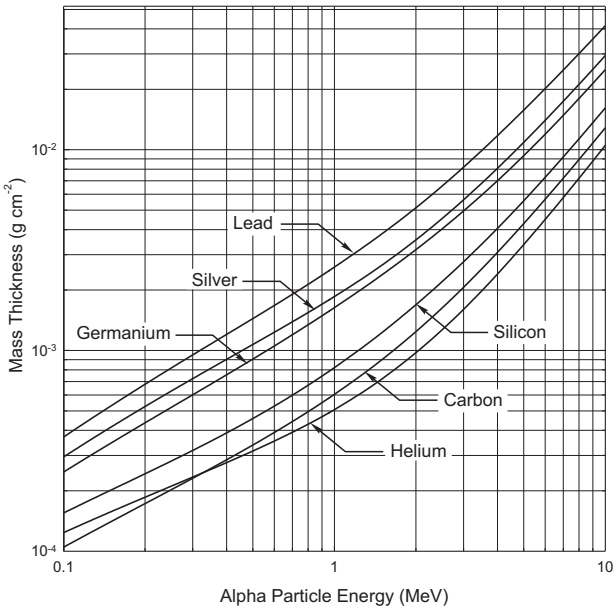

Figure 7.3. Alpha particle mean range R_p as a function of mass thickness and energy (from Ziegler, 2013).

Careful source preparation may allow an experimenter to produce an ultra-thin source backing, which produces minimal backscattering, and, thereby, effectively eliminates the backscattering problem. However, repeatability of source preparation often becomes an issue, compounded by calibration issues. Instead, it is far more common to prepare sources that reach a saturation backscatter limit. Intuitively, to achieve this limit, the source support (backing) should be $\geq R_o/2$ for the backing material; hence, a particle scattering deeper than $R_o/2$ cannot emerge from the backing material.

A general expression for alpha-particle backscattering is [Crawford 1949]

$$\eta_b = K \left[\frac{\sum_{i=1}^{N} f_i A_i^2}{A_r^{3/2} \sum_{i=1}^{N} f_i A_i^{1/2}} \right]^{1/2}, \tag{7.12}$$

where η_b is the probability that a particle is backscattered if it is emitted in the direction of the source backing, K is a constant, A_r is the atomic weight of a reference backing material, A_i are the atomic weights of the constituents in the backing material (or window material), and f_i are the atomic fractions of the elements (see also [Deruytter 1962]). For elemental source backings, Eq. (7.12) reduces to

$$\eta_b = K \left[\frac{A}{A_r} \right]^{3/4}. \tag{7.13}$$

From Eq. (7.13), the amount of backscatter increases as A (or Z) increases, indicating that low Z materials are best used for alpha-particle source backing.

Reported experimental results indicate that the alpha-particle backscatter probability measured with ^{210}Po ($E_\alpha = 5.307$ MeV) is [Hutchinson et al. 1968]

$$\eta_b = \frac{(1.30 \pm 0.08) \times 10^{-3} Z}{C_0}, \tag{7.14}$$

where C_0 is a constant measured to be 2.525 ± 0.002. Variations with alpha-particle energy and the thickness of the backing material were not considered in Hutchinson's work; presumably, saturation backscatter coefficients were investigated and measured. According to Eq. (7.14), a 5.31-MeV alpha-particle source on an Al backing has a 0.67% backscatter coefficient, while the same alpha-particle source applied to a Au backing has a 4.07% backscatter coefficient. Hutchinson et al. [1968] also report that the surface morphology of the source backing affects the backscatter coefficient, η_b being generally higher for polished source backings as opposed to unpolished source backings.

With the source of sufficient thickness to reach the asymptotic backscatter limit, Rossi and Staub [1949] approximate the backscatter probability as

$$\eta_b \simeq 0.201\phi, \tag{7.15}$$

where ϕ is a function of the effective range in the backing material, defined as $R_e = R_o - R_z$. To some degree, Eq. (7.15) takes into account the energy of the alpha particle, in which η_b is dependent upon the necessary effective range R_e. Rossi and Staub [1949] published a short table of values for ϕ that can be used to estimate η_b.

Little, if any, experimental data is available about the energy distribution of the alpha particles that are backscattered from the source backing. However, with modern Monte Carlo methods it is now possible to track alpha particles as they undergo Coulombic scattering and estimate η_b and the energies of backscattered alpha particles from any backing material. Example calculations are shown in Fig. 7.4 for an isotropic source. Notice the energy spectra are peaked towards very lower energies (for alpha particles that penetrated relatively far into the backing and took many small-angle scatters to re-emerge) and at energies close to the source energy (from particles that entered the backing at grazing angles and, hence, needed only a few scatters to re-emerge). The area under each histogram gives η_b. For example, for aluminum $\eta_b = 0.83\%$. However, if the low-energy reflected alpha particles below 0.5 MeV are ignored, then $\eta_b = 0.67\%$, a result in agreement with Hutchinson's measured value quotes from above.

MCNP6 has been used to calculate the total backscattering probability for different backing materials (see Fig. 7.5). The variation of $\eta_b(sat)$ with the Z number of the backing medium is well described, as shown

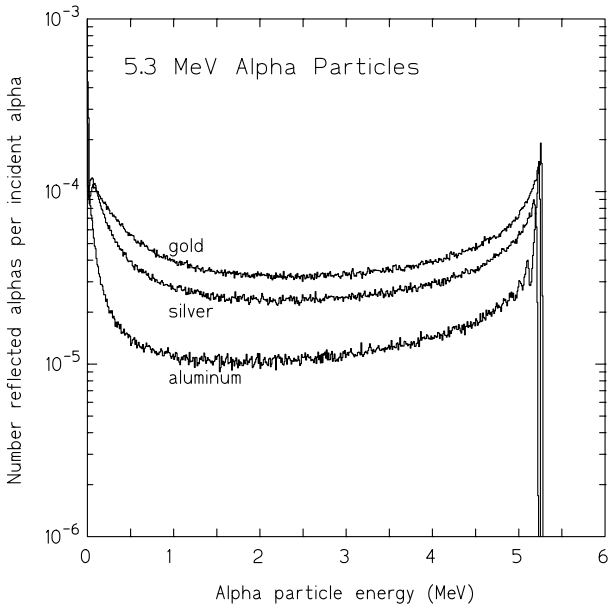

Figure 7.4. A histogram of the number of ^{210}Po alpha particles backscattered from three thick metal surfaces. Energy bin widths are 0.01 MeV. Results obtained with MCNP6 [2013].

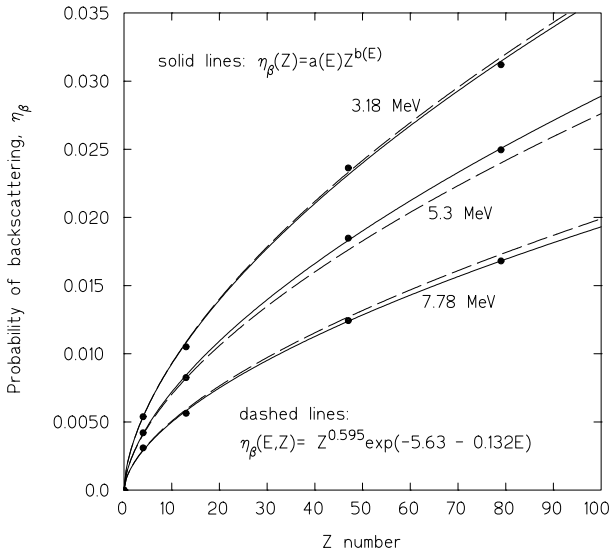

Figure 7.5. The saturation backscatter probability for alpha particles as estimated with MCNP6 [2013] (solid circles) as a function of the backscattering material Z number. The associated uncertainty is less than 0.5% for all points. Here E is the initial energy of the alpha particle and the energies 3.18 MeV, 5.30 MeV, and 8.78 MeV are the energies of the alpha particles emitted by ^{148}Gd, ^{210}Po, and ^{212}Po, respectively.

by the solid lines in Fig. 7.5, by the simple relation $\eta_b(Z) = aZ^b$, where a and b depend on the initial energy E_α of the alpha particle. Based on MCNP6 calculations shown in Fig. 7.5, the probability of backscattering is approximately (see the dashed lines in Fig. 7.5)

$$\eta_b(E_\alpha, Z) \simeq Z^{0.595} \exp(-5.63 - 0.132E_\alpha), \tag{7.16}$$

where E_α is the initial energy of the alpha particle (in MeV).

In general, when performing alpha-particle measurements, the experimenter should correct the acquired count rate g, and hence the measured activity, by using a backscattered corrected count rate $\tilde{g}$

$$\tilde{g} = \frac{g}{1+\eta_b} = \frac{g}{f_b}. \tag{7.17}$$

7.2.2 Beta Particles

As with alpha-particle sources, beta-particle sources can also suffer from attenuation (self-absorption) in the source material and its encapsulation and from backscatter effects. This latter effect can be particularly severe for backscattering from heavy elements. Hence, correction for these effects is important to measurement accuracy.

Attenuation

Consider a volume of source material of thickness d in which beta-emitting radionuclide is uniformly distributed. At any depth x in the source material beta particles are emitted isotropically with a continuum of energies up a maximum energy $E_{\max}$ such that $\chi_\beta(E)\,dE$ is the probability the beta particle (either an

electron or positron) is emitted with energy in dE about E. The probability a beta particle reaches the surface of the source material and is not absorbed in the source film can formally be written as

$$P_a^{esc} = \int_0^{E_{\max}} \chi_\beta(E) dE \int_0^{\pi} d\theta \int_0^{d} dx f_\beta(x, \theta, E), \tag{7.18}$$

where $f_\beta(x, \theta, E)$ is the probability a beta particle emitted at depth x with energy E reaches the surface traveling in direction θ with respect to the surface normal. However, there is no analytical solution or even numerical solution of Eq. (7.18), because there is no known expression for $f_\beta(x, \theta, E)$. Unlike the case of alpha particles which travel in straight lines with a well-defined range, beta particles travel along twisted trajectories (see Fig. 4.22) that can terminate at any distance from the emission point up the *continuous slowing down approximation* (CSDA) range of the beta particle. To evaluate P_a^{esc} accurately for beta particles, it is necessary to employ Monte Carlo methods.

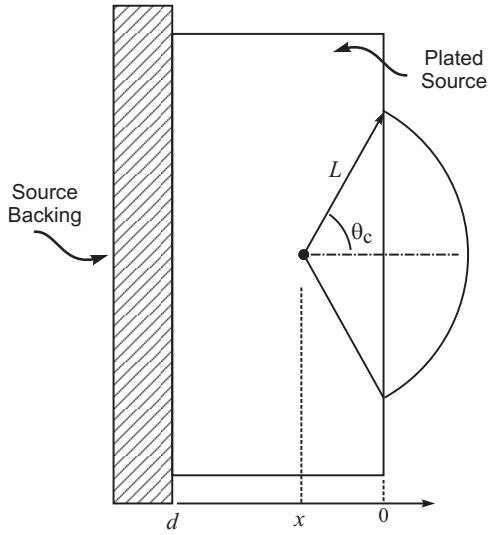

Figure 7.6. Geometry for a beta-particle source.

Although not strictly accurate, the attenuation of beta particles through a material can sometimes be modeled by an exponential function

$$\frac{I(x)}{I_0} = I_0 e^{-\mu x}, \tag{7.19}$$

where $I(x)/I_0$ is the fraction of the initial ionization measured (say) by an ion chamber after the beta particles have passed through an absorber of thickness x and μ is an effective linear attenuation coefficient. Note that Eq. (7.19) is not based on a physical phenomenon, but instead is derived from rather remarkable linear fits of beta-particle transmission data plotted upon semilogarithmic graphs [Baltakmens 1970].[3] An empirical relation that gives the mass absorption coefficient $\rho\mu$ is [Evans 1955]

$$\frac{\mu}{\rho} = \frac{17}{E_{\max}^{1.14}} \qquad \text{cm}^2\text{g}^{-1}, \tag{7.20}$$

where $E_{\max}$ is in MeV. This mass absorption coefficient only weakly depends on the Z number of the absorber increasing slightly with Z.

Consider the beta source shown in Fig. 7.6 with thickness d in which beta particles can be emitted from any depth x in the film. Assume that Eq. (7.19) is an adequate estimate for beta-particle attenuation, thereby removing the energy dependence in Eq. (7.18). Further, assume that the beta particles travel an average distance $\overline{L}$ from their emission point (an average over the beta energy spectrum). Then the escape probability for a beta particle emitted at depth x is the fraction emitted into a cone of directions with half angle $\theta_c = \cos^{-1}(x/\overline{L})$, namely $\Delta\Omega(x)/4\pi$ (see Eq. (7.8)) times the probability the beta particle is not exponentially attenuated on the way to the surface, i.e.,

$$P_a^{esc} = \frac{1}{2} \int_0^{\theta_c(x)} \int_0^{\min(\overline{L}, d)} \left(1 - \frac{x}{\overline{L}}\right) \exp\left[-\mu\left(d - \frac{x}{\cos\theta(x)}\right)\right] dx\, d\theta. \tag{7.21}$$

Even numerical evaluation of this result is difficult because average ranges $\overline{L}$ for a beta spectrum are generally unknown. But more important, this approach based on exponential attenuation of beta particles

[3] Exponential attenuation implies an infinite range which is not true for beta particles. Equation (7.19) applies only to the initial portion of the attenuation curve.

along a straight line to the source surface is approximately true only for the initial portion of the intensity versus penetration relation. Moreover, this approach does not address the change of the energy spectrum and angular distribution of the escaping electrons. However, many texts (including this one) continue to propagate this questionable approach, primarily because of its simplicity and the avoidance of a full-blown electron transport calculation.

Backscattering

An empirical formula for the backscatter coefficient for normally-incident monoenergetic electrons was proposed by Tabata et al. [1971], namely

$$\eta_b = \frac{b_1 \exp[-b_2 Z^{-b_3}]}{1 + (b_4 + b_5 Z^{-b_6})\tau^{b_7 - (b_8/Z)}}, \tag{7.22}$$

Table 7.1. Constants for the determination of beta-particle backscattering. From [Tabata et al. 1971].

Constant	Value	Constant	Value
b_1	1.15 ± 0.06	b_5	15.7 ± 3.1
b_2	8.35 ± 0.25	b_6	1.59 ± 0.07
b_3	0.525 ± 0.020	b_7	1.56 ± 0.02
b_4	0.0185 ± 0.0019	b_8	4.42 ± 0.18

where $\tau = E_\beta/(m_e c^2)$. Here E_β is the initial energy of the beta particle, Z is the atomic number of the target material, $m_e c^2$ is the rest mass energy equivalent of an electron, and the constants a_1 through a_8 are listed in Table 7.1. For energies from approximately 50 keV up to 22 MeV, and for $Z \geq 6$, Eq. (7.22) has $\simeq 7\%$ RMS deviation from the data measured by Tabata et al. [1971]. The results of Eq. (7.22) for several elements are shown in Fig. 7.7. Although Eq. (7.22) is often used for backscattering of beta particles emitted isotropically from radioisotopes, it is based on experimental data in which electrons were normally incident on the substrate. As calculated by Kuzminikh and Vorobiev [1975] the backscatter coefficient varies strongly with the incident angle with respect to the surface normal and η_b increases as the incidence angle increases. Because beta particles are emitted isotropically, an uncollimated source will produce a different average backscatter coefficient than described by Eq. (7.22). Thus, Eq. (7.22) likely underestimates η_b, but its use for beta particles, which are incident at all angles, is continued for lack of an alternative.

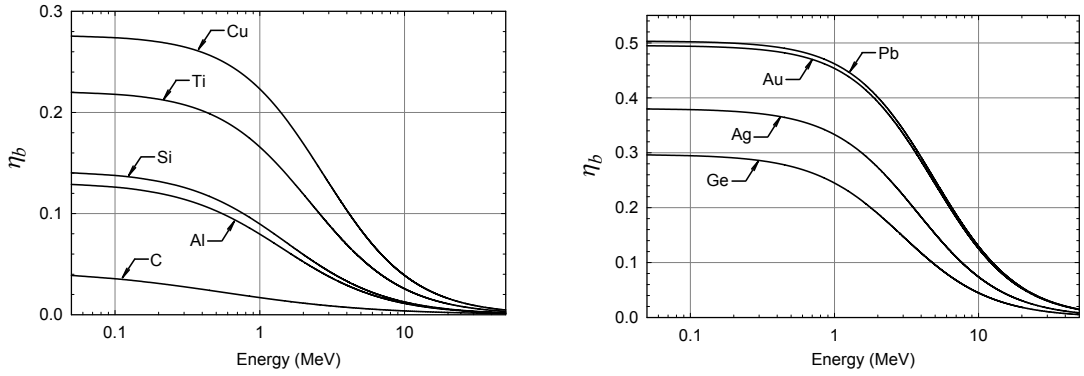

Figure 7.7. Calculated beta-particle backscatter coefficients as functions of target Z and beta-particle energy (after Tabata [1971]).

Monte Carlo Correction Factors

For beta particles, the only accurate way to account for source back scattering and attenuation by the source encapsulation is to use electron transport techniques. Several Monte Carlo codes are available to perform such calculations. Many use condensed-history models, but some are now able to use point-wise

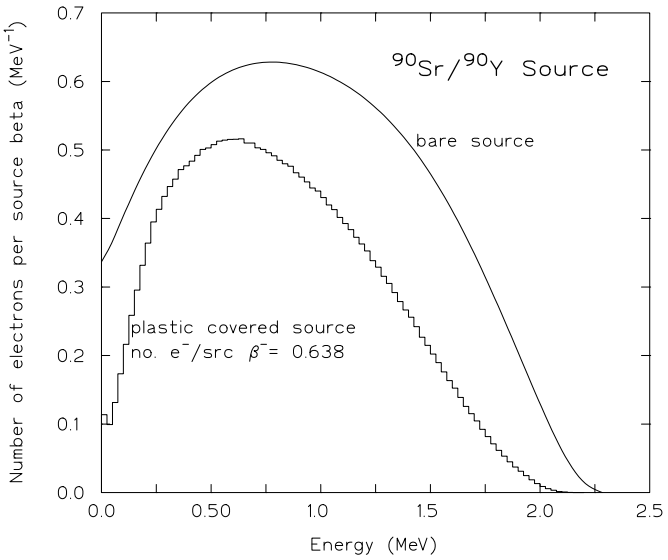

Figure 7.8. The MCNP6 calculated energy spectrum of electrons leaving a 1.55 × 2.54 mm plastic disk containing a ^{90}Sr/^{90}Y beta particle source in the center of the disk. In this example, 0.638 electrons are emitted by the disk per source beta particle.

electron interaction models. Another advantage to this approach is that both the backscatter and source encapsulation effects can be determined in a single calculation. Moreover, the energy spectrum of the emitted beta particles and electrons can be found at the same time. In Fig. 7.8 the emitted spectrum from a common ^{90}Sr/^{90}Y check source is shown.

7.2.3 Penetrating Radiations (γ rays, x rays, neutrons)

Although penetrating radiations, such as gamma rays, x rays, and neutrons, can all have backscatter and attenuation effects from the source, these effects are generally small and ignored. The exception may be for low-energy photons in heavy encapsulation. However, scattering from walls, floors and other massive objects in the room can make a significant difference in a radiation measurement, especially when dealing with neutron sources.

Often shielding is placed around and in close proximity to the source and detector to reduce roomshine and background from radiation sources outside the counting chamber. This shielding is important if a correct measurement of the source activity is to be obtained. Standard lead bricks are often used to provide such shielding. However, for photon sources, such shielding can emit copious 88-keV fluorescence when source photons photoelectrically interact with the lead. To minimize this secondary radiation, the counting chamber can be lined with metals of decreasing Z values, e.g., copper followed by aluminum. To design proper shielding and to correct for roomshine, transport codes must generally be used.

7.2.4 Source Decay During Measurement

A measurement taken in the presence of a radiation background overestimates the result for any sample under investigation. As covered in Chapter 6, corrections for the background counts or background count rate, and the associated error, must be considered for any radiation measurement.

If background is negligible by comparison to the radioactive source emission rate, but the radioactive source under test suffers appreciable decay during the measurement time t_1, i.e., $\lambda t_1 \gtrsim 0.01$, then the count rate n_0 at starting time t_0 can be determined from the total observed counts recorded between t_0 and t_1. Consider the simple case of a radionuclide sample of N_0 identical radionuclides at time t_0. The decay constant is λ and the radionuclides emit a single particle per decay, i.e., the frequency or *branching ratio* per decay is 1. Further, the detector efficiency for recording this particle is denoted by ϵ. The count rate $n(t)$ at $t \geq t_0$ is

$$n(t) = \epsilon \lambda N_0 e^{-\lambda t} \tag{7.23}$$

The average count rate $\overline{n}$ between $t_0 = 0$ and t_1 is

$$\overline{n} = \frac{\lambda N_0 \epsilon}{t_1} \int_0^{t_1} e^{-\lambda t} dt = -\frac{n_0}{\lambda t_1}(e^{-\lambda t_1} - 1), \tag{7.24}$$

where $n_0 = \lambda N_0 \epsilon$ is the count rate at t_0. Rearrangement gives

$$n_0(t_0) = \overline{n} \frac{\lambda t_1}{1 - e^{-\lambda t_1}}. \tag{7.25}$$

Finally the count rate at any time $t > 0$ is

$$n(t) = \overline{n} \frac{\lambda t_1}{1 - e^{-\lambda t_1}} e^{-\lambda t}. \tag{7.26}$$

This result applies to the more usual case in which the radionuclide emits M particles, each with a different energy. Denoting the emission frequency of the ith particle by f_i and the detector efficiency for the ith particle by ϵ_i yields the initial count rate n_0 as

$$n_0 = \lambda N_0 \sum_{i=1}^{M} \epsilon_i f_i. \tag{7.27}$$

7.2.5 Contamination

As a final word on errors associated with radioactive samples and preparation, there is always the possibility of contaminating the detector work area and/or detector with radioactive material. Radioactive sources that produce airborne daughter products (^{222}Rn for instance) can contaminate the detector aperture, a situation that causes the detector itself to become a background radiation source. Alpha particle sources are sometimes encapsulated with a boPET thin film to reduce leaks and contamination, which unfortunately reduces their use as spectroscopy standards. Gamma-ray and many beta-particle sources can be encapsulated in plastic to reduce the risk of contamination. As a precaution, radioactive sources should be checked periodically for leaks.

7.3 Detector Effects

7.3.1 Scattering and Absorption by the Detector Window

For almost all radiation detection systems the source is located outside the sensitive volume of the detector which is enclosed in some housing. Radiation then must enter the detector through a window or aperture.[4]

[4] There are exceptions. For example, gas flow proportional counters and some liquid scintillators have the source in the detecting medium.

As radiation particles reach the detector window, most pass through into the sensitive detector volume and are recorded. But a small fraction are either absorbed or scattered back by the window material as depicted in Fig. 7.1. Even if a particle passes through the window it may lose sufficient energy in doing so that the signal produced by it falls below the lower level discriminator (LLD) setting and so the particle is not recorded.

Correction for window effects is very difficult because such corrections depend on the type of radiation, its energy, its angle of incidence to the window, the window material, and the window thickness. Because of this complex dependence, there is no direct way to correct for window effects. However, to minimize window effects one should make the window as thin as possible and of a material that is as transparent as possible to the incident radiation. For low-energy photons and changed particles windows of low Z material are generally better than those made from high Z materials. For neutron detectors, window materials with very small neutron cross sections at the neutron energies of interest are preferred. Common window materials are boPET, glass, mica, or low-Z metals. Often the absorption effect of the window is incorporated into the efficiency of a detector. But for an energy spectrometer, corrections for energy loss in the window must be made separately to the spectrum.

7.3.2 Time Interval Distribution between Radioactive Decays

The times at which interactions occur in a detector from particles emitted from a radioactive (or stochastic) source have a Poisson distribution (see Section 6.7). The mean or expected rate at which interactions (or events) occur is denoted by $\bar{r}$. In a time interval t the mean number of events is, thus, $\mu = \bar{r}t$ with a variance of μ. Thus, the probability of having n events in time t is given by

$$\mathcal{P}(n|\mu) = \frac{(\bar{r}t)^n}{n!}e^{-\bar{r}t}. \tag{7.28}$$

In the following section on dead time, information about the time intervals between events is needed. In particular, the probability there is no event in a time t following an event, $P_0(t)$. From the Poisson PDF, the probability that no events are observed within a time interval t is

$$\mathcal{P}(0|\bar{r}t) = \frac{(\bar{r}t)^0}{0!}e^{-\bar{r}t} = e^{-\bar{r}t}. \tag{7.29}$$

The probability that an event occurs within some differential time interval dt about t is expressed as $\bar{r}dt$. From these two results, it follows that the probability of observing no event in the time interval $(0, t)$ and an event in the next dt interval is

$$dP_0(t) = \left(e^{-\bar{r}t}\right)(\bar{r}dt) = \bar{r}e^{-\bar{r}t}dt. \tag{7.30}$$

Therefore, the total probability that there is no event within time t is expressed as the probability that the event occurs anytime time past t, i.e.,

$$P_0(t) = \int_t^\infty dP(t) = \int_t^\infty \bar{r}e^{-\bar{r}t}dt = e^{-\bar{r}t}. \tag{7.31}$$

The probability that there are one or more events within time t is then $[1 - \exp(-\bar{r}t)]$.

7.3.3 Dead Time

All radiation detection systems operating in pulse mode have a limit on the maximum rate at which data can be recorded. The limiting component may be either the time response of the radiation detector, which is usually the case for the Geiger-Müller counter, or may be the resolving capability of the electronics.

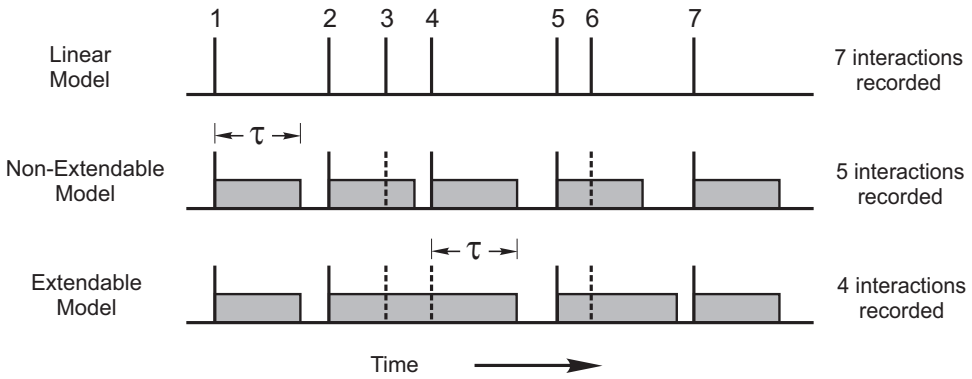

Figure 7.9. The three basic models for detector interval operation. The linear model assumes that the pulse is a delta function and has no processing time and, hence, has no dead time. The non-extendable dead time model assumes that once a pulse is registered, a preset time interval τ must pass, before another event can be processed. The extendable dead-time model assumes that each pulse entering the system restarts the dead-time interval, even during a previously initiated dead-time interval (after NCRP, 1985).

Although a radiation counting system is treated as a system that counts radiation interactions in a detector, it is instead actually recording the number of detector response time intervals initiated by a radiation particle, each time interval being terminated by the interval processing time. In other words, the detector records intervals rather than events. If two radiation particles interact within the detector during a single processing interval, only one of the interactions is recorded.

After a radiation interaction, radiation detectors generally require time to reset before they are fully sensitive to record a subsequent radiation interaction, especially for pulse mode operated electronic detectors. The time during which a detector is insensitive is commonly referred to as *dead time*, although the term is often misused. Dead time actually refers to a time duration in which a detector in insensitive to a radiation interaction. *Resolving time* is the period required before the detector can form a signal pulse large enough to register in the detector system, and is dependent upon the detector characteristics and the preset electronic conditions (lower level discriminator setting, pulse shaping time, etc.). The *recovery time* is the period required after a radiation interaction for the detector to reset to its initial starting condition. Often the dead time and resolving time are interchanged. Although technically different, the overall effect of either dead or resolving times on the radiation counting system is the same. Detector insensitivity and dead-time issues can arise from many sources, such as limitations in pulse processing times, limitations in detector signal formation, and time constants required for the device to return to its full sensitivity. The details of pulse processing are saved for Ch. 22 on nuclear electronics. In the present section, the effect that dead time and resolving time have on a radiation measurement is presented. Also, because both dead time and resolving time have the same effect on a radiation measurement, for simplicity, both are referred to in this chapter as dead time.

When a radiation interaction occurs in a detector and produces a measurable event, the detector and counting system become occupied while processing the event. As a consequence, the counting system does not respond to a subsequent event until some time τ has passed. Because the counting system is unavailable for a portion of time during a measurement, the recorded number of counts is consequently less than the number of interactions that actually occurred in the detector during the measurement time. Three possible ways in which a counting system processes a radiation event are shown in Fig. 7.9.

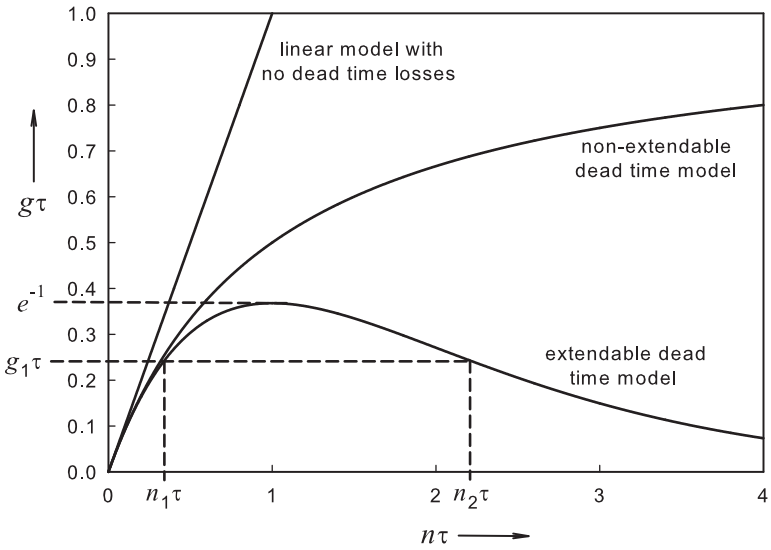

Figure 7.10. The three basic models for detector interval operation. The linear model assumes no processing time, hence has no dead-time losses. The non-extendable dead-time model shows a gradual reduction in the observed events $g\tau$ as the interaction rate $n\tau$ increases. The extendable dead-time response has a maxima in observed events as the interaction rate $n\tau$ increases, beyond which the observed event rate $g\tau$ decreases. Note that the extendable model produces for a single observable event rate, $g_1\tau$, two possible interaction rates (shown as $n_1\tau$ and $n_2\tau$).

7.3.4 Models for Dead Time

There are three basic models regarding pulse intervals produced in a radiation detector. These models, each with different processing times, are depicted in Fig. 7.10. The simplest is the linear model, in which events (pulses) are treated as delta functions and there is no processing time interval associated with a radiation event. The second model, referred to as the non-extendable (or non-paralyzing) model (NCRP, 1985; Evans, 1955), treats the intervals as preset time periods, unalterable in length by additional events arriving during the pulse processing interval. Hence, after the time interval τ begins, it remains the same length regardless if more events interact in the detector during the interval τ. The third model, referred to as the extendable (or paralyzing) model, treats an initial pulse interval τ as being restarted with another time τ for subsequent interactions arriving during the entire pulse interval. Hence, regardless of when in the initial interval a previous radiation interaction occurs, the interval is extended from that time forward by τ. The total processing interval time, whether using the extendable or non-extendable model, is generally referred to as the system *dead time* and denoted by τ.

Typically, the dead-time responses of detector systems consist of a combination of extendable and non-extendable characteristics. However, most detection systems are designed in such a way that the extendable dead-time effect is the least contributor, with the goal of producing a system that performs with non-extendable characteristics.

Extendable (Paralyzable) Dead Time

In an extendable system, only events with time intervals greater than the dead time τ can be registered, because there are no recorded events with time intervals less than the dead time. Suppose n represents the *true* average number of events per unit time. For large n, the number of events g, per unit time, observed

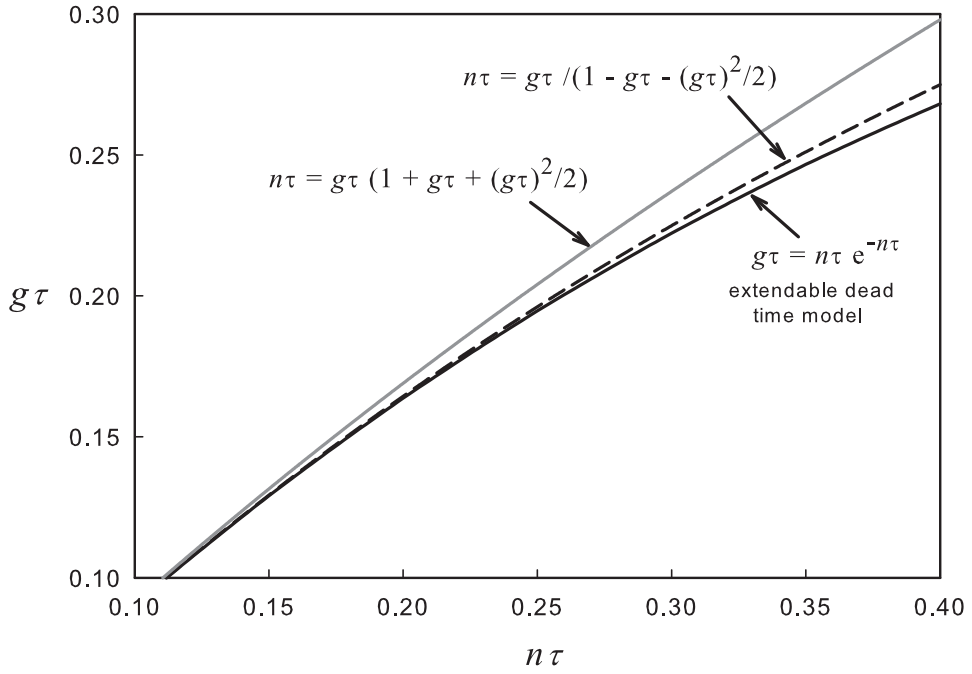

Figure 7.11. Comparison of extendable dead time and approximations from Eq. (7.35) and Eq. (7.37).

with intervals longer than τ is found with Eq. (7.31) to be

$$g = ne^{-n\tau} \qquad \text{or} \qquad g\tau = n\tau e^{-n\tau}. \tag{7.32}$$

If the true event rate n is small, then few events are missed, and $n \gtrsim g$. To find the exact true event rate after observing g, n must be expressed as a function of g. Unfortunately, a closed form solution to Eq. (7.32) cannot be found analytically. For small dead-time losses, $g \simeq n$, and Eq. (7.32) can be approximated as [NCRP 1985]

$$g\tau = n\tau e^{-n\tau} \simeq n\tau e^{-g\tau}, \tag{7.33}$$

which yields

$$n\tau \simeq g\tau e^{g\tau}. \tag{7.34}$$

This result can be expanded for $g\tau \ll 1$ as

$$n\tau \simeq g\tau \left(1 + g\tau + \frac{(g\tau)^2}{2!}\right), \tag{7.35}$$

which, unfortunately, underestimates $n\tau$. However, for $\epsilon = g\tau \ll 1$, the following approximation compensates, partially, for the underestimate

$$\left(1 + g\tau + \frac{(g\tau)^2}{2!}\right) \simeq (1 + \epsilon) \simeq \frac{1}{(1 - \epsilon)}. \tag{7.36}$$

Substitution of this result into Eq. (7.35) gives another approximation for $n\tau$, namely

$$n\tau \simeq \frac{g\tau}{1 - g\tau - (g\tau)^2/2}. \tag{7.37}$$

Equation (7.37) produces a result with less than 0.1 percent error for dead-time losses of $\leq 10\%$. A comparison of Eq. (7.32) with Eq. (7.35) and Eq. (7.39) is shown in Fig. 7.11.

For high dead-time losses, an exact solution for n can easily be found numerically by iteration. The maximum observable event rate, g_{max}, for an extendable system can be found by differentiating Eq. (7.32) and solving for maxima, i.e.,

$$\frac{dg}{dn} = e^{-n\tau}\,(1 - n\tau) = 0, \tag{7.38}$$

from which the maximum is seen to occur at $n\tau = 1$. The maximum is thus

$$g_{max} = ne^{-1} = 0.368n. \tag{7.39}$$

This result implies a dead-time loss exceeding 63% at the count rate maxima. The extendable dead-time response function is shown in Fig. 7.10 where it is observed that the observed event rate decreases beyond $n\tau = 1$ even as n is increasing. The extendable dead-time response can be dangerous in high radiation environments. An operator using a radiation detection device with extendable dead time can observe a low count rate, when in fact the radiation environment is actually at highly dangerous levels.[5]

Non-Extendable (Non-Paralyzable) Dead Time

For a system with non-extendable dead-time intervals, a system is insensitive to radiation for time interval τ directly after an event, but no longer than this time interval. Therefore, for an observed count rate g over a measurement interval t, the system is dead for the fraction of time $n\tau$ and, therefore, the system is *live* for the fraction of time $1 - n\tau$. The true count rate n is related to g by

$$\frac{g}{n} = 1 - g\tau \quad \text{or} \quad n = \frac{g}{1 - g\tau}. \tag{7.40}$$

At low count rates, $g\tau \ll 1$, and this last result can be approximated as

$$n \simeq g\,(1 + g\tau)\,. \tag{7.41}$$

As $n\tau$ increases, the maximum number of events that can be observed is limited to the maximum number of intervals τ that fit within the counting time interval t. Hence, the maximum observed count rate asymptotically approaches $g_{max} = 1/\tau$. The non-extendable dead time response function is shown in Fig. 7.10 where it is seen that the observed event rate continues to increase as $n\tau$ increases, asymptotically approaching g_{max}.

Note that the term $g\tau$ is the fraction of the time that the detector is unable to respond to additional ionization in the active volume of the detector. In the design of a counting system, it is best to minimize these losses by trying, if possible, to ensure that $g\tau \lesssim 0.05$. For example, for a GM counter with a typical dead time of $\tau = 100\ \mu$s, the maximum count rate would be 500 counts/s.

[5] Such an event occurred after the Chernobyl accident, when Geiger-Müller (GM) counters were used as survey meters. Radioactive core debris outside the reactor building, after the explosion, caused such high dead times that the GM counters falsely showed low level radiation fields, when in reality the fields were dangerously high.

7.3.5 Counting Error Associated with Dead Time

The variance of the observed counts is often assumed to be that of a Poisson distribution and is frequently approximated with a normal distribution. Then the observed count rate g over some counting interval t is assumed to be the total number of true events for the measurement, i.e., $N = \bar{r}t$. Such an approach is valid for detector systems with negligible dead times in which $g\tau \simeq n\tau$.

However, for systems with appreciable dead-time losses, those theoretical intervals Δt between events for which $\Delta t < \tau$ are removed; hence, the interval distribution of recorded events does not strictly follow a Poisson PDF and the variance must be corrected. Recall that a Poisson distribution has a variance equal to the total number of observed counts, where $\sigma^2 = gt$ and with standard deviation $\sigma = \sqrt{gt}$. However, a counting system actually records the number of time intervals registered during a measurement, and not the actual number of events occurring in the detector. Because there are no intervals recorded for which $\Delta t < \tau$, the actual standard deviation for nt is reduced by

$$\sigma(gt) = (1 - g\tau)\sqrt{gt}. \tag{7.42}$$

Furthermore, as derived by Vincent [1973], the standard deviation for the corrected number of recorded counts nt is greater than the Poisson prediction by

$$\sigma(nt) = \sqrt{(1 + n\tau)\, nt}. \tag{7.43}$$

From Chapter 6, the net count rate is determined by $n = g - b$, where g is the observed count rate and b is the observed background count rate. However, this result does not correct g and b for the detector dead time. Denote by a subscript c the dead-time corrected rates, and assume a non-paralyzable detector, then from Eq. (7.40) the corrected true event rate becomes

$$n_c = g_c - b_c = \frac{g}{1 - g\tau} - \frac{b}{1 - b\tau} = \left(\frac{G}{t_G}\right)\frac{1}{1 - (G\tau/t_G)} - \left(\frac{B}{t_B}\right)\frac{1}{1 - (B\tau/t_B)}, \tag{7.44}$$

where G is the total number of counts observed over measurement time t_G, and B is the total number of background counts observed over measurement time t_B. Use of error propagation, discussed in Section 6.9, the variance is

$$\begin{aligned}\sigma^2(n_c) = \left(\frac{\partial r}{\partial G}\right)^2\sigma_G^2 + \left(\frac{\partial r}{\partial B}\right)^2\sigma_B^2 &= \left[\left(\frac{1}{t_G}\right)\frac{1}{1 - (G\tau/t_G)} + \left(\frac{G}{t_G}\right)\left(\frac{1}{1 - (G\tau/t_G)}\right)^2\left(\frac{\tau}{t_G}\right)\right]^2\sigma_G^2 \\ &\quad + \left[\left(\frac{1}{t_B}\right)\frac{1}{1 - (B\tau/t_B)} + \left(\frac{B}{t_B}\right)\left(\frac{1}{1 - (B\tau/t_B)}\right)^2\left(\frac{\tau}{t_B}\right)\right]^2\sigma_B^2 \\ &= \left(\frac{1}{1 - (G\tau/t_G)}\right)^4\frac{G}{t_G^2} + \left(\frac{1}{1 - (B\tau/t_B)}\right)^4\frac{B}{t_B^2}.\end{aligned} \tag{7.45}$$

Typically, the background count rate is small so that $b\tau \ll 1$, and Eq. (7.45) reduces to

$$\boxed{\sigma^2(n_c) = \left(\frac{1}{1 - (G\tau/t_G)}\right)^4\frac{G}{t_G^2} + \frac{B}{t_B^2}} \quad . \tag{7.46}$$

7.3.6 Methods for Measuring Dead Time

There are many methods of measuring the dead time of a detector system and some of the more popular methods are outlined here. The measurement of dead time may be dictated by the availability of sources and equipment. The user is advised that these methods vary in accuracy; hence, the choice of a method may also be dictated by how much error is acceptable.

Two Source Method

The determination of dead time by the two source method is a simplification of the multi-source method. Two nearly identical calibrated sources are used in this measurement method. Often these sources are available as "split pairs." For instance, the two sources in a split-pair beta-particle source, identified as sources 1 and 2, are often conveniently shaped as two halves of a disc.

Sources 1 and 2 are measured independently in the system to yield count rates 1 and 2, or g_1 and g_2. Afterwards, both sources are measured together to produce a combined count rate g_{12}. In order to reduce possible geometric anomalies from source placement, a common practice is to place one source in the detection location for measurement, followed by a second source, and finally the removal of the first source. For instance, source 1 is located in the detection region to measure g_1. Next, the second source is carefully placed next to the first source to measure g_{12}. Afterwards, the first source is carefully removed, so as to not disrupt the location of source 2, in order to measure g_2. A background measurement then follows.

Non-Extendable Dead-Time Model First consider a detector with a non-extendable dead time. The true event rates for each measurement are related by

$$n_{c1} - n_{cb} + n_{c2} - n_{cb} = n_{c12} - n_{cb}. \tag{7.47}$$

With the use of Eq. (7.40) and Eq. (7.44), this result yields

$$\frac{g_1}{1 - g_1\tau} + \frac{g_2}{1 - g_2\tau} = \frac{g_{12}}{1 - g_{12}\tau} + \frac{b}{1 - b\tau}. \tag{7.48}$$

An approximate solution for the dead time τ can be found by use of the approximation, valid for $g\tau \ll 1$, namely

$$\frac{g}{1 - g\tau} \simeq g(1 + g\tau). \tag{7.49}$$

Equation (7.48) then becomes

$$g_1(1 + g_1\tau) + g_2(1 + g_2\tau) \simeq g_{12}(1 + g_{12}\tau) + b(1 + b\tau), \tag{7.50}$$

which is readily solved for τ to give

$$\boxed{\tau \simeq \frac{g_{12} + b - g_1 - g_2}{g_1^2 + g_2^2 - g_{12}^2 - b^2}} \quad . \tag{7.51}$$

However, Eq. (7.51) can introduce significant error because it is based on a first order expansion. Equation (7.48) can be rearranged to produce the following quadratic equation

$$\left(g_1 g_2(g_{12} + b) - g_{12} b(g_1 + g_2)\right)\tau^2 - 2\left(g_1 g_2 - g_{12} b\right)\tau + (g_1 + g_2 - g_{12} - b) = 0, \tag{7.52}$$

whose solution for the smaller of the two positive roots is

$$\boxed{\tau = \frac{1}{2A}\left[-B - \sqrt{B^2 - 4AC}\right]} \quad , \tag{7.53}$$

where $A = g_1 g_2(g_{12} + b) - g_{12} b(g_1 + g_2)$, $B = 2\,(g_{12} b - g_1 g_2)$, and $C = g_1 + g_2 - g_{12} - b$.

This expression for τ can be simplified by the assumption that the background count rate is insignificant ($b \simeq 0$). The result is

$$\boxed{\tau = \frac{1}{g_{12}}\left[1 - \left[1 - \frac{g_{12}}{g_1 g_2}\,(g_1 + g_2 - g_{12})\right]^{1/2}\right]} \quad . \tag{7.54}$$

If the background is negligible and if $g_1 \simeq g_2$, then in Eq. (7.48) one can approximate both $(1 - g_1\tau)$ and $(1 - g_2\tau)$ by $[1 - (g_1 + g_2)\tau/2]$. With these approximations Eq. (7.48) yields the result

$$\boxed{\tau = \frac{2(g_1 + g_2 - g_{12})}{(g_1 + g_2) g_{12}}} \quad . \tag{7.55}$$

Example 7.1: A split-pair source is used to determine the dead time of a common Geiger-Müller tube detector, where the following count rates are measured:

$G_1 = 93,600$ counts	$t_{G_1} = 60$ seconds	$G_2 = 106,800$ counts	$t_{G_2} = 60$ seconds
$G_{12} = 173,400$ counts	$t_{G_{12}} = 60$ seconds	$B = 30,600$ counts	$t_B = 30$ minutes

Determine and compare the dead times calculated with Eqs. (7.51), (7.53), (7.54), (7.55), and (7.53).

Solution:
The estimated count rates are:

$$g_1 = \frac{G_1}{t_{G_1}} = \frac{93600 \text{ cts}}{60 \text{ seconds}} = 1560 \text{ cps} \qquad g_2 = \frac{G_2}{t_{G_2}} = \frac{106,800 \text{ cts}}{60 \text{ seconds}} = 1780 \text{ cps}$$

$$g_{12} = \frac{G_{12}}{t_{G_{12}}} = \frac{173,400 \text{ cts}}{60 \text{ seconds}} = 2890 \text{ cps} \qquad b = \frac{B}{t_B} = \frac{30600 \text{ cts}}{(30 \text{ minutes})(60 \text{ sec/min})} = 17 \text{ cps}$$

Solution 1: Substitution of g_1, g_2, g_{12} and b into Eq. (7.51) gives

$$\tau \simeq \frac{g_{12} + b - g_1 - g_2}{g_1^2 + g_2^2 - g_{12}^2 - b^2} = \frac{2890 + 17 - 1560 - 1780}{(1560)^2 + (1780)^2 - (2890)^2 - (17)^2} = 1.574 \times 10^{-4} \text{ seconds} = 157.4\ \mu\text{s}.$$

Solution 2: From Eq. (7.54),

$$\tau = \frac{1}{g_{12}}\left[1 - \left[1 - \frac{g_{12}}{g_1 g_2}\,(g_1 + g_2 - g_{12})\right]^{1/2}\right] = \frac{1}{2890}\left[1 - \left[1 - \frac{2890}{(1560)(1780)}\,(1560 + 1780 - 2890)\right]^{1/2}\right]$$

$$= 9.372 \times 10^{-5} \text{ s} = 93.72\ \mu s$$

Solution 3: The dead time is determined from Eq. (7.55) as

$$\tau = \frac{2(g_1 + g_2 - g_{12})}{(g_1 + g_2)g_{12}} = \frac{2(1560 + 1780 - 2890)}{(1560 + 1780)2890} = 9.324 \times 10^{-5} \text{ s} = 93.24\ \mu s$$

Solution 4: From Eq. (7.53), coefficients A, B and C are determined as

$$\begin{aligned} A &= g_1 g_2(g_{12} + b) - g_{12} b(g_1 + g_2) = [(1560)(1780)(2890 + 17)] \\ &\quad -[(2890)(17)(1560 + 1780)] = 7,908,063,400 \\ B &= 2\,(g_{12} b - g_1 g_2) = 2\,[(2890)(17) - (1560)(1780)] = -5,455,340 \\ C &= g_1 + g_2 - g_{12} - b = 1560 + 1780 - 2890 - 17 = 433. \end{aligned}$$

Substitution of these values into Eq. (7.53) gives the dead time

$$\tau = \frac{1}{2A}\left[-B - \sqrt{B^2 - 4AC}\right] = 9.151 \times 10^{-5} \text{ s} = 91.51\ \mu s.$$

The exact solution, $\tau = 91.51$ μs, was found with Eq. (7.53). The approximation calculated by Eq. (7.51), $\tau = 157.4$ μs, overestimates the exact answer by a factor of 1.72, a consequence of the use of a first order expansion approximations with a relatively large value of $g\tau \simeq 0.15$. However, the approximate value found from Eq. (7.54), $\tau = 93.72$ μs, overestimates the exact answer by a factor of only 1.024 (2.4%). The best approximate value was found with Eq. (7.55), yielding 93.24 μs, noting that this approximation works only if $b \ll g_1$, g_2 and g_{12}, and $g_1 \simeq g_2$. It can be concluded that Eq. (7.54) can be used to calculate the dead time provided that the background count rate is much less than the radioactive sample count rate, and Eq. (7.55) can be used with the added stipulation that the count rates of g_1 and g_2 are similar. Otherwise, it is best to use the more tedious operation required by Eq. (7.53).

Extendable Dead-Time Model The extendable dead-time model is transcendental and has no closed form solution for τ. However, there are methods to find an acceptable approximation to the dead time, one of which, reported elsewhere [NCRP 1985] is derived here. Assume an extendable model with negligible background, so the true count rates are related by Eq. (7.47), namely

$$n_1 + n_2 = n_{12}.$$

The measured rates g_i are then related through Eq. (7.32) as

$$g_1 e^{g_1 \tau} + g_2 e^{g_2 \tau} = g_{12} e^{g_{12} \tau}.$$

Assume that the count rates of g_1 and g_2 are similar, i.e., $g_1 \tau \simeq g_2 \tau$ so the above relation can be written as

$$g_1 e^{g_1 \tau} + g_2 e^{g_1 \tau} \simeq g_1 e^{g_2 \tau} + g_2 e^{g_2 \tau} = g_{12} e^{g_{12} \tau}. \tag{7.56}$$

By using only the $\exp[g_1/\tau]$ terms in this result, one can solve for τ as

$$\frac{g_1 + g_2}{g_{12}} \simeq e^{(g_{12} - g_1)\tau},$$

from which

$$\tau \simeq \frac{1}{g_{12} - g_1} \ln\left(\frac{g_1 + g_2}{g_{12}}\right). \tag{7.57}$$

In a similar fashion, using only the $\exp[g_2/\tau]$ in Eq. (7.56), one obtains

$$\tau \simeq \frac{1}{g_{12} - g_2} \ln\left(\frac{g_1 + g_2}{g_{12}}\right). \tag{7.58}$$

A better estimate of τ should be obtained by averaging these two results, namely

$$\tau \simeq \frac{1}{2}\left[\frac{1}{(g_{12} - g_1)} + \frac{1}{(g_{12} - g_2)}\right] \ln\left(\frac{g_1 + g_2}{g_{12}}\right) \simeq \frac{1}{2}\left[\frac{(g_{12} + g_{12} - (g_1 + g_2))}{(g_{12}^2 + g_1 g_2 - g_{12}(g_1 + g_2)}\right] \ln\left(\frac{g_1 + g_2}{g_{12}}\right).$$

Because $g_1 + g_2 \simeq g_{12}$, this approximation for τ reduces to that stated by the NCRP [1985]

$$\boxed{\tau \simeq \left[\frac{g_{12}}{2g_1 g_2}\right] \ln\left(\frac{g_1 + g_2}{g_{12}}\right)} \quad . \tag{7.59}$$

This approximation for τ of Eq. (7.59) is based on the assumptions that $g\tau$ is a small number, background is negligible, and the count rates g_1 and g_2 are similar. To obtain the exact solution of Eq. (7.3.6) for the dead time, a computer program based, for example, on the bisection method can be used to iteratively arrive at a numerical solution for τ. This numerical method can treat all values of $g\tau$.

Pulser Methods

There may be occasions when an experimenter does not have access to a split-pair source to measure the dead time of a detector system. For such instances, Baerg [1965] derived an approximation for non-extendable dead-time systems which uses a periodic pulse generator (pulser) and a single radiation source. Suppose a pulser inserts test pulses of frequency ν into the test port of the detector's preamplifier. The pulser signal by itself is not stochastic; however, if a radiation source is present, then the probability of observing a count from the pulser is dependent upon the randomness of a count being registered by a radiation event, namely $(1 - g\tau)$. Here g is the observed source count rate without the pulser. Hence, the observed pulser count rate p in the presence of the radiation source is $p = \nu(1 - g\tau)$.

A pulser input activates the electronics and causes the detector system to be inactive for time τ. Consequently, the observed count rate g_1 from the radiation source, with the pulser activated, is

$$g_1 = g(1 - p\tau) = g(1 - \nu(1 - g\tau)\tau). \tag{7.60}$$

The total count rate is determined by adding the probability of observing a count from the pulser with the probability of observing a count from the radioactive source, namely

$$g_{1p} = \nu(1 - g\tau) + g(1 - \nu(1 - g\tau)\tau) = \nu + g - 2\nu g\tau - \nu g^2\tau^2, \tag{7.61}$$

which can be solved for τ to yield

$$\boxed{\tau = \frac{1}{g}\left[1 - \left(\frac{g_{1p} - g}{p}\right)^{1/2}\right]} \quad . \tag{7.62}$$

Given the pulser frequency ν, the experimenter need only take measurements with (g_{1p}) and without (g) the pulser to determine the dead time. Note that the assumptions used to arrive at Eq. (7.62) can lead

to inaccuracies in the dead-time measurements, but the accuracy is considered to be acceptable for pulser signals with frequencies $\nu < 1/(3\tau)$ [Müller 1973, 1976].

There is no exact analytical solution for extendable dead time; however, an approximate solution for extendable dead time with the use of a single pulser is offered by NCRP [1985], namely,

$$\tau \simeq \frac{\xi e^{-\xi}}{g}, \qquad \text{where} \quad \xi = (q^2 + 4q - 1)^{1/2} - (q + 1) \quad \text{and} \quad q = \nu/(g_{1p} - g). \tag{7.63}$$

The NCRP [1985] states Eq. (7.63) as being accurate to better than 0.3% over a wide range of pulser frequencies, provided that $g\tau \leq 0.20$.

A method introduced by Baerg [1965], and described in more detail later by Müller [1973], uses two pulse generators to measure the dead time of an electronic system without the detector. Suppose two pulsers are used with different frequencies ν_1 and ν_2, where the frequency ratio is not an integer, then an exact system dead time is given by

$$\tau = \frac{g_{\nu 1} + g_{\nu 2} - g_{\nu 1 \nu 2}}{2 g_{\nu 1} g_{\nu 2}}, \tag{7.64}$$

where $g_{\nu 1}$ is the count rate from pulser frequency ν_1, $g_{\nu 2}$ is the count rate from pulser frequency ν_2, and $g_{\nu 1 \nu 2}$ is the count rate with both pulsers operating. If the highest pulser frequency has $\nu < 1/(2\tau)$ then the solution to Eq. (7.64) provides the value of τ regardless of whether the dead time is extendable or non-extendable.

However, if $\nu > 1/(2\tau)$ then Eq. (7.64) provides a method to determine if the dead time is extendable or non-extendable. If ν_{av} is the average frequency of the combined pulsers after passing dead time τ, with $T = 1/\nu \equiv \min(T_1, T_2)$, then the response from a *non-extendable* dead-time system is

$$\nu_{av} = \begin{cases} \nu_1 + \nu_2 - 2\tau\nu_1\nu_2, & \text{for } 0 < \tau < T/2 \ , \\ \nu, & \text{for } T/2 < \tau < T \ . \end{cases} \tag{7.65}$$

For an *extendable* dead-time system

$$\nu_{av} = \begin{cases} \nu_1 + \nu_2 - 2\tau\nu_1\nu_2, & \text{for } 0 < \tau < T \ , \\ 0, & \text{for } \tau > T \ . \end{cases} \tag{7.66}$$

The dead time is determined from

$$\tau = \frac{g_{\nu 1} + g_{\nu 2} - g_{\nu_{av}}}{2 g_{\nu 1} g_{\nu 2}}. \tag{7.67}$$

A comparison of results for ν_{av} beyond $\tau > T/2$ reveals the type of dead-time for the system [Müller 1973].

Decaying Source Method

A rapidly decaying source, such as ^{116m}In ($t_{1/2} = 54.2$ min), is measured at incremental times as the sample undergoes radioactive decay. The count rate is monitored, corrected for background, and plotted on a semi-log graph. If there were no dead time, the plot would decrease linearly in time. But at high count rates dead-time effects are important, and a plot such as that of Fig. 7.12 is obtained after the sample decays through several half-lives.

The slope M of the linear portion of the semilogarithmic plot is then found by fitting a straight line to the measured data. Typically, the experimenter determines this slope from a least squares fit to the lower count rate data that yields an acceptable coefficient of determination.[6] The slope M then yields the half-life from

[6] The coefficient of determination, often denoted R^2, is an indicator of linearity for a linear regression curve fit. Values converging on $R^2 = 1$ are considered "perfect" predictors of an unknown variable.

$t_{1/2} = \ln(2)/M$. This experimentally determined half-life can be compared to the literature value, thereby providing another test for accuracy.

At the high count-rate end of the plot, the measured count rates g_i underpredicts the true event rate n_i, which varies exponentially in time, because dead time prevents some events from being recorded. For a non-extendable detector the predicted and observed count rates are related by Eq. (7.40), from which the dead time is found to be

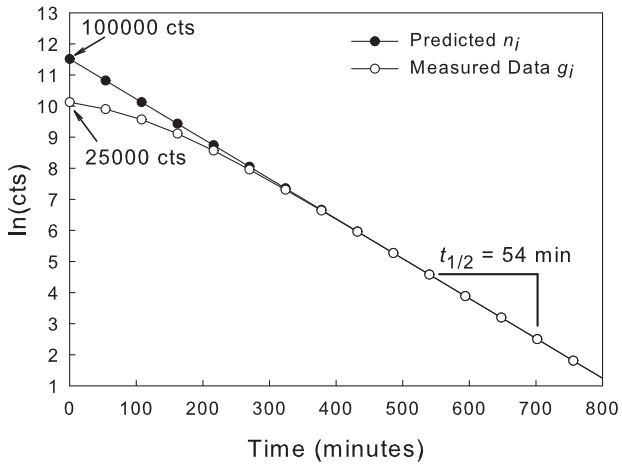

Figure 7.12. The dead time is determined by plotting the logarithm of the measured counts versus the decay time. From the plot the expected values of n_i are determined and the dead time τ if found from either Eq. (7.40) or Eq. (7.32).

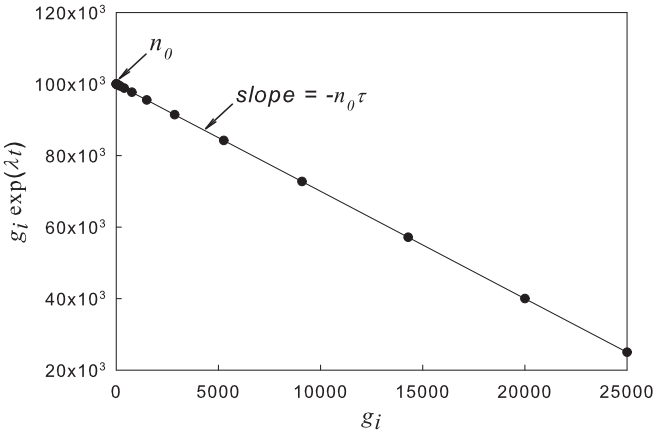

Figure 7.13. The dead time for a non-extendable detector is found by plotting $g_i \exp(\lambda t)$ versus g_i. The slope of straight line fitted to the data is τn_0. Note one must wait through several half-lives until dead-time effects are negligible and an accurate value of n_0 is obtained.

$$\tau = \frac{n_i - g_i}{g_i n_i}. \tag{7.68}$$

Note that in the linear portion of Fig. 7.12, $n_i \simeq g_i$ and Eq. (7.68) yields $\tau \simeq 0$. To find τ use the highest count-rate measurements and the predicted true event rate

$$n_i = n(t_i) = g_n \exp[\lambda(t_n - t_i)], \tag{7.69}$$

where g_n is an observed count rate well into the linear portion of the decay curve. Typically, one uses $n_i = n_0$, the initial observation. Substitution of measured value g_n and predicted value n_i into Eq. (7.68) yields τ (see Fig. 7.12).

An alternative approach is to use the decay relation

$$n(t) = n_0 \exp(-\lambda t), \tag{7.70}$$

where $t_0 = 0$, and substitute it into Eq. (7.40) for a non-extendable dead-time detector to obtain [Martin 1961]

$$g(t) \exp[\lambda t] = -g(t)\, n_0 \tau + n_0. \tag{7.71}$$

This is a linear equation, where $-n_0\tau$ is the slope. Hence, by plotting the left-hand side of Eq. (7.71) versus $g(t)$ a plot similar to that of Fig. 7.13 is obtained, from which the slope S of the resulting straight line can be determined. The dead time is then found as $\tau = -n_0/S$.

For an extendable dead-time detector, the dead time is found from Eq. (7.32), with $t_i = t_0$, from the relation between n_0 and g_0, namely

$$g_0 = n_0 \exp(-n_0\tau). \tag{7.72}$$

This result must be solved numerically. However, a similar graphical method can be used, as described for the non-extendable dead-time case, where substitution of Eq. (7.70) into Eq. (7.32) yields

$$\lambda t + \ln(g) = -n_0 \tau \exp[-\lambda t] + \ln[n_0]. \tag{7.73}$$

Eq. (7.73) is another linear equation in which $-n_0\tau$ is the slope. Thus, the procedure is to plot the left-hand side of Eq. (7.73) versus $e^{-\lambda t}$, find the slope of the resulting straight line, and evaluate $\tau = -n_0/S$.

The advantage of the graphical methods using Eq. (7.71) and Eq. (7.73) over the methods of Eq. (7.68) and Eq. (7.72) is debatable. Both methods for finding the dead time improve as the sample is allowed to decay through more half-lives. Regardless, these graphical estimations are generally considered inaccurate [NCRP 1985], although accuracy can be improved by subtracting background count rates and collecting data through enough half-lives so that dead-time effects are negligible and a reasonably accurate value of n_0 can be determined.

Increasing Power Method

The increasing power method has some similarity to the decaying source method, and requires a variable field radiation source, such as a nuclear reactor. The detector is placed in the measurement location and a background measurement is acquired. The radiation field is increased and measured systematically at various power levels, preferably increasing in power if a nuclear reactor is used.[7]

The detector response without dead time should be linear with respect to the power level. A simple least squares fit through the low count rate data points yields a linear function for comparison to the measured values at high count rates. For non-extendable dead time, the difference between a linear response plotted through the low radiation field measurements and the high field measurements yields the dead time from Eq. (7.68), where p is the projected correct count rate from the linear fit and g is the measured count rate. For extendable dead time, Eq. (7.72) is used. Accuracy is limited by error in the linear curve fit for low counting rates.

7.4 Geometric Effects: View Factors

Not all radiation emitted by a radioactive source, of strength S_{tot} particles/second, enters the detector aperture. The fraction of emitted radiation that does enter the detector, in the absence of any radiation attenuation between the source and detector, is called here the *view factor* P_v. No account of backscatter or direction of radiation incidence on the aperture is made. The view factor is strictly a geometric probability depending only on the shapes and sizes of the source and aperture and their relative orientation to each other. With this quantity, the *intrinsic efficiency* ϵ_I of the detector is

$$\epsilon_I = \frac{C_{obs}}{S_{tot} P_v}, \tag{7.74}$$

where C_{obs} is the observed count rate (corrected for dead time).

Two general classes of view factors are considered in this section. The first class consists of view factors for point isotropic sources and for plane detector apertures of simple shapes. Such sources are frequently encountered in measurements of radioactive samples. The second class is for plane sources with different shapes.

Finally, in this section it is assumed that source radiation is emitted isotropically, a good assumption for most photon sources. However, the encapsulation of charged particle sources can make the emission quite anisotropic. Such anisotropic sources are not considered here.

[7] Although the experiment can be conducted by starting at a high reactor power and incrementally lowering the power, it takes much longer because a reactor's power can be raised more quickly than it can be decreased.

7.4.1 Point Isotropic Sources

The view factor for an aperture of area A is closely related to the solid angle subtended at the source point by the aperture. The basic equation for the solid angle is

$$\Omega = \int_A \frac{\hat{\mathbf{n}} \bullet d\mathbf{A}}{R^2}, \tag{7.75}$$

where R is the distance between the source and dA, $\hat{\mathbf{n}}$ is a unit vector along R, $\hat{\mathbf{n}} \bullet d\mathbf{A}$ is the area of the projection of dA on the plane perpendicular to R. The view factor is simply $P_v = \Omega/4\pi$, namely, the fraction of the emitted radiation particles into the solid angle Ω.

Solid Angle for dA on a Sphere

Consider a radioactive point source placed at the origin of spherical coordinate system, as shown in Fig. 7.14. Given a sphere of radius r, a direction vector extending from the origin can be described by Cartesian unit vectors

$$\mathbf{r} = r \sin\theta \cos\phi \ \mathbf{i} + r \sin\theta \sin\phi \ \mathbf{j} + \cos\theta \ \mathbf{k}. \tag{7.76}$$

Emissions isotropically radiating from the source uniformly intersect a sphere centered about the origin. A differentially small area dA, defined by the limits $r \sin\theta$ and $r \sin\theta + d\theta$ and also ϕ and $\phi + d\phi$ through which a portion of this radiation passes is

$$dA = r \ \sin\theta \ d\theta \ r \ d\phi = r^2 \ \sin\theta \ d\theta \ d\phi. \tag{7.77}$$

The solid angle is defined as dA/r^2. Integration over the entire sphere surface gives

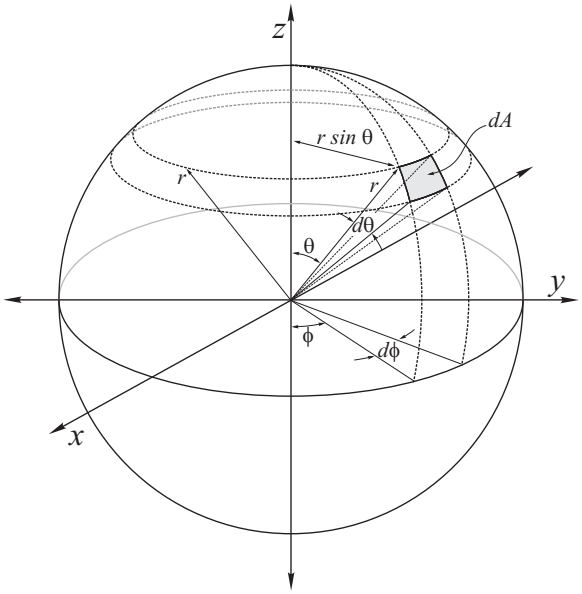

Figure 7.14. Coordinate system for isotropic radiation emissions (at the origin) intersecting differential area dA.

$$\int_{4\pi} d\Omega = \int_{4\pi} \frac{dA}{r^2} = \int_0^{\pi} \sin\theta \ d\theta \int_0^{2\pi} d\phi = 4\pi. \tag{7.78}$$

This result shows that the solid angle for the entire surface of the sphere surface is 4π. The solid angle is actually dimensionless, yet units of steradians (sr) are typically attributed to the solid angle; hence there are 4π steradians subtended by the surface of a sphere, regardless of radius r. The solid angle for a detector of face area A can be determined with the method of Eq. (7.78).

Solid Angle for a Point Source and a Cylindrical Detector

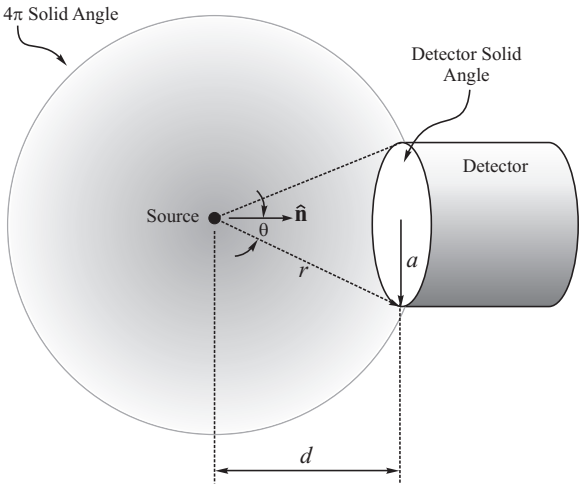

Figure 7.15. Representation of the relationship between a radioactive point source and a cylindrical radiation detector of radius a with the face spaced a distance d away from the source.

A typical geometry for a radiation detector is a cylinder with radius a, as shown in Fig. 7.15. The projected area (or solid angle) of the meniscus formed at the intersection of the cylinder and the sphere is found from

$$\int_{4\pi} d\Omega = \frac{1}{r^2}\int_0^{\theta} r^2 \sin\theta d\theta \int_0^{2\pi} d\phi = 2\pi\left(1-\cos\theta\right), \tag{7.79}$$

where θ is defined by the angle between a normal vector $\hat{\mathbf{n}}$ and $\mathbf{r}$.
Because

$$\cos\theta = \frac{d}{\sqrt{d^2+a^2}}, \tag{7.80}$$

where d is the distance from the radioactive point source to the center of the detector face, Eq. (7.79) becomes

$$\Omega = 2\pi\left(1-\frac{d}{\sqrt{d^2+a^2}}\right). \tag{7.81}$$

The fraction P_v of radiation emissions that pass through the detector face is found by dividing the detector solid angle by the solid angle of the sphere, namely

$$P_v = \frac{\Omega}{4\pi} = \frac{1}{2}\left(1-\frac{d}{\sqrt{d^2+a^2}}\right). \tag{7.82}$$

Example 7.2:
A 3-inch × 3-inch right cylindrical NaI:Tl detector[8] is placed 6 inches away from a ^{60}Co source for a radiation measurement. What are the solid angle and the view factor for the detector? Assume no intermediate absorption of the gamma rays.

Solution:
Here $d = 6$ inches and $a = 1.5$ inches
From Eq. (7.81), the solid angle is

$$\Omega = 2\pi\left(1-\frac{d}{\sqrt{d^2+a^2}}\right) = 2\pi\left(1-\frac{6}{\sqrt{6^2+1.5^2}}\right) = 0.188 \text{ sr}. \tag{7.83}$$

The view factor is thus

$$P_v = \Omega/(4\pi) = 0.015. \tag{7.84}$$

Thus, only 1.5% of radiation emissions from the source cross the detector aperture.

---

[8]The common notation refers to the diameter and length of a right straight cylinder.

Point Source Offset from Center of Circular Aperture

Consider the case of an isotropic point source set a distance d from the plane of a circular aperture of radius a. The source is also offset by a distance s from the center of the disk. Paxton [1959] obtained analytic solutions for the solid angle Ω subtended by the disk at the source. The view factor is thus $P_v = \Omega/4\pi$. The expressions, however, are quite complicated and involve complete elliptic integrals of the first and third kinds. This problem is more easily obtained by Monte Carlo analyses, the results of which, for a few geometries, are shown in Fig. 7.16.

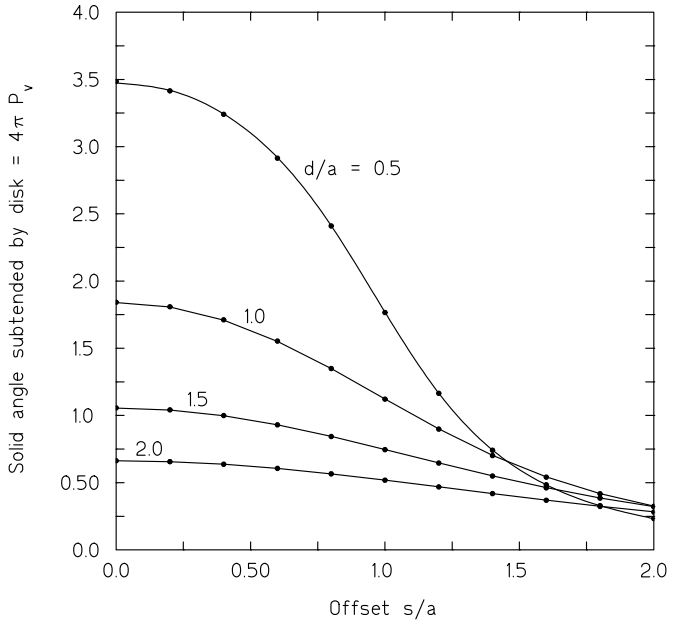

Figure 7.16. The solid angle subtended by a circular aperture at a point source a distance d from the aperture plane and offset from the disk center by s. The circles are Monte Carlo results and the lines are spline fits to data reported by Paxton [1959].

Point Source and a Rectangular Aperture

The view factor for a point source at some distance d above the *center* of a detector with a rectangular aperture with dimensions $a \times b$ is [Gossman et al. 2010, 2011]

$$P_v(a/d, b/d) = \frac{1}{\pi} \arcsin \left[\frac{(a/d)(b/d)}{\sqrt{[(a/d)^2 + 4][(b/d)^2 + 4]}} \right] . \tag{7.85}$$

The view factors for rectangular apertures are shown in Fig. 7.17. For case of a square aperture with dimension a, Eq. (7.85) reduces to

$$P_v(a/d) = \frac{1}{\pi} \arcsin \left[\frac{(a/d)^2}{(a/d)^2 + 4} \right] . \tag{7.86}$$

Of more utility is the case when the point source is a distance d above a corner of a rectangular aperture with dimensions $a \times b$. For this case, the view factor is one-quarter that of Eq. (7.85) with $a \rightarrow 2a$ and

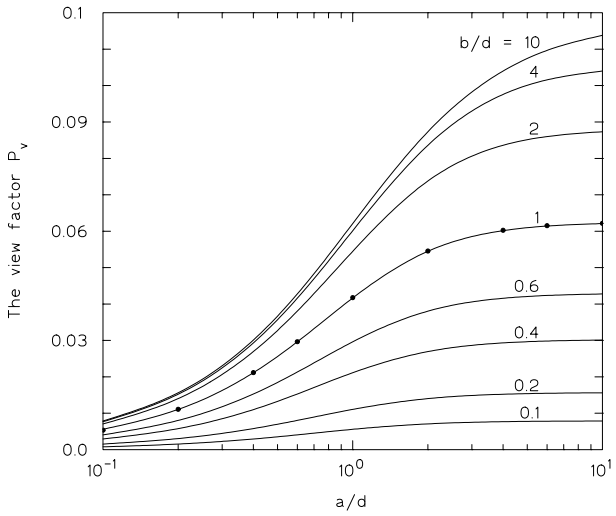

Figure 7.17. The view factor for a point source over the center of a rectangular aperture as calculated by Eq. (7.85). Data points are Monte Carlo calculated values using MCNP6 [2013].

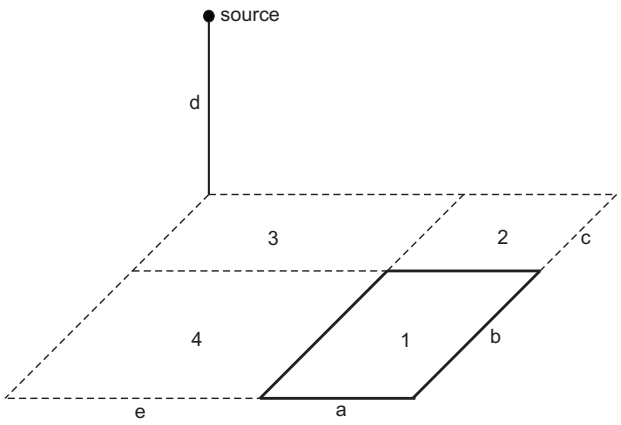

Figure 7.18. Calculation of the view factor for a point source offset from a rectangular detector aperture (solid lines) when the source, a distance d above the aperture plane. With Eq. (7.87) the view factor for the aperture is $P_v^1 = P_v^{1+2+3+4} - P_v^{2+3} - P_v^{3+4} + P_v^3$, where the superscript is the union of indicated rectangular regions.

$b \to 2b$. The result is

$$P_v(a/d, b/d) = \frac{1}{\pi} \arcsin\left[\frac{(a/d)(b/d)}{\sqrt{[(a/d)^2+1][(b/d)^2+1]}}\right]. \tag{7.87}$$

With this result the view factor can be calculated for the point source located above any point in the aperture plane! If the source is above the aperture, then a perpendicular line extending from the source to the detector divides the aperture into four smaller rectangular apertures.

Likewise if the source is not above the aperture, the aperture view factor can be found by adding and subtracting the view factors for each rectangular region, each of which has the source over a corner. See Fig. 7.18 for an example. Note, however, that radiations can now enter the side of the detector if the source is offset from the detector aperture, thereby confusing the view factor situation altogether. Hence, an additional calculation is needed to account for radiations entering into the side of the detector.

Approximation Method for the View Factor: Under the condition that the point source is sufficiently far from the detector aperture, and the dimensions of the aperture are similar ($a \simeq b$), the view factor can be approximated by replacing the rectangular aperture by a circular one with the same area. Hence, the aperture area $A = ab = \pi\tilde{a}^2$ from which the equivalent aperture radius $\tilde{a}$ is obtained. Then, from Eq. (7.82) the view factor is

$$P_v^{approx} \simeq \frac{1}{2}\left(1 - \frac{d}{\sqrt{d^2 + A/\pi}}\right) = \frac{1}{2}\left(1 - \frac{d}{\sqrt{d^2 + ab/\pi}}\right), \tag{7.88}$$

where A is the projected area of the detector aperture. Typically, the distance d should be at least equal to the sum of the aperture's vertical and horizontal dimensions. Notice that once again P_v depends only on dimensionless ratios a/d and b/d. Comparison of Eq. (7.85) with Eq. (7.88) shows that if a/d is no greater than $\pm 40\%$ of b/d, then P_v^{approx} overestimates P_v by less than 4%.

Example 7.3:

A gas-filled detector with a 3-inch × 2-inch aperture is placed 3 inches away from a ^{137}Cs source for a radiation measurement. The source is on the detector axis. What is the solid angle subtended by the NaI:Tl detector and the resulting view factor? How does the approximation method compare to the exact results? Assume no intermediate absorption of the gamma rays.

Solution:

From Eq. (7.85)

$$\Omega = 4\pi P_v(a/d, b/d) = 4 \arcsin \frac{(a/d)(b/d)}{\sqrt{[(a/d)^2+4][(b/d)^2+4]}}$$

$$= 4 \arcsin \frac{(3/3)(2/3)}{\sqrt{[(3/3)^2+4][(2/3)^2+4]}} = 0.568 \text{ sr.}$$

The view factor is thus $P_v = \Omega/(4\pi) = 0.0452$.

The approximate method for P_v is given by Eq. (7.88) so

$$\Omega = 4\pi P_v^{approx} \simeq 2\pi \left(1 - \frac{3}{\sqrt{3^2 + (2)(3)/\pi}}\right), = 0.576 \text{ sr.}$$

Thus, the approximate method overestimates by about 1.5%.

7.4.2 Isotropic Area Sources

Solid Angle for a Disk Source and a Cylindrical Detector

As shown in Fig. 7.19, a radioactive disk source of radius a_s is centered and placed a distance d from circular aperture or radius a_d. The planes of both disks are parallel. Decay particles can reach the detector aperture from any location on the disk source. The source emits radiation isotropically at a rate of S_0 particles per unit area per unit time. The rate at which radiation emitted from a differential area of the source, $dA_s = r_1 dr_1 d\theta_1$, reaches a differential area on the detector aperture, $dA_d = r_2 dr_2 d\theta_2$, is

$$dN = \frac{S_0 \ (\hat{\mathbf{n}} \cdot \mathbf{R}) \ dA_s \ dA_d}{4\pi R^3}. \tag{7.89}$$

Here $\mathbf{n}$ is a unit vector perpendicular to the source, and the term $\hat{\mathbf{n}} \cdot \mathbf{R}/R$ is the cosine of the angle between $\mathbf{R}$ and $\mathbf{n}$, namely d/R. Thus,

$$dN = \frac{S_0 \ d \ dA_s \ dA_d}{[d^2 + r_1^2 + r_2^2 - 2r_1 r_2 \cos(\phi_1 - \phi_2)]^{3/2}}. \tag{7.90}$$

The total emission rate from the radioactive source is $N_0 = S_0 4\pi a_s^2$. Division of Eq. (7.90) by N_0 then gives differential view factor for radiation from dA_s to dA_d, i.e.,

$$dP_v = \frac{1}{4\pi^2 a_s^2} \frac{d \ dA_s \ dA_d}{[d^2 + r_1^2 + r_2^2 - 2r_1 r_2 \cos(\phi_1 - \phi_2)]^{3/2}}. \tag{7.91}$$

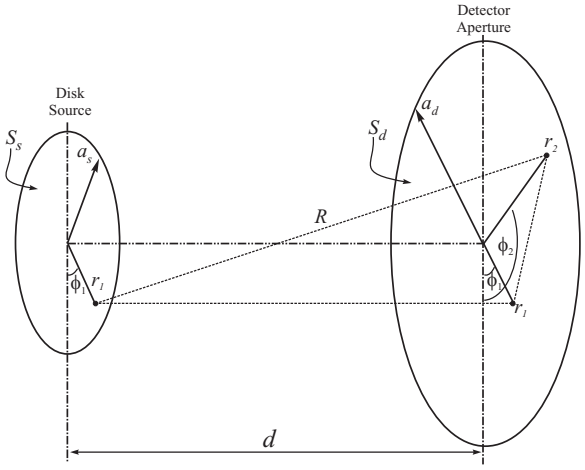

Figure 7.19. Geometry used to determine the solid angle for a disk source and cylindrical detector.

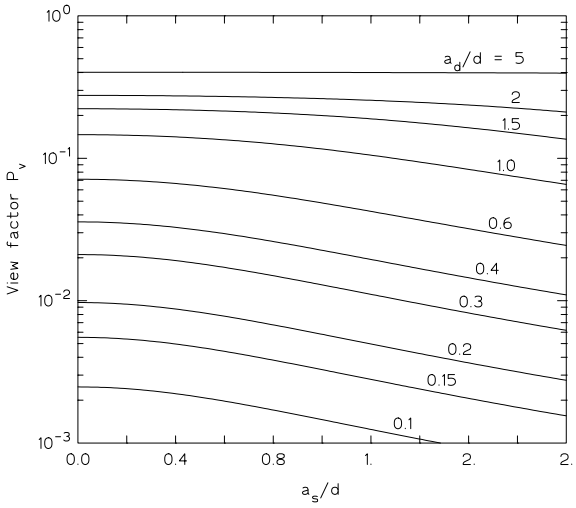

Figure 7.20. The view factor for an axially aligned disk source and disk detector apertures as calculated with Eq. (7.93).

To obtain the total view factor, the above result must be integrated over all dA_s and dA_d. Ruby [1994] expressed the result as a single integral involving Bessel functions of the first kind of order one, namely

$$P_v \frac{a_d}{a_s} \int_0^\infty \frac{dk}{k} \exp[-kd] J_1(ka_s) J_1(ka_d). \tag{7.92}$$

This expression, like previous view factors, can be expressed in terms of dimensionless parameters by defining $kd = k'$. Equation (7.92) becomes

$$P_v(a_s/d, a_d/d) = \frac{(a_d/d)}{(a_s/d)} \int_0^\infty \frac{dk'}{k'} \exp[-k'] J_1(k' \frac{a_s}{d}) J_1(k' \frac{a_d}{d}). \tag{7.93}$$

Although this result cannot be evaluated analytically, it is easily evaluated using numerical integration. Example results are shown in Fig. 7.20.

Ruby [1994], by substituting a truncated series approximation for the Bessel functions in Eq. (7.93), found

$$P_v \simeq \omega^2 \left\{ 1 - \left(\frac{3}{4}\right)(\psi^2 + \omega^2) + \left(\frac{15}{24}\right)(\psi^4 + \omega^4 + 3\psi^2\omega^2) - \left(\frac{35}{64}\right)\left[\psi^6 + \omega^6 + 6\psi^2\omega^2(\psi^2 + \omega^2)\right] \right\}, \tag{7.94}$$

where $\psi = a_s/d$ and $\omega = a_d/d$. Accuracy increases as the distance between the source and detector increases. In other words, the accuracy increases as ψ and ω decrease, where the error is $< 1\%$ for $\psi < 0.2$ and $\omega < 0.5$. Another much more complicated, but perhaps a more accurate approximation to Eq. (7.93) was published later [Vega-Carrillo 1996, 2005]. However, it turns out that numerous solutions and tables for various geometries for the disk source/cylindrical detector geometry have been published [Jaffey 1954; Paxton 1959; Hubbell et al. 1961], offering a simplistic alternative method for arriving at view factors for a disk source.

7.4.3 Monte Carlo Approach to View Factor Angle Calculations

The number of source/detector combinations for which the view factors can be evaluated analytically, or even approximated, is quite limited. However, Monte Carlo techniques can be easily used to numerically determine view factors, from simple to very complex geometries. Sources and detector apertures of any shape and orientation to each other are readily treated. Indeed, the programming effort to numerically evaluate Eq. (7.93) is far greater than that needed for a Monte Carlo evaluation. Monte Carlo results are shown to agree well with analytical and experimental results for several examples shown earlier in this section.

More important, all of the examples given in this section have assumed isotropic emissions from the various sources. However, there are many cases in which the emission is quite anisotropic. For example, radiation emitted from the outer surface of a shielded source is often proportional to some power of the cosine of the emission angle with respect to the outward normal to the surface. Similarly, radiation emitted from a collimated source, such as a beam port of a nuclear reactor, is quite anisotropic. Monte Carlo methods can treat such cases with little extra effort.

7.5 Geometric Corrections: Detector Parallax Effects

Uncollided gamma rays are exponentially attenuated as they travel through a medium. The probability a gamma ray makes, at least, its first interaction after traveling a distance x in the detector is, thus,

$$P_{int}(x) = 1 - e^{-\mu(E)x}, \tag{7.95}$$

where $\mu(E)$ is the total interaction coefficient for gamma rays of energy E in the medium inside the detector.

As a first approximation, Eq. (7.95) describes the expected fraction of photons that have undergone a single interaction while traveling a distance x. For a photoelectric interaction, the photon's full energy is transferred to the detector medium less, perhaps, some losses from x-ray escape events. Compton scattering and pair production lead to partial energy deposition. Equation (7.95) does not take into account small-angle Compton or incoherent scattering, which usually deposits very little energy in the detector with the secondary photon continuing on in nearly the same direction with almost the same energy. This possibility can be accounted for by removing incoherent and small-angle Compton scattering components from the interaction coefficient $\mu(E)$ in Eq. (7.95).

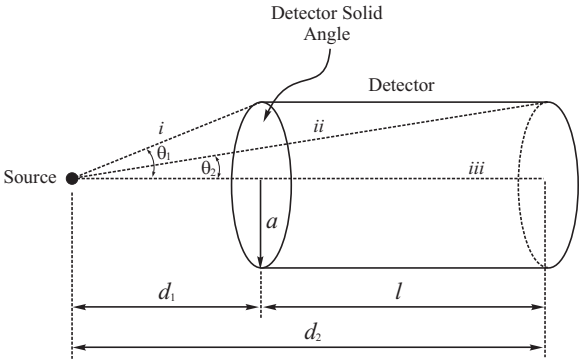

Figure 7.21. A radioactive point source at distance d_1 from the center of the aperture of a cylindrical detector. Particles entering the detector encounter different mass thicknesses of the detector medium depending on their trajectories. Shown by the dotted lines are the three limiting trajectories.

Hence, the intrinsic efficiency, as given by Eq. (7.74), pertains to the efficiency of the detector to have at least one radiation interaction within the detector volume after radiation particles have crossed the plane of the detector aperture. Because some events may deposit energy below the system's electronic threshold, then Eq. (7.74) and Eq. (7.95) give the best possible efficiency that can be achieved by the detector.

Consider the situation of Fig. 7.21, depicting a cylindrical detector of radius a and length l. The radiation source is placed at distance d_1 from the center of the aperture of the cylindrical detector. However, the source is also at distance d_2 from the exit aperture of the detector. The interaction probability of gamma rays entering the aperture at angle θ_1 is zero. Gamma rays entering the detector at angles between θ_1 and

θ_2 have a probability of interaction in the range

$$0 \le p(x) \le 1 - \exp\left[-\frac{\mu(E)l}{\cos\theta_2}\right],$$

while those entering between θ_2 and 0° have an interaction probability in the range

$$1 - \exp\left[-\frac{\mu(E)l}{\cos\theta_2}\right] \ge p(x) \ge \exp[-\mu(E)l].$$

Although Eq. (7.74) indicates that ϵ_I is constant for all values of $\theta \in [0, \theta_1]$ because all source particles emitted in this range reach the detector aperture, parallax effects reduce this efficiency because different angles of incidence lead to different probabilities that the incident photon will interact within the detector and lead to a recorded count. A measured efficiency is only reliable for a single geometry. Parallax effects change the efficiency as the geometry is scaled as by, for example, altering the distance between the source and detector.

The intrinsic efficiency is determining by both the view factor P_v, the probability a source particle is emitted toward the detector aperture, and the probability that such particles interact in the detector upon crossing the aperture. For gamma rays and neutrons, the interaction probability is described by the exponential dependence of Eq. (7.95). The number of particles interacting within the detector divided by the number of particles crossing the detector aperture gives the intrinsic efficiency of the detector. If one assumes a point isotropic source and that any interaction results in a detectable signal, the intrinsic efficiency, modified to account for the interaction probability $p(x)$ in the detector, is given by

$$\widehat{\epsilon}_I = \frac{\dfrac{1}{4\pi}\dfrac{1}{r^2}\displaystyle\int_0^\theta r^2\left(1 - \exp\left[-\mu(E)l(\theta)\right]\right)\sin\theta\, d\theta \int_0^{2\pi} d\phi}{\dfrac{1}{4\pi}\dfrac{1}{r^2}\displaystyle\int_0^\theta r^2 \sin\theta\, d\theta \int_0^{2\pi} d\phi} = \frac{\displaystyle\int_0^\theta \left(1 - \exp\left[-\mu(E)l(\theta)\right]\right)\sin\theta\, d\theta}{\displaystyle\int_0^\theta \sin\theta\ d\theta}. \tag{7.96}$$

For the cylindrical case shown in Fig. 7.21, the modified intrinsic efficiency is,

$$\widehat{\epsilon}_I = \frac{1}{1-\cos\theta_1}\left[\int_0^{\theta_2}\left(1 - \exp\left[-\frac{\mu(E)l}{\cos\theta}\right]\right)\sin\theta\, d\theta + \int_{\theta_2}^{\theta_1}\left(1 - \exp\left[-\frac{\mu(E)(a\cos\theta - d_1\sin\theta)}{\cos\theta\ \sin\theta}\right]\right)\sin\theta\, d\theta\right]. \tag{7.97}$$

This result cannot be evaluated analytically and numerically methods must be used. Note that most often a detector is operated with a discriminator level set to reduce (or eliminate) electronic noise and background radiations. Consequently, the lower level discriminator (LLD) rejects electronic signals that fall below the set threshold, thereby producing a lower intrinsic detector efficiency than predicted in Eq. (7.97).

The detection efficiency for charged particles is usually adequately described by Eq. (7.74); however, *parallax clipping* can yield a measured efficiency that is lower than the theoretical treatment, another consequence of the signal discrimination level. As shown in Fig. 7.22, an alpha-particle point source subtends a solid angle Ω defined by distance d and aperture radius a. However, alpha particles deposit energy through ionization along their straight-line trajectories, and sufficient energy must be deposited within the detector to produce a signal above the LLD setting. At large angles from the detector axis, alpha particles can strike the detector wall before depositing sufficient energy and hence avoid detection. Suppose the average ionization required to produce a measurable signal requires a transit length in the detector of $\ge h$. Consequently, the solid angle that defines intrinsic efficiency, denoted Ω' in Fig. 7.22, is defined by the virtual aperture $a' = a - h\sin\theta'$.

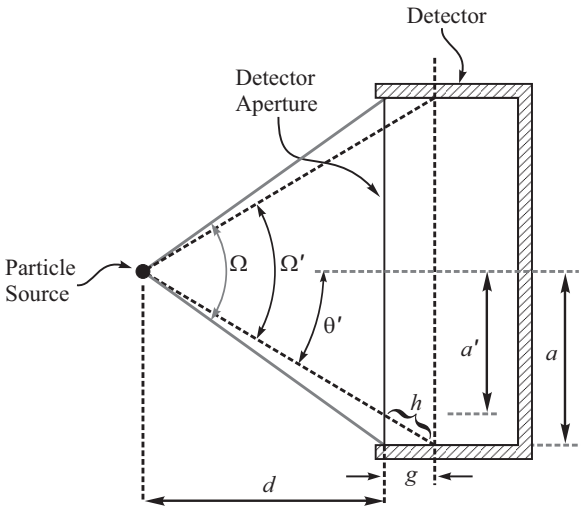

Figure 7.22. A radioactive point source of alpha particles at distance d from the center of the detector aperture. The energy deposited in the detector depends on the emission angle from the axis. Ω is the solid angle determined by d and the aperture radius a from Eq. (7.81). The distance h represents the transit length that a particle must travel to deposit enough energy for detection. Consequently, the actual solid angle for detection, Ω', is determined by $a' = a - h\sin\theta'$ and the distance d.

7.5.1 Attenuation and Scattering Effects Outside the Detector

X and Gamma Rays

The determination of a detector's response is complicated when absorption and attenuation in the environment around the detector are considered. Gamma rays emitted towards a detector may be scattered away from the detector or otherwise interact in the intervening air. For large distances between the source and detector, the air attenuation may be significant, although parallax effects are greatly reduced. The attenuation length of gamma rays, defined as the mean-free-path length, is given by $1/\mu(E)$ and is shown in Fig. 7.23 for different air temperatures at sea level. Such far-field measurements are also made more complex by photons scattered into the detector from the air and other objects around the detector. Corrections for such skyshine, roomshine, groundshine, etc., generally require transport analyses.

Gamma-ray attenuation is most pronounced in air and in the source and detector encapsulations for low-energy photons. Almost all radiation detectors are in sealed packages. Gas detectors are sealed within a gas chamber, scintillators are typically hermetically sealed in a reflecting cannister, and semiconductor detectors are sealed in light-tight encapsulation to reduce electromagnetic noise. Also, many types of semiconductor detectors are chilled to low temperatures, thereby requiring isolation in vacuum cannisters to prevent icing and convective warming. In all of these packaging cases, low-energy x rays and gamma rays can be attenuated as they pass through the container towards the detecting medium.

Alpha Particles

Corrections for alpha-particle (and other heavy charged particle) detectors can be more complicated than just parallax effects. Recall that charged particles deposit energy through Coulombic interactions along their straight-line trajectories. They lose energy as they travel through any material between their emission points and the sensitive volume of the detector.

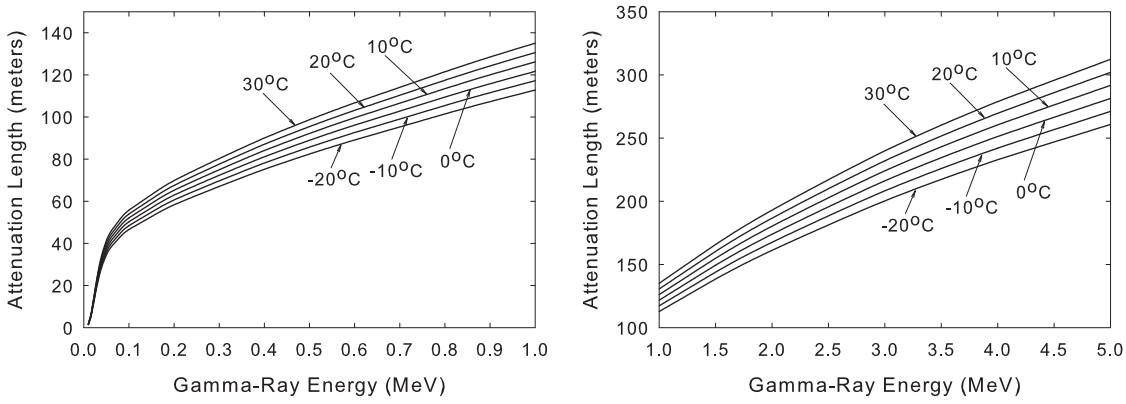

Figure 7.23. Gamma-ray attenuation lengths, $1/\mu(E)$, in air as a function of energy and temperature at sea level. Calculated values based on data in the *Radiological Health Handbook* [1970].

In Fig. 7.24 are shown two cases for a gas-filled detector having a thin window for the aperture. Such windows are commonly fabricated from aluminized boPET, thereby allowing energetic alpha particles to pass through to the detection gas. In the case of Fig. 7.24(a), the alpha-particle point source is placed such that the range of the alpha particles can reach any location on the detector aperture. The view factor is determined by the solid angle Ω subtended at the source by the aperture. As discussed earlier, because of parallax effects, the actual solid angle that allows alpha particles to deposit energy above the discriminator setting is $\Omega' < \Omega$. Note that energy loss per unit distance $(-dE/dx)$ is typically higher in the boPET than the medium between the source and detector, thereby strongly influencing Ω'.

In the case of Fig. 7.24(b), the alpha-particle point source is placed such that the range of the alpha particles is too short to reach all locations on the detector aperture. Consequently, the aperture radius a does not determine the solid angle within which particles can reach the aperture. Instead, the solid angle Ω_s is determined by a smaller effective a_s, where a_s is the greatest radius inside of which the alpha particles have enough energy to reach the detector. Again, due to parallax and energy loss in the window, the actual solid angle that allows alpha particles to deposit energy above the discriminator setting is Ω'.

In both cases shown in Fig. 7.24, use of Ω to correct the count underestimates the source strength. To determine the correct emission rate, the correct solid angle to use is Ω', which accounts for both parallax and window energy-loss effects. The correction is further complicated by the fact that energy deposition by alpha particles is defined by the Bragg ionization curve, in which $-dE/dx$ is not constant. Hence, the length h, the minimum distance the alpha particle must travel within the detector to be detected, is not a constant value.

A common method to reduce solid angle and parallax effects for alpha particle measurements is to highly collimate the alpha-particle source. As a result, the count rate diminishes, thereby requiring significantly longer measurement times. Also, energy dissipation in the intermediate medium (typically air) can be eliminated by placing the alpha particle source and detector in a vacuum chamber, a measurement method usually used for alpha-particle spectroscopy with a semiconductor detector, but not with a gas-filled detector.[9]

[9]The gas pressure inside a gas-filled detector can cause the boPET window to expand like a balloon if operated in vacuum, further complicating the calculation of a correction factor.

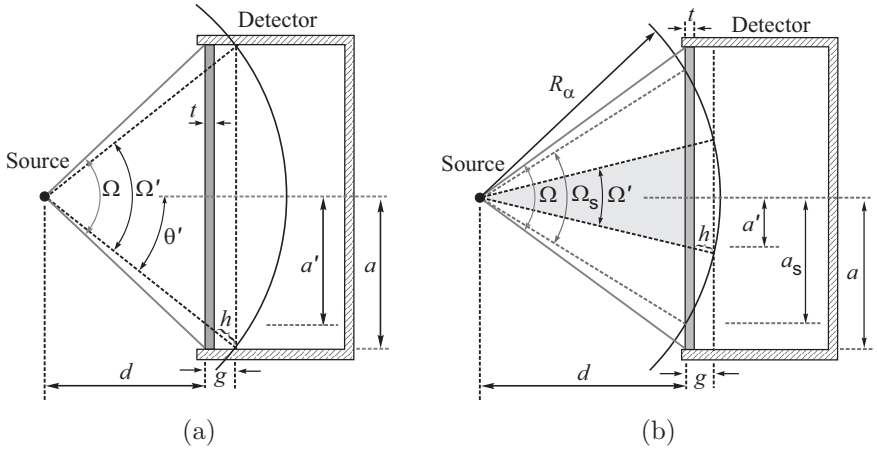

Figure 7.24. In (a) the range of the alpha particle is greater that the longest distance to the outer boundary of the detector aperture, whereas in (b) the range of the alpha particle is shorter than this distance. Note that Ω is defined by the detector aperture, Ω_s is defined by the maximum range that the alpha particles can reach the detector aperture, and Ω' is defined by the required transit length that a particle must pass through to still deposit enough energy for detection.

Beta Particles

Because beta particles, as they give up energy to the ambient medium, travel in very tortuous trajectories, the above discussion for heavy charged particles does not apply. As discussed in Section 7.2.2, parallax effects, along with source reflection, air and aperture attenuation, and source encapsulation effects can all be treated by using a single Monte Carlo simulation. There are no simple methods.

Neutrons

In many neutron experiments, the neutrons travel through air from their source to a detector. Thermal neutrons, in particular, can undergo significant air scattering, primarily by the nitrogen in air. For example, consider thermal neutrons produced in a reactor that travel down a reactor beam port to some experimental area. Such neutrons have a Maxwellian energy distribution characterized by a neutron temperature T and a thermal-averaged total interaction coefficient (or macroscopic cross section), as given by [Lamarsh 1966], namely

$$\overline{\Sigma}_t = \frac{\sqrt{\pi}}{2}\Sigma_t(E_o)\sqrt{\frac{T_o}{T}}. \tag{7.98}$$

Here E_o is a reference energy (usually 0.0253 eV) and T_o is a reference temperature (usually taken as 293 K).[10]

For dry air at STP, $\Sigma(E_o)$ is 5.01×10^{-4} cm^{-1}. Thus, the average distance thermal neutrons, with $T = T_o$, travel before they interact in air is $\lambda_t = 1/\Sigma_t = 2.00$ m. This result shows that for every 2 m of neutron travel in air, the fraction that interact is $1 - e^{-1} = 0.63$. To avoid such losses, sometimes a beam port is fitted with a long polyethylene tube inflated and sealed with a non-interacting gas, such as ^{4}He, or other canister containing a vacuum or ^{4}He.

[10] The most probable neutron energy in a Maxwellian flux distribution with a neutron temperature T_o is $E_o = 0.0253$ eV.

PROBLEMS

1. A thin layer of a radioisotope that emits 4.13-MeV, 5.1-MeV and 6.95-MeV alpha particles is electroplated on an iron substrate opposite and alpha-particle detector. What fraction of the alpha particles of each energy emitted towards the substrate are reflected back towards the detector? How would one distinguish alpha particles emitted directly towards the detector from those that are reflected from the substrate?

2. Plot the backscatter coefficient for monoenergetic electrons from an iron target for energies between 0.1 and 10 MeV.

3. An ^{241}Am alpha-particle source is placed in a 2π counter which has a dead time of 30 μs. The source was prepared with a 4-mm diameter, 50-angstrom thick plated deposit upon a 1-mm Ni backing. The lower level discriminator (LLD) is set to 100 keV. What is the expected count rate, per source particle, in the detector?

4. A ^{137}Cs disk source of 1-cm radius is placed and centered 25 cm away from a 3-in $\times$ 3-in NaI:Tl detector. Determine the fraction of gamma rays that intersect the detector aperture.

5. An ^{116m}In foil is activated in a nuclear reactor to use as a source to measure the dead time of a gas-filled proportional counter. Radiation measurements are performed at set time intervals, each measurement being 10 sec long, with the following results:

Data for dead-time determination for an ^{116m}In foil source.

T (min)	0	54	108	163	216	270
Counts	331204	260509	182493	114217	65323	35034
T (min)	324	378	432	486	540	594
Counts	18302	9308	4689	2402	1197	604

(a) Use the dead-time decay measurement method of Eq. (7.68)-Eq. (7.69) to find the detector dead time. (b) Use the dead-time decay measurement method of Eq. (7.71) to find the detector dead time. (c) Compare the results and discuss.

6. A radiation measurement is conducted in air for a ^{137}Cs source with a 5-in $\times$ 5-in NaI:Tl detector at a distance of 100 meters. Estimate the fraction of unscattered gamma rays that reach the detector.

7. An ^{241}Am alpha-particle source is centered and placed 3 mm away from the circular aperture of a gas-filled proportional counter. The aperture is 5.04 cm in diameter and is composed of 0.4 mg cm^{-2} boPET. The experiment is conducted at sea level and at 30°C. Assume that the alpha particle must pass through at least 2.5 mm of gas in the detector to be recorded. Radiation measurements are performed for 3 min each. After each measurement, the source is moved backwards by 2.5 mm, followed by a new measurement, resulting in the tabular data shown below.

Data for the determination of alpha-particle range.

D (mm)	3	5.5	8	10.5	13	15.5	18	20.5
Counts	237170	224568	210324	193868	176166	159315	142533	125979
D (mm)	23	25.5	28	30.5	33	35.5	38	40.5
Counts	109079	91118	73509	54969	36693	18363	1283	1

(a) After correcting for equivalent air thickness of the window, plot counts versus range.

(b) Based on the subtended solid angle, correct for counts per measurement and plot atop the previous graph. Determine source strength. Discuss features.

(c) Using the virtual aperture, correct the counts and plot atop the previous graph. Determine source activity. Discuss the features.

Chapter 8

Essential Electrostatics

I happen to have discovered a direct relation between magnetism and light, also electricity and light, and the field it opens is so large and I think rich.

Michael Faraday

Numerous radiation detectors rely on the current produced by the motion of mobile charges created by radiation events. Radiation interactions within the detector volume ionize the absorbing medium, thereby creating mobile point charges, usually referred to as charge carriers (because these particles carry the charge through the detector). The detector may be a solid, liquid or gas, within which two or more electrodes are installed. Generally, a voltage is applied to the detector electrodes to move, or *drift*, the mobile charges across the detector volume to produce the current.

Electronic detectors range from simple radiation counters to complex radiation spectrometers. The former are used to indicate the presence of ionizing radiation, whereas the latter can also identify the energies and types of radiation. In either case, the fundamental physics of current induction formed by mobile charge carriers applies. Introduced in this chapter are the basic concepts governing charge and current induction in electronic radiation detectors.

8.1 Electric Field

Consider a point charge of Q coulombs, as shown in Fig. 8.1. The charge itself has *electric field* lines emanating from it radially outward (or inward). If a point charge is centered within an imaginary spherical surface, the electric field lines intersect the surface at right angles (perpendicular), with the imaginary surface area $4\pi r^2$, where r is the radius of the sphere. Suppose the number of field lines is denoted by N, then the surface density of field lines becomes $N/(4\pi r^2)$ per unit area. It is easy to understand that the electric field line density decreases with r^2 as the spherical surface area increases. The electric field vector (with SI units of volts/meter or, equivalently newtons/coulomb) at the surface of the sphere is

$$\boldsymbol{\mathcal{E}} = \frac{Q}{4\pi\epsilon_o r^2}\hat{\mathbf{r}}, \tag{8.1}$$

where $\hat{\mathbf{r}}$ is a unit vector normal to the spherical surface and ϵ_o is the *permittivity of free space* $\simeq 8.854\times10^{-12}$ farads per meter or, equivalently, A s V^{-1} m^{-1}. The magnitude of $\mathcal{E}$ is

$$\mathcal{E} = \boldsymbol{\mathcal{E}}\bullet\hat{\mathbf{r}} = \frac{Q\cos\theta}{4\pi\epsilon_o r^2}. \tag{8.2}$$

Because the field lines are perpendicular to the spherical surface, then multiplication by the area of the sphere $A = 4\pi r^2$ gives

$$\mathcal{E}A = \frac{Q\cos\theta}{4\pi\epsilon_o r^2}4\pi r^2 = \frac{Q}{\epsilon_o}. \tag{8.3}$$

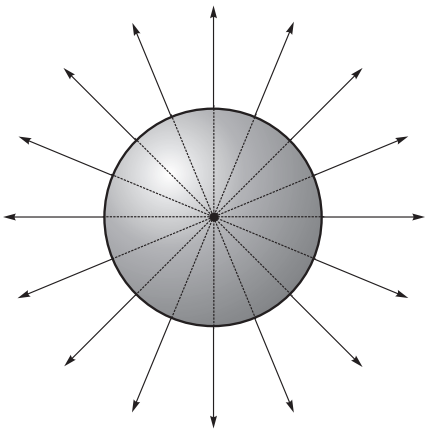

Figure 8.1. An imaginary spherical surface enclosing a point charge at the center.

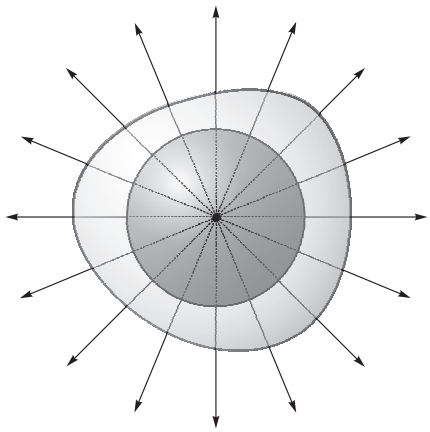

Figure 8.2. An irregularly shaped surface surrounding both the spherical surface and the point charge.

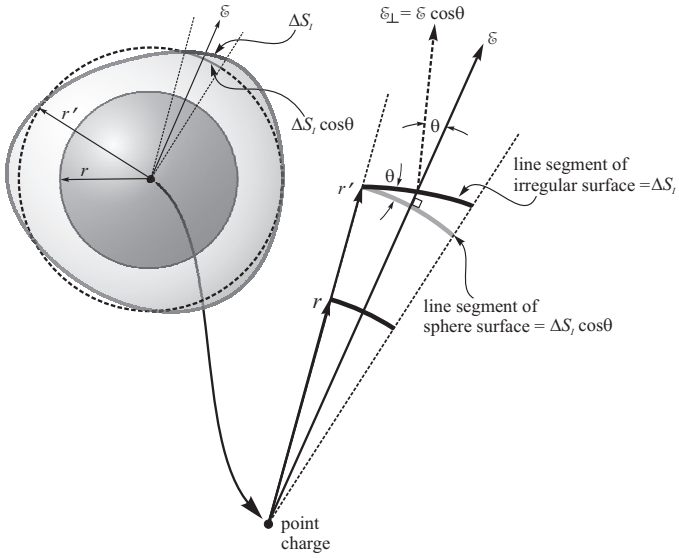

Figure 8.3. An irregularly shaped surface surrounding both the spherical surface and the point charge. The spherical surface is expanded to a new radius of r' that intersects the irregular surface.

Note that if the charge is positive, then the electric field lines point outwards (or positive direction), and if the charge is negative, then the electric field lines point inwards (or negative direction). In either case, Eq. (8.3) is still correct. From this result it is seen Q/ϵ_o is independent of the size of the sphere. If the imaginary spherical surface is then surrounded by an irregularly shaped surface, as shown in Fig. 8.2, the product $\mathcal{E}A$ can be shown to still be the same.

Suppose that the sphere of radius r is expanded to a radius r' such that portions of the new spherical surface lie inside and outside the irregular surface, as shown in Fig. 8.3. The electric field lines are still orthogonal to the sphere of radius r'. Consider a small segment ΔS_I along the irregular surface and a small line segment ΔS_S along the spherical surface. The angle between the two small line segments is designated θ; hence the length of the line segment on the sphere must be $\Delta S_I \cos\theta$. Notice also that the angle between electric field vector and the normal vector to the irregular surface is also θ.

Now apply the same argument to a small area segment ΔA_I on the irregular surface that intersects the spherical surface (see Fig. 8.4). The small area formed by projecting ΔA_I back onto the spherical surface is denoted ΔA_S. From the previous results for the line segments, the product $\mathcal{E}\Delta A_I$ for the irregular surface becomes $\Delta A_S = \mathcal{E}\Delta A_I \cos\theta$ for the spherical surface. In the limit as $\Delta A_I \to dA_I$ and $\Delta A_S \to dA_S$, the integration of $\mathcal{E}\cos\theta dA_I$ over the irregular surface must equal the integration of $\mathcal{E}dA_S$ over the spherical

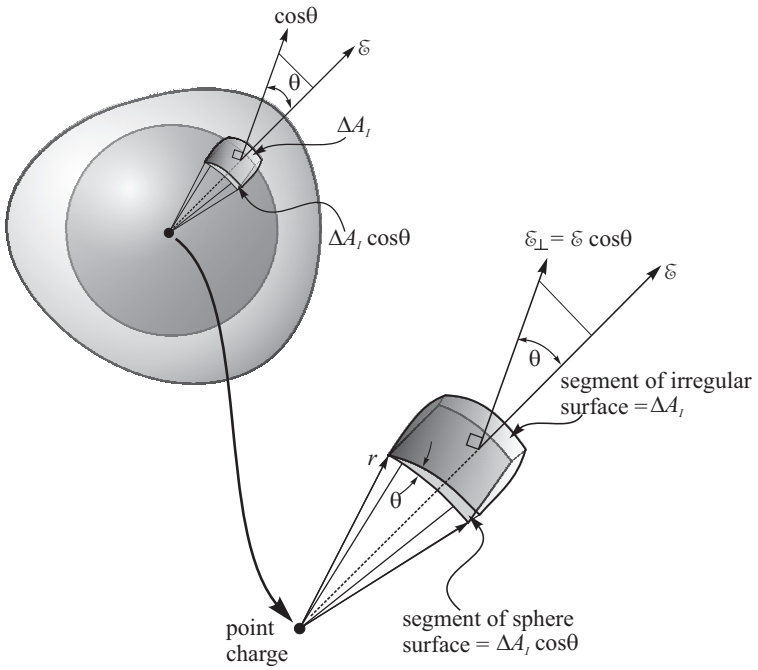

Figure 8.4. It can be shown that the electric field normal to the irregular surface ($E_\perp$) is related to the spherical surface by a factor of $\cos\theta$. Similarly, the small area on the irregular surface, ΔA_I, is related to the small area projected onto the spherical surface, ΔA_S, by a factor of $\Delta A_I \cos\theta$.

surface, which from Eq. (8.3) equals Q/ϵ_o, i.e.,

$$\int_{A_I} \mathcal{E}\cos\theta\, dA_I = \int_{A_S} \mathcal{E}\, dA_S = \frac{Q}{\epsilon_o}. \tag{8.4}$$

Thus, the product of the electric field and total surface area always is Q/ϵ_o regardless of the shape of a *closed* surface surrounding a point charge! Because the irregular surface is arbitrary, this also means the point charge can be anywhere inside this surface. For multiple point charges inside S_I, each charge Q_i contributes Q_i/ϵ_o, meaning that the total charge is the summation of charges within the surface surrounding the charges $Q_{total} = \sum_i Q_i$.

Finally, if $\hat{\mathbf{n}}$ is a unit vector perpendicular to any closed surface S, then $\mathcal{E}\cos\theta\, dA_S = \boldsymbol{\mathcal{E}}\bullet\hat{\mathbf{n}}\, dA_S$ and Eq. (8.4) can be written as

$$\boxed{\int_{A_S} \boldsymbol{\mathcal{E}}\bullet\hat{\mathbf{n}}\, dA_S = \iint_S \boldsymbol{\mathcal{E}}\bullet\hat{\mathbf{n}}\, dS = \frac{\sum_i Q_i}{\epsilon_o} = \frac{Q_{total}}{\epsilon_o}.} \tag{8.5}$$

This is commonly referred to as *Gauss' Law.*[1]

[1] Eq. (8.5), credited to Carl Friedrich Gauss, is actually an application of his Law of Quadratic Reciprocity that he rediscovered in 1795. This result was actually derived by Joseph-Louis Lagrange many years earlier in 1785.

8.1.1 Alternate Derivation of Gauss' Law

A more mathematically direct way, although not so insightful, to derive Gauss' law is to start with the first of Maxwell's four equations of electromagnetism, namely

$$\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{D}}(\mathbf{r}) = \boldsymbol{\nabla}\bullet\left[\kappa\epsilon_o\boldsymbol{\mathcal{E}}(\mathbf{r})\right] = \rho_V(\mathbf{r}), \tag{8.6}$$

where $\boldsymbol{\mathcal{D}}(\mathbf{r})$ is the dielectric displacement, κ is the dielectric constant, and $\rho_V(\mathbf{r})$ is the volumetric charge density (coulombs per cubic meter). Usually the dielectric constant is unchanged through a medium, although not always. Suppose in this example that the charge is in an evacuated space surrounded by a surface. Hence, $\kappa = 1$ and Eq. (8.6) can be rewritten as,

$$\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}}(\mathbf{r}) = \frac{\rho_V(\mathbf{r})}{\epsilon_o}, \tag{8.7}$$

Equation 8.7 is integrated over a closed volume V to obtain

$$\iiint_V \boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}}(\mathbf{r})\,dV = \frac{1}{\epsilon_o}\iiint_V \rho_V(\mathbf{r})\,dV = \frac{Q_{total}}{\epsilon_o}. \tag{8.8}$$

Here Q_{total} is the total charge contained in the volume V. The remaining volume integral can be converted to an integral over the surface S of V by using Gauss' divergence theorem [Riley et al. 2006] to obtain

$$\iint_S \boldsymbol{\mathcal{E}}\bullet\hat{\mathbf{n}}\,dS = \frac{Q_{total}}{\epsilon_o}, \tag{8.9}$$

where $\hat{\mathbf{n}}$ is the outward unit normal to the surface S. Equation (8.6), or the alternative form Eq. (8.7), are usually referred to as Gauss' law in differential form, while Eq. (8.9) is Gauss' law in integral form.

8.2 Electrical Potential Energy

An electric field causes mobile charges to move, hence an electric field does *work* on a mobile charge. The work required to move the particle from position $\mathbf{r}_1$ to position $\mathbf{r}_2$ is given by

$$W = \int_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{F}\bullet d\mathbf{l} = \int_{\mathbf{r}_1}^{\mathbf{r}_2} F\cos\theta\ dl, \tag{8.10}$$

where $\mathbf{F}$ is the force vector applied to the particle, $d\mathbf{l}$ is a differential length along the direction of travel, and θ is the angle between these two vectors. Coulomb's law states that the force on a particle at $\mathbf{r}'$ with charge q' from a second particle at $\mathbf{r}$ with charge q is

$$\mathbf{F} = \frac{QQ'(\mathbf{r}-\mathbf{r}')}{4\pi\epsilon_o|\mathbf{r}-\mathbf{r}'|^3} \qquad \text{with magnitude} \qquad F = \frac{QQ'}{4\pi\epsilon_o r^2}, \tag{8.11}$$

where r is the distance between the charges.

Consider the electric field of a point charge Q shown in Fig. 8.1. If another point charge Q' is placed in the electric field of the first charge Q, then the electric field of Q exerts a force on Q', and the electric field of Q' exerts an equal force on Q.

In Fig. 8.5, a single charge Q' is moving in the electric field of a second charge Q from position r_1 to position r_2 across the field lines of Q. In the limit of decreasing angles between field lines, $\Delta\omega \to d\omega$, $\Delta l \to dl$, $\Delta r \to dr$, and $\theta_1 = \theta_2 = \theta$. From Fig. 8.5, the relationship between the differential distance traveled dl and the differential change in distance between the charges dr is

$$\cos\theta\ dl = dr. \tag{8.12}$$

Substitution of Eq. (8.12) into Eq. (8.10) then yields the work done on the point charge Q' as it moves from some point $\mathbf{r}_1$ to $\mathbf{r}_2$,

$$W = \int_{\mathbf{r}_1}^{\mathbf{r}_2} F dr = \int_{\mathbf{r}_1}^{\mathbf{r}_2} \frac{1}{4\pi\epsilon_o}\frac{QQ'}{r^2} dr = \frac{QQ'}{4\pi\epsilon_o}\left(\frac{1}{r_1} - \frac{1}{r_2}\right). \tag{8.13}$$

This result shows that the path taken from $\mathbf{r}_1$ to $\mathbf{r}_2$ is immaterial, but instead only the change in radial distance from Q determines the work done. In other words, it is only the starting and ending locations that determine the total work performed on the charge moving in the electric field.[2]

The potential energy of a particle with charge Q located a distance r away from another particle of charge Q' is represented by

$$U = \frac{1}{4\pi\epsilon_o}\frac{QQ'}{r}. \tag{8.14}$$

Suppose that the particle with charge Q' is surrounded by n particles with charge Q_i at distance r_i from the particle with charge Q'. The total potential energy exerted on the particle with charge Q' from the collective electric fields of the surrounding particles is

$$U = \frac{Q'}{4\pi\epsilon_o}\left(\frac{Q_1}{r_1} + \frac{Q_2}{r_2} + \frac{Q_3}{r_3} + ... + \frac{Q_n}{r_n}\right) = \frac{Q'}{4\pi\epsilon_o}\sum_{i=1}^{n}\frac{Q_i}{r_i}. \tag{8.15}$$

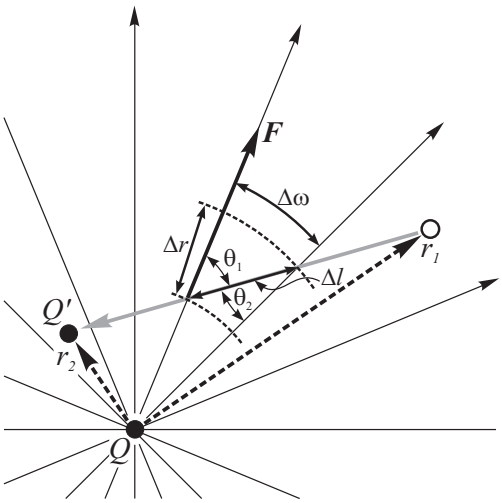

Figure 8.5. Depiction of charge Q' moving through the electric field of charge Q.

The potential energy of an individual charged particle is useful, and is important for understanding signal formation within an electronic radiation detector. However, it is more common to use the general term *potential*, which is defined as the potential energy per unit charge,

$$V = \frac{U}{Q'} = \frac{1}{4\pi\epsilon_o}\sum_{i=1}^{n}\frac{Q_i}{r_i}, \tag{8.16}$$

and is expressed in units of volts (or joules per coulomb). Note that the potential is no longer dependent upon the "test" charge Q'.[3] The force exerted upon Q' may also be expressed in terms of the electric field, produced by one or more point charges, in which $\mathbf{F} = Q'\boldsymbol{\mathcal{E}}$. Substitution of $q'\boldsymbol{\mathcal{E}}$ into Eq. (8.13) and division by Q' gives the potential difference between two points within the electric field. Hence, the potential difference between arbitrary locations a and b is

$$V_{ab} = \Delta V = \int_a^b \boldsymbol{\mathcal{E}}\bullet d\mathbf{l} = \int_a^b \mathcal{E}\cos\theta\ dl. \tag{8.17}$$

[2]The path independence is a consequence that $\mathbf{F}$ of Eq. (8.11) is given by the gradient of a *scalar field potential*, i.e.,

$$\mathbf{F} = \boldsymbol{\nabla}\left(\frac{QQ'}{4\pi\epsilon_o r}\right).$$

As a result $\boldsymbol{\nabla}\bullet\mathbf{F} = 0$. Force fields with this property are called *conservative* force fields.

[3]The normalization unit charge Q' is that of a free electron, q_e, such that $Q' = q_e N'$ where N' is an integer. For a single electron, N' must equal unity. Other charges are therefore integer representations of q_e, namely, $Q_i = q_e N_i$.

In summary, Eq. (8.17) is the voltage that an experimenter would measure between two points (a and b) within an electric field. The work done on a unit test charge moving from some point a to another point b in the electric field is $Q'V_{ab}$.

8.3 Capacitance

Consider the arrangement depicted in Fig. 8.6. Two conductive plates, separated by a distance d, have equal, but opposite, charges. An electric field is produced between the plates by the charges on the plates. The positively charged plate (or terminal) has a voltage V_1 and the negatively charged plate has a voltage V_2. The *capacitance* of the two plates is defined as the ratio of the charge magnitude on either plate to the magnitude of the potential difference between the plates,

$$C = \left| \frac{Q}{\Delta V} \right|. \tag{8.18}$$

If ΔV is taken as the applied voltage V between the electrodes, then the above definition gives the important relation

$$CV = Q \tag{8.19}$$

The SI unit for capacitance is the farad (one coulomb per volt). The reader should understand that the charge stored in a capacitor has a summed positive charge on one terminal and an equal summed negative charge stored on the opposite terminal; hence, a capacitor with stored charge Q actually has $+Q$ on one terminal and $-Q$ on the other terminal.

Many radiation detectors use a voltage applied between two conductive terminals. Of these detectors, the parallel plate configuration, similar to that shown in Fig. 8.6, is the simplest and easiest to understand. The finite area of either plate has a charge of magnitude Q. Hence, there is an average charge magnitude per unit area, defined as a surface charge density σ. Assume that there is a vacuum between the conductive plates and that the conductive plates have equal areas A and are separated by a distance d, then the magnitude of the electric field between the parallel plates is

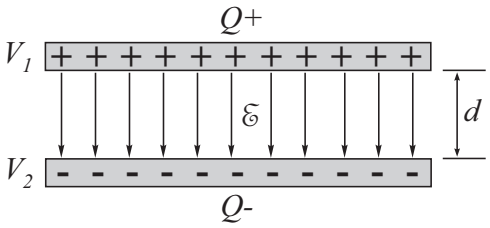

Figure 8.6. Two conductive plates separated by distance d have equal, but opposite, charges stored upon them. The cumulative charges produce an electric field, with a voltage of V_1 at the positive charge terminal and a voltage V_2 at the negative charge terminal.

$$\mathcal{E} = \frac{\sigma}{\epsilon_o} = \frac{Q}{\epsilon_o A}. \tag{8.20}$$

From Eq. (8.17), the voltage difference between the plates is

$$V = \mathcal{E}d = \frac{Qd}{\epsilon_o A}. \tag{8.21}$$

Substitution of Eq. (8.21) into Eq. (8.19) yields the capacitance

$$C = \epsilon_o \frac{A}{d}. \tag{8.22}$$

A radiation detector has a radiation absorbing medium, such as a gas or semiconductor, between the conductive electrodes. The permittivity of the radiation absorbing material must be substituted into Eq. (8.22), which is accomplished by multiplying ϵ_o by the *dielectric correction constant* κ_s of the radiation absorbing material,

$$C = \kappa_s \epsilon_o \frac{A}{d}. \tag{8.23}$$

Note that the electric field, voltage and charge terms are not necessary to define capacitance; hence, the capacitance is dependent only upon the device dimensions and permittivity of the insulating material between the electrodes.

Many advanced detector designs do not have simple parallel plate geometries, and many detectors are designed to reduce capacitive effects. Gas filled detectors are often designed in a coaxial configuration with a single anode wire through the center with a much larger cylindrical outer conductive cathode shell. There are detector designs with numerous anodes (or cathodes), some detectors have concentric spherical electrodes, and many detectors have a variety of different electrode shapes. Because Eq. (8.23) applies only to simple planar geometries, capacitance for these other detector geometries must be found by deriving a fundamental form of Eq. (8.19) for each particular geometry of interest.

8.4 Current and Stored Energy

Capacitors are generally used as charge storage devices, and these charges are transported to a capacitor through an electronic circuit. Consider the movement of charge ΔQ to a capacitor in some time interval Δt. The *current* I is defined as the amount of charge transported divided by the time taken for the charge movement, i.e.,

$$I = \frac{\Delta Q}{\Delta t} = C\frac{\Delta V}{\Delta t}. \tag{8.24}$$

The rate at which charge flows to a capacitor, or other electronic components may not be constant in time; hence, the instantaneous current is defined as

$$I = \frac{dQ}{dt} = C\frac{dV}{dt}. \tag{8.25}$$

Charges flowing to a capacitor build up the charges on one side of the capacitor, which causes charges of the opposite polarity to accumulate on the opposing electrode. Consequently, work is performed to accumulate the change in charge ΔQ in the capacitor. From Eq. (8.10), the work to increase the electrode charge by dq

$$dW = dq \int \mathcal{E} \cos\theta \; dl = V \, dq = \frac{q}{C} dq. \tag{8.26}$$

where V is the magnitude of the voltage on the capacitor at a time when the accumulated charge is q. If no charge is initially stored on the capacitor, Eq. (8.26) is integrated to find the total work performed to accumulate charge Q on the capacitor, i.e.,

$$W = \int_0^W dW = \int_0^Q \frac{q}{C} dq = \frac{Q^2}{2C}. \tag{8.27}$$

With Eq. (8.19), the work performed to store Q, which is also the *energy* stored by the capacitor, can be expressed as

$$W = \frac{Q^2}{2C} = \frac{QV}{2} = \frac{CV^2}{2}. \tag{8.28}$$

This result is important for electronic radiation detectors. Suppose a radiation interaction occurs within an electronic radiation detector, on which a voltage V_0 is applied across the detector terminals. The mobile charges created by the radiation event are caused to move (or *drift*) through the detector. Positive charges drift towards the negatively charged electrode and negative charges drift towards the positively charged electrode. As these charges separate, they form a small, time-dependent electric field of opposite polarity to that of the electric field applied to the detector. As a result, a small change in voltage appears between the

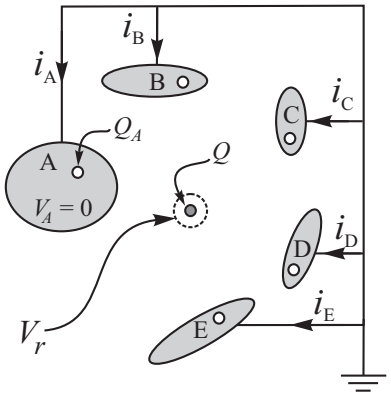

Figure 8.7. A point charge Q is placed in the vicinity of grounded conductive surfaces, and produces image charges on those surfaces.

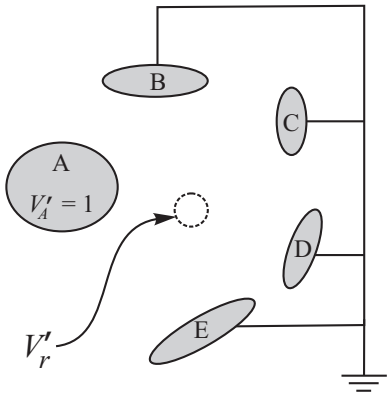

Figure 8.8. The point charge is removed and a potential equal to unity is applied to **A**. All other electrodes remain grounded.

electrodes caused by the electric field of the drifting charges. Hence, stored energy is expended to move the charges, and the energy expended to move the charges can be measured as a change in current or voltage that, typically, is performed by an externally connected circuit.

Charges moving in a detector cause current to flow in an externally connected circuit through a process called *induction*. In other words, mobile charges moving in the detector cause electron current to flow in the circuit externally connected to the detector. The change in electron current can be measured directly, commonly referred to as *current mode operation*, or it can flow to a capacitor in the external circuit and be stored, thereby providing a measure of the voltage change as defined by Eq. (8.19). This change in voltage ΔV, or voltage *pulse*, signals the occurrence of a radiation interaction event in the detector. Such measurements are referred to as *pulse mode operation*.

8.5 Basics of Charge Induction

Many radiation detectors are based on the principle of charge induction, whereby moving point charges work to induce a current in an external circuit. The detector itself is a capacitor, and charges moving in the detector cause current flow to or from the device terminals or electrodes. The charge or current induced on any electrode can be found through Shockley's or Ramo's method (both methods are essentially the same) [Ramo 1939; Shockley 1938].

Consider a single point charge Q situated at position $\mathbf{r}_q$ in a vacuum within which there are an arbitrary number of grounded conducting surfaces, as depicted in Fig. 8.7. The point charge Q will cause electrons on the surrounding conductive surfaces to change in position. If Q is negative, then the surface electrons will be slightly repelled, while if positive, slightly attracted to the surface. The overall effect is to have the apparent appearance of an *image charge* of opposite sign on the conductive surface. Suppose the goal is to determine the induced current and induced charge produced upon electrode **A** by the point charge Q, thereby producing an image charge of Q_A on the electrode. Perhaps the other electrodes are also affected, but it will shortly be seen to be of no consequence to this derivation. Surround the point charge Q by a small equipotential conducting sphere. From Gauss' law one has

$$\int_{sph} \boldsymbol{\mathcal{E}} \cdot \hat{\mathbf{n}}\, ds = \int_{sph} \frac{\partial V}{\partial n}\, ds = \frac{Q}{\epsilon_o}, \tag{8.29}$$

where $\hat{\mathbf{n}}$ is the outward unit normal to the surface and $\partial V/\partial n$ denotes $\boldsymbol{\nabla} V \bullet \hat{\mathbf{n}}$.

Because there are no charges in the vacuum bounding the electrodes and the small sphere, the electrostatic field is given by Laplace's equation

$$\boldsymbol{\nabla}^2 V(\mathbf{r}) = 0, \quad \mathbf{r} \in \text{ all space outside the conducting surfaces.} \tag{8.30}$$

The boundary conditions needed to specify a unique solution of Eq. (8.29) are $V(\mathbf{r}) \to 0$ as $|\mathbf{r}| \to \infty$ and by the voltages on the electrodes. The voltage on the small imaginary sphere is denoted by $V_r = V(\mathbf{r})$.

Now for the same set of electrodes with the charge Q removed, electrode **A** is given a voltage V_A with the other electrodes still grounded, as shown in Fig. 8.8. The new electrostatic field, $V'(\mathbf{r})$, is described by

$$\nabla^2 V'(\mathbf{r}) = 0, \tag{8.31}$$

with boundary conditions specified by the voltage on all surfaces. The voltage at $\mathbf{r}$ at the surface of the imaginary sphere is now $V'_r = V'(\mathbf{r})$. Apply Green's theorem [Riley et al. 2006] to all surfaces, namely

$$\int_{vol} [V' \nabla^2 V - V \nabla^2 V'] dv = \int_S \left[V' \frac{\partial V}{\partial n} - V \frac{\partial V'}{\partial n} \right] ds. \tag{8.32}$$

Here the surface integration is over all electrode surfaces, the imaginary surface, and the surface at infinity, and the volume integration is over all space bounded by all the surfaces. From Eq. (8.30) and Eq. (8.31) the left-hand side of Eq. (8.32) is seen to vanish. On the right-hand side the surface integral at infinity vanishes because $V(\mathbf{r} \to \infty) = V'(\mathbf{r} \to \infty) = 0$. The surface integrals around all grounded electrodes also have the potential V and V' equal to zero, hence, the right side of Eq. (8.32) vanishes for these electrodes. Thus, only the surface integrals around the charged electrode **A** and around the small sphere remain, and Eq. (8.32) reduces to [Ramo 1939],

$$V'_A \int_{S_A} \frac{\partial V_A}{\partial n} ds - V_A \int_{S_A} \frac{\partial V'_A}{\partial n} ds + V'_r \int_{sph} \frac{\partial V_r}{\partial n} ds - V_r \int_{sph} \frac{\partial V'_r}{\partial n} ds = 0. \tag{8.33}$$

From Gauss' law the first integral equals Q_A/ϵ_o, where Q_A is the image charge on electrode **A**. Similarly, the third integral equals Q/ϵ_o. The second term vanishes because $V_A = 0$. From Eq. (8.29), the fourth integral vanishes because there is no charge inside the small imaginary sphere. Thus,

$$V'_A \frac{Q_A}{\epsilon_o} + V'_r \frac{Q}{\epsilon_o} = 0 \qquad \text{or} \qquad Q_A = -Q \frac{V'_r}{V'_A}. \tag{8.34}$$

From this result the induced current produced by the point charge in Fig. 8.7, moving in any direction between the electrodes with vector velocity $\mathbf{v} = d\mathbf{r}/dt$, is

$$I_A = \frac{dQ_A}{dt} = -\frac{Q}{V'_A} \frac{dV'_r}{dt} = -\frac{Q}{V'_A} \boldsymbol{\nabla} V'_r(\mathbf{r}) \bullet \frac{d\mathbf{r}}{dt} = \frac{Q}{V'_A} \boldsymbol{\mathcal{E}}'(\mathbf{r}) \bullet \mathbf{v}, \tag{8.35}$$

where $\boldsymbol{\mathcal{E}}'(\mathbf{r})$ is the electric field at point $\mathbf{r}$ under the condition that the "potential" at electrode **A** is set at V_A with all other electrodes grounded.

It is useful to normalize $V'(\mathbf{r})$ by setting V'_A to one volt, i.e., define $V_w(\mathbf{r}) \equiv V'_Q(\mathbf{r})/V'_A$. This normalized "voltage" V_w is called the *weighting potential* although it is dimensionless. In terms of this normalized potential, Eq. (8.34) and Eq. (8.35) are expressed as

$$\boxed{Q_A = -Q V_w(\mathbf{r}) \qquad \text{and} \qquad I_A = -Q \boldsymbol{\nabla} V_w(\mathbf{r}) \bullet \frac{d\mathbf{r}}{dt} = Q \boldsymbol{\mathcal{E}}_w(\mathbf{r}) \bullet \mathbf{v}} \tag{8.36}$$

where the normalized or weighting electric field is $\boldsymbol{\mathcal{E}}_w = \boldsymbol{\mathcal{E}}'/V'_A = -\boldsymbol{\nabla} V_w$. This result can be applied to any one of the electrodes by setting its potential to one volt and grounding all other electrodes [see also Jen 1941; Beck 1953]. The results of Eq. (8.36) are significant and important, and are often referred to as *Ramo's Theorem*.[4] Hence, for any geometric detector structure, the expected current induction for the electrode tied to the readout circuit can be found from Eq. (8.36).

One can calculate the weighting potential for practically any electrode configuration by solving Laplace's equation (Eq. (8.30)) with the boundary conditions that (1) the contact connected to the readout electronics is set to unity and (2) all other contacts are grounded (set to zero). Weighting potentials for a few select geometries are easily calculated by analytical means, while weighting potentials for more complicated electrode geometries may be calculated by finite difference methods.

8.5.1 Green's Reciprocation Theorem

Suppose there is an array of M conductors in a vacuum and charges $Q_i,\ i = 1, \ldots, M$ are placed on the conductors to produce potentials $V_i,\ i = 1, \ldots, M$. Then if these charges are replaced by different charges $Q'_i,\ i = 1, \ldots, M$ a different set of potentials $V'_i,\ i = 1, \ldots, M$ would result. How are the old charges and potentials related to the new charges and potentials?

The potential fields are given by $\nabla^2 V(\mathbf{r}) = 0$ and $\nabla^2 V'(\mathbf{r}) = 0$ with appropriate boundary conditions. Equation (8.32) is Green's theorem and relates V to V'. Because $\nabla^2 V(\mathbf{r}) = 0$ and $\nabla^2 V'(\mathbf{r}) = 0$, the left-hand side of Eq. (8.32) vanishes. Also the integral over the surface at infinity, where both V and V' are zero, vanishes. Thus, Eq. (8.32) reduces to [Smythe 1989]

$$\sum_{i=1}^{M} \int_{S_i} \left[V_i' \frac{\partial V}{\partial n} - V_i \frac{\partial V'}{\partial n} \right] ds_i = 0,$$

where S_i is a closed surface around electrode i. The V and V' are constant on the surface so Eq. (8.5.1) can be written as

$$\sum_{i=1}^{M} V_i' \int_{S_i} \frac{\partial V}{\partial n} ds_i = \sum_{i=1}^{M} V_i \int_{S_i} \frac{\partial V'}{\partial n} ds_i, \tag{8.37}$$

which, from Gauss' law (see Eq. (8.29)), yields the important result

$$\boxed{\sum_{i=1}^{M} Q_i V_i' = \sum_{i=1}^{M} Q_i' V_i.} \tag{8.38}$$

This result is commonly referred to as *Green's reciprocation theorem* [for more details, see Jeans 1943; Jackson 1975; Smythe 1989].

8.6 Charge Induction for a Planar Detector

The simplest geometry for a radiation detector that depends on charge induction is the *planar device* and consists of two parallel conductors or terminals separated by a radiation absorbing medium. This configuration is often used for simple gas-filled or semiconductor radiation detectors. A voltage is typically applied

[4] Although Eq. (8.36) is commonly referred to as "Ramo's theorem," the same result was actually published by Shockley in 1938 a year before Ramo's publication in 1939. Because both V_w and $\boldsymbol{\mathcal{E}}_w$ are dimensionless, Eqs. (8.36) are dimensionally correct, although many forget this fact.

across the terminals to produce an electric field throughout the radiation absorbing medium. When a radiation interaction occurs within the detector volume, N_o electron-ion pairs are created. Because of the electric field across the device, free electrons, with charge $-q$ and positive ions, with charge q drift within the detector medium toward the conductive surfaces, with negative charges moving towards the anode and positive charges moving towards the cathode. Both conductive terminals are connected within the same circuit, as shown in Fig. 8.9.

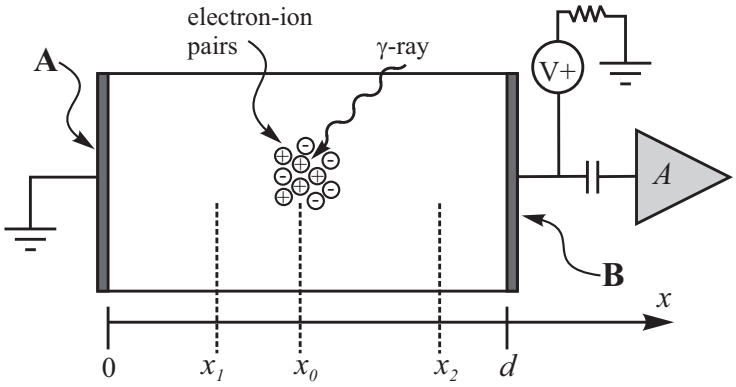

Figure 8.9. Depiction of a planar radiation detector where a gamma ray is absorbed at location x_0. The figure shows a preamplifier attached to the positively biased electrode at $x = d$.

The electrostatic field within the absorbing medium, in the absence of free charges, is given by Laplace's equation $\nabla^2 V(\mathbf{r}) = 0$.[5] By picking the x-axis to be perpendicular to the terminals, with the origin at the grounded terminal, as shown in Fig. 8.9, the potential varies only with x and the potential is given by

$$\nabla^2 V(x) = \frac{d^2 V(x)}{dx^2} = 0, \tag{8.40}$$

subject to the boundary conditions $V(0) = 0$ and $V(d) = V_B$. Integration of Eq. (8.40) twice and application of the boundary conditions to evaluate the two constants of integration yields

$$V(x) = \frac{V_B}{d}\, x. \tag{8.41}$$

The dimensionless weighting potential $V_w(x)$ is obtained by dividing this result by V_B or, equivalently, by setting $V_B = 1$ volt. In either way, for a planar device $V_w(x) = x/d$. With this weighting potential, the induced charge in the electrodes is readily calculated.[6]

In some circumstances, it is important to separately calculate the induced charge contributions from the electrons and positive ions liberated by radiation. Instances requiring separate treatments may involve

[5] Laplace's equation is simply Poisson's equation with ρ equal to zero,

$$\nabla^2 V(\mathbf{r}) = -\nabla \bullet \boldsymbol{\mathcal{E}}(\mathbf{r}) = -\frac{\rho}{\kappa \epsilon_o}. \tag{8.39}$$

[6] Some textbooks describe the output of a planar detector with conservation of energy methods. However, the reader is warned that the conservation of energy approach is generally incorrect, although it may appear to work for special cases. The consequence of using the conservation of energy approach is especially problematic with semiconductor detectors and should be avoided.

different charge carrier velocities or different recombination/trapping times for electrons and ions. Such treatments are covered in later chapters. Here it is assumed that charge carrier velocities and trapping are of no consequence, so the separate contributions of electrons and positive ions to the induced current can be determined in a straightforward manner. Consider the situation depicted in Fig. 8.9, where a radiation interaction event occurs at distance x_0 between two electrodes, labeled **A** and **B**, separated by a distance of d. A positive voltage potential is applied at electrode **B**, such that electrons drift to electrode **B** and positive ions drift to electrode **A**.

The change in the induced charge on electrode **B** resulting from the total displacement of N_o charge pairs moving between the electrodes can be found by using Ramo's Theorem. Upon integration of the induced current given by Eq. (8.36), the induced charge on the electrodes ΔQ after the ions have moved from x_0 to x_1 and the electrons have moved from x_0 to x_2 is

$$\begin{aligned}\Delta Q &= \int_0^{t(x_1)} I_A(t)\,dt\bigg|_{ions^+} + \int_0^{t(x_2)} I_A(t)\,dt\bigg|_{e^-} \\ &= -q_e N_o \int_0^{t(x_1)} \boldsymbol{\nabla} V_w \bullet \frac{d\mathbf{r}}{dt}\,dt\bigg|_{ions^+} - (-q_e N_o)\int_0^{t(x_2)} \boldsymbol{\nabla} V_w \bullet \frac{d\mathbf{r}}{dt}\,dt\bigg|_{e^-},\end{aligned} \tag{8.42}$$

where q_e is the magnitude of the electron charge, $t(x_1)$ is the time required for the ions to move from x_0 to x_1, and $t(x_2)$ is the time required for the free electrons to move from x_0 to x_2. In this geometry $V_w(\mathbf{r}) = V_w(x) = x/d$ so Eq. (8.42) can be evaluated as follows.

$$\begin{aligned}\Delta Q &= -q_e N_o \int_0^{t(x_1)} \frac{dV_w}{dx}\left(\frac{dx}{dt}\right) dt\bigg|_{ions^+} - (-q_e N_o)\int_0^{t(x_2)} \frac{dV_w}{dx}\frac{dx}{dt}\,dt\bigg|_{e^-} \\ &= -q_e N_o \int_0^{t(x_1)} \frac{d}{dx}\left(\frac{x}{d}\right)\frac{dx}{dt}\,dt\bigg|_{ions^+} + q_e N_o \int_0^{t(x_2)} \frac{d}{dx}\left(\frac{x}{d}\right)\frac{dx}{dt}\,dt\bigg|_{e^-} \\ &= -q_e N_o \int_{x_0}^{x_1} \frac{1}{d}\,dx\bigg|_{ions^+} + q_e N_o \int_{x_0}^{x_2} \frac{1}{d}\,dx\bigg|_{e^-} = q_e N_o \left[\frac{x_0 - x_1}{d}\bigg|_{ions^+} + \frac{x_2 - x_0}{d}\bigg|_{e^-}\right],\end{aligned} \tag{8.43}$$

which yields the final result,

$$\boxed{\Delta Q|_{planar} = q_e N_o \left[\frac{x_2 - x_1}{d}\right].} \tag{8.44}$$

Hence, the total displacement of the free carriers divided by the detector active region width yields the change in the induced charge measured by the detector. If all of the electrons drift to the positive contact at $x = d$ and all of the positive ions drift to the negative contact at $x = 0$, then $x_2 - x_1 = d - 0$, and the induced charge becomes $Q = q_e N_o$.

Analysis Based on Green's Reciprocation Theorem

The induced charge can also be found by using Green's reciprocation theorem as stated by Eq. (8.38). Consider the two electrodes in the planar device, both of equal dimensions separated by distance d. Two different situations are now considered. In Case 1, a charge Q_o is placed between the plates on an imaginary infinitely small conductor (labeled conductor 3). Plate **A** has, as a consequence, an induced charge Q_A and plate **B** has an induced charge Q_B. The potentials on the electrodes **A** and **B** are zero (Case 1). The induced charges Q_A and Q_B are to be determined by Green's reciprocation theorem. In Case 2 the charge Q_o is removed from imaginary conductor 3 (so that $Q_o = 0$), and placed on electrode **B**. In both cases the potentials and resulting induced charges are unknown and are summarized in Table 8.1.

Table 8.1. Charge and potential conditions for two electrodes between which a unit mobile charge (Q_o) is present.

	Case 1 (unprimed)			Case 2 (primed)		
Electrode	**A**	**B**	3	**A**	**B**	3
Charge	Q_A	Q_B	Q_o	Q'_A	Q_o	0
Potential	0	0	V_o	V'_A	V'_B	V'_o

From Green's reciprocation theorem of Eq. (8.38) for a general electrode problem

$$Q_1V'_1 + Q_2V'_2 + Q_3V'_3 = Q'_1V_1 + Q'_2V_2 + Q'_3V_3,$$

or rewritten for this specific case,

$$Q_AV'_A + Q_BV'_B + Q_oV'_o = Q'_AV_A + Q'_BV_B + Q'_3V_o.$$

In the present analysis, $V_A = V_B = Q'_3 = 0$ and the above general relation reduces to

$$Q_AV'_A + Q_BV'_B + Q_oV'_o = 0. \tag{8.45}$$

Because the sum of the induced charges and the charge Q_o, causing the induced charges, must sum to zero, one also has

$$Q_A + Q_B + Q_o = 0. \tag{8.46}$$

From Eq. (8.45) and Eq. (8.46) the induced charges in Case 1 are found to be

$$Q_A = -Q_o\frac{V'_o - V'_B}{V'_A - V'_B} \qquad \text{and} \qquad Q_B = -Q_o\frac{V'_A - V'_o}{V'_A - V'_B}. \tag{8.47}$$

What does this mean? The charge induced by the test charge on a given electrode is proportional to the potential difference between the location where the charge originally appeared (in our case, at x_o) and the opposite electrode. It is a change in the induced charge that causes induced current to flow, and we seek to find the change in the induced charge as the test charge moves through the space between the electrodes.

With these results, the change in induced charges on the terminal electrodes as the test charge Q_o in Case 1 is moved to a new location between the terminals. The potential on the imaginary electrode in Case 2 changes from V'_o to V'_n. The change on electrode **A** is thus

$$\Delta Q_A = \left(-Q_o\frac{V'_n - V'_B}{V'_A - V'_B}\right) - \left(-Q_o\frac{V'_o - V'_B}{V'_A - V'_B}\right) = -Q_o\frac{V'_n - V'_o}{V'_A - V'_B}, \tag{8.48}$$

and the change in the induced charge on electrode **B** is

$$\Delta Q_B = \left(-Q_o\frac{V'_A - V'_n}{V'_A - V'_B}\right) - \left(-Q_o\frac{V'_A - V'_o}{V'_A - V'_B}\right) = Q_o\frac{V'_n - V'_o}{V'_A - V'_B}. \tag{8.49}$$

Notice that Eq. (8.48) and Eq. (8.49) have opposite charge signs, hence ΔQ_A on electrode **A** is opposite in sign for ΔQ_B on electrode **B**. A knowledge of the equipotential lines between the conductors is needed in order to apply the results of Eqs. (8.48) and (8.49), otherwise referred to as the weighting potential. As stated before, the weighting potential can be calculated by solving Laplace's equation with the electrode of interest placed at a unit potential while all other electrodes are grounded. Hence, the difference $V'_A - V'_B$ becomes unity, and the normalized potentials V'_o and V'_n can be determined.

Once again consider the situations shown in Fig. 8.9. Suppose that the electrons move in the positive x direction to point x_2 with potential $V'(x_2) = V_2'$ and the positive ions move in the negative x direction to point x_1 with potential $V'(x_1) = V_1'$. From Eq. (8.49), the change in induced charge on electrode **B**, from both the contribution of the negative electrons and positive ions, is

$$\Delta Q_B = -q_e N_o \frac{V_2' - V_o'}{V_A' - V_B'}\bigg|_{e^-} \qquad \text{and} \qquad + q_e N_o \frac{V_1' - V_o'}{V_A' - V_B'}\bigg|_{ions^+},$$

where N_o is the number of electron-ion pairs in motion. A unit negative charge on electrode **B** would produce a potential profile described by Eq. (8.41), namely

$$V(x) = -V_o \frac{x}{d}. \tag{8.50}$$

A normalized potential difference within the device is

$$\frac{V(x_2) - V(x_1)}{-V_o} = \frac{x_2}{d} - \frac{x_1}{d} = \frac{x_2 - x_1}{d}. \tag{8.51}$$

This result shows that the potential between the two parallel terminals is simply the displaced distance divided by d. With the proper charge sign for the ions and electrons, the two contributions to Eq. (8.6) are

$$-q_e N_o \frac{V_2' - V_o'}{V_A' - V_B'}\bigg|_{e^-} = -q_e N_o \frac{x_2 - x_0}{d} \qquad \text{and} \qquad q_e N_o \frac{V_1' - V_o'}{V_A' - V_B'}\bigg|_{ions^+} = q_e N_o \frac{x_1 - x_0}{d}. \tag{8.52}$$

Addition of these two results and use of Eq. (8.49) yields

$$\Delta Q_B = -q_e N_o \frac{x_1 - x_0}{d} + q_e N_o \frac{x_2 - x_0}{d} = q_e N_o \frac{x_2 - x_1}{d}.$$

This is the same result as Eq. (8.44) obtained by using Ramo's theorem. With the use of the same method, it can be shown that the change in the induced charge on electrode **A** is

$$\Delta Q_A = q_e N_o \frac{x_1 - x_0}{d} - q_e N_o \frac{x_2 - x_0}{d} = -q_e N_o \frac{x_2 - x_1}{d}.$$

Although Ramo's theorem and Green's reciprocation relations give the same result for the induced charge, it is obvious that Ramo's theorem is considerably easier to use than Green's reciprocation theorem.

8.6.1 Planar Detector with Stationary Space Charge

Now consider a planar detector in which a stationary uniform distribution of space charge is present as shown in Fig. 8.10. Such space charge is typical for many *semiconductor* detector devices. In this case the induced charge can be found once again from Ramo's theorem; however, the operating potential must be solved using Poisson's equation for electricity.

First, consider Green's reciprocation theorem for two cases. In Case 1 there is a single mobile charge Q_o placed on a small imaginary electrode and a single stationary charge Q_s also on a small imaginary electrode, both located between electrodes **A** and **B**, with potentials V_o and V_s, respectively. Now in Case 2, each charge is independently placed upon electrode **A** and analyzed. The charges Q_{Ao} and Q_{Bo} are the charges induced by the mobile charge Q_o on electrodes **A** and **B**, and the charges Q_{As} and Q_{Bs} are the charges induced by the stationary charge Q_s on electrodes **A** and **B**, respectively. The electrode **M** is the

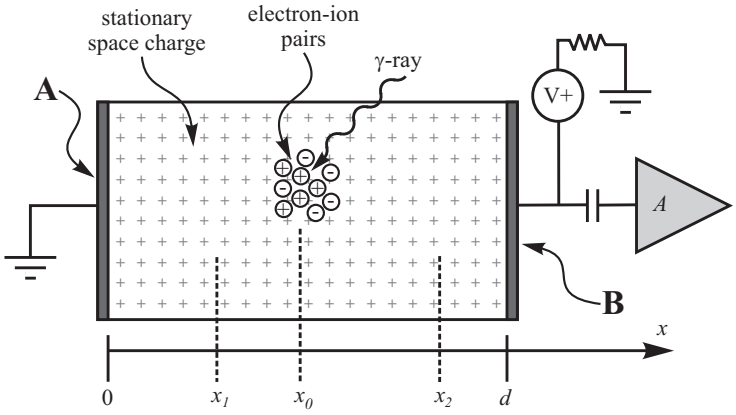

Figure 8.10. Depiction of a planar radiation detector with a uniform distribution of positive stationary space charge. The gamma ray is absorbed at location x_0.

Table 8.2. Charge and potential conditions for two electrodes between which a unit space charge Q_s and a unit mobile charge Q_o are present.

		Case 1 (unprimed)				Case 2 (primed)			
Mobile Charge	Electrode	**A**	**B**	**M**	**S**	**A**	**B**	**M**	**S**
	Charge	Q_{Ao}, Q_{As}	Q_{Bo}, Q_{Bs}	Q_o	Q_s	Q_o, Q_{As}	Q'_{Bo}, Q_{Bs}	0	Q_s
	Potential	0, 0	0, 0	V_o	V_s	$V'_{Ao}, 0$	$V'_{Bo}, 0$	V'_o	V_s
Stationary Charge	Electrode	**A**	**B**	**M**	**S**	**A**	**B**	**M**	**S**
	Charge	Q_{Ao}, Q_{As}	Q_{Bo}, Q_{Bs}	Q_o	Q_s	Q_{Ao}, Q_s	Q_{Bo}, Q'_{Bs}	Q_o	0
	Potential	0, 0	0, 0	V_o	V_s	$0, V'_{As}$	$0, V'_{Bs}$	V_o	V'_s

imaginary electrode at the initial location of the mobile charge and electrode **S** is the imaginary electrode at the location of the stationary charge. The Green's reciprocation conditions for the mobile and stationary charges are summarized in Table 8.2, in which V'_{A0} and V'_{B0} are the potentials produced at electrodes **A** and **B**, respectively, by the mobile point charge Q_o, and V'_{As} and V'_{Bs} are the potentials produced at electrodes **A** and **B**, respectively, by the stationary point charge Q_s. The induced charges on electrodes **A** and **B**, shown in Table 8.2, have been separated for the stationary and mobile charges.

Green's reciprocation theorem of Eq. (8.38) is used for this analysis

$$\sum_{i=1}^{12} Q_i V'_i = \sum_{i=1}^{12} Q'_i V_i,$$

which, upon using values from Table 8.2, expands as

$$Q_{Ao}V'_{Ao} + (Q_{As}\times 0) + Q_{Bo}V'_{Bo} + (Q_{Bs}\times 0) + Q_oV'_o + Q_sV_s + (Q_{Ao}\times 0) + Q_{As}V'_{As} + (Q_{Bo}\times 0) + Q_{Bs}V'_{Bs} + Q_oV_o + Q_sV'_s = (Q_o\times 0) + (Q_{As}\times 0) + (Q'_{Bo}\times 0) + (Q_{Bs}\times 0) + (V_o\times 0) + Q_sV_s + (Q_s\times 0) + (Q_{Ao}\times 0) + (Q'_{Bs}\times 0) + (Q_{Bo}\times 0) + Q_oV_o + (V_s\times 0).$$

This result simplifies to

$$Q_{Ao}V'_{Ao} + Q_{Bo}V'_{Bo} + Q_oV'_o + Q_{As}V'_{As} + Q_{Bs}V'_{Bs} + Q_sV'_s = 0. \tag{8.53}$$

The sum of the charge and its resulting induced charges must equal zero, i.e.,

$$Q_{Ao} + Q_{Bo} + Q_o = 0 \qquad \text{and} \qquad Q_{As} + Q_{Bs} + Q_s = 0. \tag{8.54}$$

From Eqs. (8.53) and Eqs. (8.54), the induced charge on electrodes **A** and **B** are

$$Q_A = Q_{Ao} + Q_{As} = -Q_o\frac{V'_o - V'_{Bo}}{V'_{Ao} - V'_{Bo}} - Q_s\frac{V'_s - V'_{Bs}}{V'_{As} - V'_{Bs}}, \tag{8.55}$$

and

$$Q_B = Q_{Bo} + Q_{Bs} = -Q_o\frac{V'_{Ao} - V'_o}{V'_{Ao} - V'_{Bo}} - Q_s\frac{V'_{As} - V'_s}{V'_{As} - V_{Bs}}. \tag{8.56}$$

Now suppose that m space charges are added between the electrodes. The induced charge upon the output electrode **B** becomes

$$Q_B = -Q_o\frac{V'_{Ao} - V'_o}{V'_{Ao} - V'_{Bo}} - \sum_{i=1}^{m} Q_{s_i}\frac{V'_{As_i} - V'_{s_i}}{V'_{As_i} - V'_{Bs_i}}. \tag{8.57}$$

The observed change in the induced charge upon electrode **B** if the mobile charge moves from position x_0 to a new position x_n is

$$\Delta Q_B = \left\{-Q_o\frac{V'_{Ao} - V'_n}{V'_{Ao} - V'_{Bo}} - \sum_{i=1}^{m} Q_{s_i}\frac{V'_{As_i} - V'_{s_i}}{V'_{As_i} - V'_{Bs_i}}\right\}$$

$$- \left\{-Q_o\frac{V'_{Ao} - V'_o}{V'_{Ao} - V'_{Bo}} - \sum_{i=1}^{m} Q_{s_i}\frac{V'_{As_i} - V'_{s_i}}{V'_{As_i} - V'_{Bs_i}}\right\} = Q_o\frac{V'_n - V'_o}{V'_{Ao} - V'_{Bo}}.$$

This is the same answer as Eq. (8.49)! Hence, it is seen that any space charge does not affect the change in the induced charge created by the mobile charge. Also notice that the potential change is with respect to the potential distribution that is created by the mobile charge $(V'_{Ao} - V'_{Bo})$ and *not* the applied voltage or the potential distribution created by the numerous m number of stationary charges. As a result, the change in the induced charge for the planar device, even with stationary space charge present, yields the same result as given by Eq. (8.44), i.e.,

$$\Delta Q|_{planar} = qN_o\left[\frac{x_2 - x_1}{d}\right].$$

The operating potential is determined, in general, from Poisson's equation,

$$\nabla^2 V(\mathbf{r}) = -\frac{\rho(\mathbf{r})}{\epsilon_s}, \tag{8.58}$$

subject to suitable boundary conditions. For the planar detector $V(\mathbf{r}) \rightarrow V(x)$ and ρ is constant. Thus, Poisson's equation becomes

$$\frac{d^2V(x)}{dx} = -\frac{d\mathcal{E}(x)}{dx} = -\frac{\rho}{\epsilon_s}, \tag{8.59}$$

where the $\epsilon_s = \kappa_s \epsilon_o$ is the permittivity of the detector material. Integration of Eq. (8.59) gives the electric field as

$$\mathcal{E}(x) = \frac{\rho}{\epsilon_s} x + C_1,$$

where C_1 is a constant of integration. For simplicity, it is assumed that the device is fully depleted so that the electric field vanishes at $x = 0$ so that $C_1 = 0$.[7] Integration once again gives $V(x)$

$$\int \frac{dV(x)}{dx} dx = -\int \mathcal{E}(x) dx = -\int \frac{\rho}{\epsilon_s} x \, dx \qquad \text{or} \qquad V(x) = -\frac{\rho}{2\epsilon_s} x^2 + C_2.$$

The boundary condition $V(0) = 0$ requires that $C_2 = 0$ so the voltage in this planar detector is

$$V(x) = -\frac{\rho}{2\epsilon_s} x^2, \tag{8.60}$$

and the corresponding electric field is

$$\mathcal{E}(x) = -\frac{dV}{dx} = \frac{\rho x}{\epsilon_s}. \tag{8.61}$$

Notice that the voltage distribution is parabolic, while the electric field is linear.

The voltage normalized to unity at $x = d$ is

$$\frac{V(x)}{V(d)} \equiv V_n(x) = \left(\frac{\rho x^2}{2\epsilon_s}\right) \Big/ \left(\frac{\rho d^2}{2\epsilon_s}\right) = \frac{x^2}{d^2}, \tag{8.62}$$

and is shown in Fig. 8.11. Also notice that the weighting potential is linear, just as in a planar device with no space charge while the operating potential is clearly non-linear.

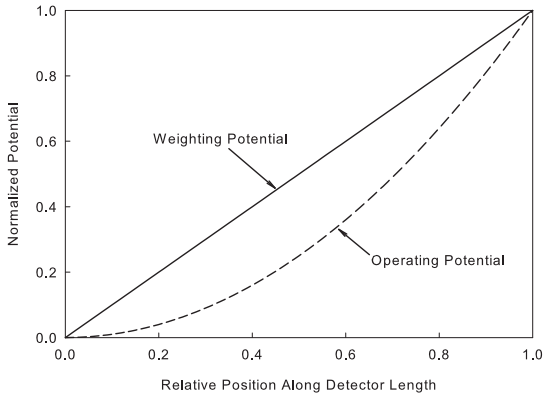

Figure 8.11. A comparison of the weighting potential and the normalized operating potential for a planar detector with uniform space charge.

The above analysis for a planar device with uniform space charge reveals an important point: the space charge in a detector does not affect the weighting potential distribution, but does affect the operating potential. Intuitively, the result should be obvious because Gauss' law shows that the electric field produced by a unit of charge in a volume is independent of the electric fields produced by other charges in the volume. Hence, the induced current produced by the moving charge is independent of the electric field or potential produced by the space charge, and produces the same effect as if there were no space charge. The observed induced charge produced by a charge moving from one point to another depends on the weighting potential between two specific points, and is independent of the trajectory taken from one point in the detector to another.

However, the operating potential does affect the performance of the detector. The operating potential and the accompanying electric field determine the charge carrier velocities and the active volume of a device. The shape of the operating potential and the electric field also determines the charge carrier trajectories as they travel through the detector volume. In gas-filled detectors, the operating potential determines the operation region (ion chamber, proportional, Geiger-Müller). Further, for semiconductor devices the operating potential determines the extent of recombination, trapping and detrapping effects.

[7] The variation of the voltage and electric field in semiconductors is explored in greater detail in Chapter 15.

Historical Note

During the decade of the 1960s, there was some disagreement about the application of Ramo's theorem to detectors with space charge, or more precisely, about how the theorem could be applied to semiconductor detectors. The confusion arose from the role of space charge in the depleted or active regions of the semiconductor material, and how the charge induction from mobile free carriers was affected. As it turns out, space charge within any radiation detector alters the electric field and, as a consequence, changes the charge carrier velocities. When analyzing a detector, one must take great caution in analyzing the *operating potential*, which is found by solving Poisson's equation for electric fields with the boundary condition that voltages are set to the actual operating voltages. However, from Gauss' law of electricity, the applied voltages do *not* affect the voltage or electric field resulting from a point charge and, hence, the space charge also does not affect the charge induction of a point charge as it moves in the cavity of the detector [Martini and Ottaviani 1969]. It can be concluded that (1) the analyst can use the normalized Laplace equation (weighting potential) with all contacts grounded except for the collecting electrode to determine the charge or current induction as a function of charge position and displacement, and (2) the analyst must use Poisson's equation with the actual operating voltages on all contacts to determine the charge carrier trajectories and velocities within the detector cavity.

8.6.2 A Planar Detector Composed of Two Materials

In the previous analysis of a planar device, the medium between the two terminals was a single homogeneous material. Now consider a planar device composed of two dielectric materials, as shown in Fig. 8.12. In such a device, the electric field intensity is no longer constant in each material, although the dielectric displacement is constant in each region.

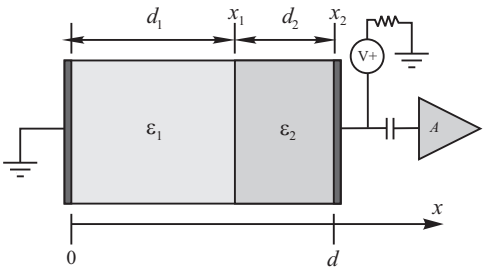

Figure 8.12. A planar detector composed of two dielectric materials.

The dielectric displacement is defined as

$$\mathbf{D} = \epsilon_s \mathbf{E}, \tag{8.63}$$

where $\mathbf{E}$ is the electric field and $\epsilon_s = \kappa_s \epsilon_o$ is the dielectric constant of the material. Recall from Maxwell's equations or, equivalently, Gauss' differential law of electricity that

$$\boldsymbol{\nabla}\bullet\mathbf{D} = \boldsymbol{\nabla}\bullet\epsilon_s\boldsymbol{\mathcal{E}} = \rho, \tag{8.64}$$

where ρ is the space charge density. Note that Eq. (8.64) indicates that $\mathbf{D}$ must be constant if the space charge density is zero. The dielectric constant is constant in most situations, so that Eq. (8.64) can represented as

$$\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}} = \frac{\rho}{\epsilon_s}. \tag{8.65}$$

However, in the device considered here, the dielectric constant is not constant across the device, and Poisson's equation cannot be used. Instead, for this one-dimensional geometry one has

$$\frac{d[\epsilon_s(x)\mathcal{E}(x)]}{dx} = \epsilon_s \frac{d\mathcal{E}(x)}{dx} + \mathcal{E}(x)\frac{d\epsilon_s(x)}{dx} = \rho(x), \tag{8.66}$$

and if no space charge is present, as in the present case,

$$\epsilon_s(x)\frac{d\mathcal{E}(x)}{dx} + \mathcal{E}(x)\frac{d\epsilon_s(x)}{dx} = 0. \tag{8.67}$$

For a detector with two different dielectric materials and no space charge in the device, the dielectric displacement is constant and is given by

$$D = \epsilon_1 \mathcal{E}_1 = \epsilon_2 \mathcal{E}_2.$$

However, the electric field across the device is *not* constant if the dielectric constants of both regions are not the same. The voltage across the region between 0 to x_1, a width of d_1, is

$$V_1 = (x_1 - 0)\mathcal{E}_1 = d_1 \mathcal{E}_1,$$

and across the region x_1 to x_2, of width d_2, is

$$V_2 = (x_2 - x_1)\mathcal{E}_2 = d_2 \mathcal{E}_2,$$

where the total voltage across the entire device is

$$V_T = V_1 + V_2 = d_1 \mathcal{E}_1 + d_2 \mathcal{E}_2 = D\left(\frac{d_1}{\epsilon_1} + \frac{d_2}{\epsilon_2}\right).$$

Here V_1 and V_2 are the voltage drops across region d_1 and d_2, respectively. The capacitance of this detector is

$$C = \frac{Q}{V_T} = \frac{Q}{D}\left(\frac{\epsilon_1 \epsilon_2}{d_1 \epsilon_2 + d_2 \epsilon_1}\right).$$

The voltage $V(x)$ increases in a piecewise linear manner from $V(0) = 0$ to $V(x_2) = V_T$, i.e., as

$$V(x) = \begin{cases} x\mathcal{E}_1 = \dfrac{xD}{\epsilon_1}, & \text{for } x \in [0, x_1] \\ (x - x_2)\mathcal{E}_2 + V_1 = (x - x_2)\dfrac{D}{\epsilon_2} + \dfrac{d_1 D}{\epsilon_1}, & \text{for } x \in [x_1, x_2] \end{cases}. \tag{8.68}$$

The weighting potential is thus $V_w(x) = V(x)/V_T$.

If a gamma ray is absorbed in this planar device and produces N_o ion-electron pairs, the induced charge after the ions and electrons have drifted and are separated by a distance Δx is

$$\Delta Q = \begin{cases} \dfrac{qN_oD}{V_T}\dfrac{\Delta x}{\epsilon_1} = \dfrac{qN_oV_1}{V_T}\dfrac{\Delta x}{d_1}, & 0 \le \Delta x \le x_1 \\ \dfrac{qN_oD}{V_T}\dfrac{\Delta x}{\epsilon_2} = \dfrac{qN_oV_2}{V_T}\dfrac{\Delta x}{d_2}, & x_1 \le \Delta x \le x_2 \end{cases}. \tag{8.69}$$

Notice that charge induction increases as the dielectric constant decreases. Hence, a point charge moving identical distances in both regions induces more charge when moving in the region of lower ϵ. One could conceivably create a device that concentrates most of the charge induction to a small region with a low dielectric constant, which is aligned with a larger volume with a high dielectric constant. In the present case, the weighting potential and the operating potential for the device are identical in shape. The weighting potential is scaled from 1 to 0, whereas the operating potential is scaled from the highest voltage V_{high} at one contact to the lowest voltage V_{low} at the opposite contact.

8.7 Charge Induction for a Cylindrical Detector

Often detectors are formed into cylindrical shapes, in which the active region is between an inner electrode of radius r_1 and an outer electrode of radius r_2. This geometry makes it possible to construct a volumetrically large device while maintaining a relatively low capacitance on the smaller inner electrode. To take advantage of the geometry and low capacitance, the signal is typically read from the smaller radius inner electrode.

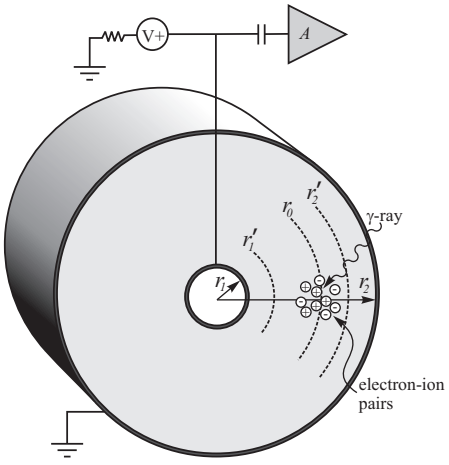

Figure 8.13. Depiction of a cylindrical radiation detector where a gamma ray is absorbed at radius r_0. The figure shows a preamplifier attached to the positively biased inner electrode at $r = r_1$.

The Laplacian operator for cylindrical geometry is

$$\nabla^2 V = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 V}{\partial \phi^2} + \frac{\partial^2 V}{\partial z^2} = 0. \tag{8.70}$$

If the detector is a long coaxial cylinder, then the change in potential with angle θ and length z is negligible, so that $V(r, \phi, z) \rightarrow V(r)$ and Eq. (8.70) reduces to

$$\nabla^2 V = \frac{1}{r}\frac{d}{dr}\left(r\frac{dV(r)}{dr}\right) = \frac{dV(r)}{dr} + r\frac{d^2V(r)}{dr^2} = 0. \tag{8.71}$$

Equation (8.71) can be rewritten as

$$\mathcal{E}(r) + r\frac{d\mathcal{E}(r)}{d} = 0 \qquad \text{or} \qquad \frac{d[\mathcal{E}(r)r]}{dr} = 0.$$

Because the derivative of $\mathcal{E}(r)r$ is zero, then the product must be a constant, i.e., $E(r)r = C_1$ or

$$\mathcal{E}(r) = \frac{C_1}{r}. \tag{8.72}$$

The potential is then found as

$$V(r) = \int \mathcal{E}(r)dr = \int \frac{C_1}{r}dr = C_1 \ln(r) + C_2. \tag{8.73}$$

From Fig. 8.13, the preamplifier readout is seen to be attached to the inner electrode, which has a positive bias V^+. To find the potential, the inner electrode potential $V(r_1)$ is set to V^+ volts and the voltage $V(r_2)$ on the outer electrode is set to zero. Use these boundary conditions to evaluate the constants C_1 and C_2. Substitution for C_1 and C_2 in Eq. (8.73) gives

$$V(r) = V^+ \ln\left(\frac{r}{r_2}\right)\left[\ln\left(\frac{r_1}{r_2}\right)\right]^{-1}. \tag{8.74}$$

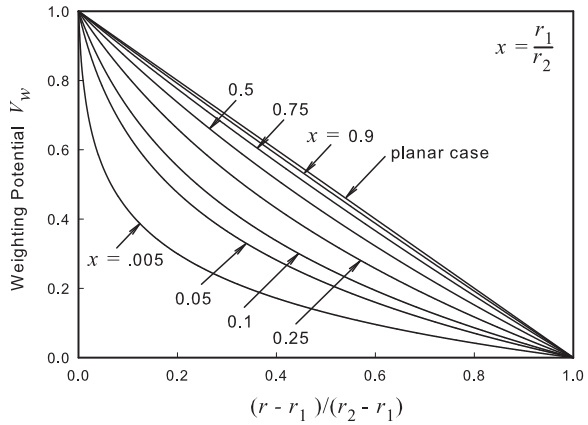

Figure 8.14. Weighting potentials for various values of r_1/r_2 versus the normalized distance from r_1 to r_2 for a cylindrical detector.

The corresponding electric field, from Eq. (8.72), is

$$\mathcal{E}(r) = \frac{V^+}{r}\left[\ln\left(\frac{r_1}{r_2}\right)\right]^{-1}. \tag{8.75}$$

The weighting potential is found by setting $V^+ = 1$ in Eq. (8.74), namely

$$V_w(r) = \ln\left(\frac{r}{r_2}\right)\left[\ln\left(\frac{r_1}{r_2}\right)\right]^{-1}. \tag{8.76}$$

The weighting potentials, as a function of the ratio r_1/r_2 for a cylindrical detector, are shown in Fig. 8.14. At small values of r_1/r_2, the weighting potential shows a strong increase near the small anode, r_1. This increase means that charges moving near the inner electrode create more induced charge than those free carriers moving near the large outer electrode. Also it is seen that the weighting potential approaches that of a planar detector as r_1/r_2 approaches unity.

The ΔQ induced by the motion of free carriers as they drift toward the electrodes can be found from Ramo's theorem. After time $t(r_1')$ the electrons have drifted from where they were created at r_0 to r_1' and after $t(r_2')$ the ions have drifted to a radial distance r_2'. From Ramo's theorem one has

$$\begin{aligned}\Delta Q &= \int_0^{t(r_2')} I(t)\,dt\Big|_{ions^+} + \int_0^{t(r_1')} I(t)\,dt\Big|_{e^-} \\ &= -qN_o \int_0^{t(r_2')} \boldsymbol{\nabla} V_w \bullet \frac{d\mathbf{r}}{dt}\,dt\Big|_{ions^+} - (-qN_o)\int_0^{t(r_1')} \boldsymbol{\nabla} V_w \bullet \frac{d\mathbf{r}}{dt}\,dt\Big|_{e^-}. \end{aligned} \tag{8.77}$$

In this geometry V is a function only of r so Eq. (8.77) is evaluated as follows.

$$\Delta Q = -qN_o \int_{r_0}^{r_2'} \frac{dV_w(r)}{dr}\,dr\Big|_{ions^+} - (-q)N_o \int_{r_0}^{r_1'} \frac{dV_w(r)}{dr}\,dr\Big|_{e^-} \tag{8.78}$$

Substitution of Eq. (8.76) for $V_w(r)$ gives

$$\begin{aligned}\Delta Q &= -qN_o \left[\ln\left(\frac{r_1}{r_2}\right)\right]^{-1} \left\{\int_{r_0}^{r_2'} \frac{d}{dr}\ln\left(\frac{r}{r_2}\right)dr - \int_{r_0}^{r_1'} \frac{d}{dr}\ln\left(\frac{r}{r_2}\right)dr\right\} \\ &= qN_o \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \left\{\ln\left(\frac{r_2'}{r_0}\right) - \ln\left(\frac{r_1'}{r_0}\right)\right\} \end{aligned} \tag{8.79}$$

which yields the final result,

$$\boxed{\Delta Q = qN_o \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \ln\left(\frac{r_2'}{r_1'}\right).} \tag{8.80}$$

This result shows that the induced charge is a function of only the total charge carrier displacement in r. If the electrons drift to the positive contact at r_1 and the positive ions drift to the negative contact at r_2, then $r_1' = r_1$ and $r_2' = r_2$, and the induced charge becomes $Q = qN_o$. It is important to note that the weighting potential for a cylinder is not linear, and depends strongly upon the values of r_1 and r_2, whereas the weighting potential for the planar device is linear with x.

8.8 Charge Induction for Spherical and Hemispherical Detectors

Another detector configuration that has been successfully demonstrated is the hemispherical device, in which a half sphere has the rounded outermost surface coated as the cathode contact and small spot at the center is the anode contact. Typically, the preamplifier, used to measure the induced charge signal, is connected to the small innermost contact. Fig. 8.15 shows a section of a spherical detector, which has the same characteristics as a hemispherical detector. Ramo's theorem is used to determine ΔQ induced by free charge carriers moving in the device.

But first the weighting potential must be found. In spherical coordinates, the Laplacian for the detector of Fig. 8.15 is

$$\nabla^2 V = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2} = 0. \tag{8.81}$$

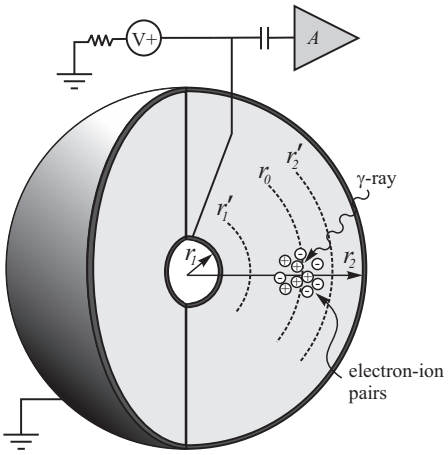

Figure 8.15. Depiction of a spherical radiation detector where a gamma ray is absorbed at radius r_0. The figure shows a preamplifier attached to the positively biased inner electrode at $r = r_1$.

Because of the spherical symmetry in the present geometry, the potential changes with r but not with ϕ or θ. Equation (8.81) then reduces to

$$\nabla^2 V = \frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dV(r)}{dr}\right) = 0, \tag{8.82}$$

which can be rewritten as

$$\frac{dV(r)}{dr} + \frac{r}{2}\frac{d^2V(r)}{dr^2} = \frac{d}{dr}\left(\frac{d[rV]}{dr}\right) = 0.$$

Integration over r twice gives

$$rV(r) = C_1 r + C_2, \tag{8.83}$$

where C_1 and C_2 are constants of integration to be found from the boundary conditions. As before, the weighting potential is found from Eq. (8.83) with boundary conditions of $V_w(r_1) = 1$ and $V_w(r_2) = 0$. The result is

$$V_w(r) = \left(\frac{r_1}{r_2 - r_1}\right)\left(\frac{r_2}{r} - 1\right). \tag{8.84}$$

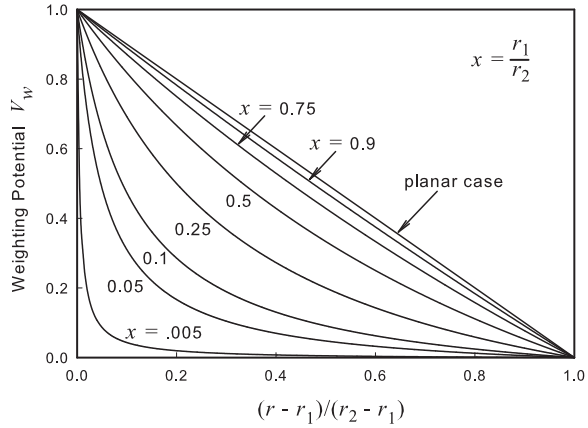

Figure 8.16. Weighting potentials for various values of r_1/r_2 versus the normalized distance from r_1 to r_2 for a spherical detector.

The weighting potentials are shown in Fig. 8.16 as a function of the ratio r_1/r_2 for a spherical (or hemispherical) detector. At small values of r_1/r_2, the weighting potential shows a strong increase near the small anode at r_1, which means that charges moving in the vicinity near the inner contact have more influence on the induced charge than those free carriers moving near the large electrode at r_2. As with the cylindrical detector, the weighting potential approaches that of the planar device as r_1/r_2 approaches unity. One should notice that the weighting potential for a spherical detector is much more skewed than for the cylindrical detector.

The induced charge is now found with Ramo's Theorem with the contributions of the electrons and ions being analyzed separately. Because $V_w(r)$ is a function of only r, as in the previous cylindrical geometry, Eq. (8.78) is applicable to the spherical geometry as well. Substitution of the weighting potential from Eq. (8.84) into Eq. (8.78) yields

$$\Delta Q = -qN_o\left(\frac{r_1}{r_2 - r_1}\right)\left\{\int_{r_0}^{r_2'}\frac{d}{dr}\left(\frac{r_2}{r}\right)dr - \int_{r_0}^{r_2'}\frac{d}{dr}\left(\frac{r_2}{r}\right)dr\right\}$$

$$= qN_o\left(\frac{r_1}{r_1 - r_2}\right)\left\{\left(\frac{r_2}{r_2'} - \frac{r_2}{r_0}\right) - \left(\frac{r_2}{r_1'} - \frac{r_2}{r_0}\right)\right\},$$

which, upon rearrangement, yields the final result,

$$\boxed{\Delta Q = qN_o \frac{r_1 r_2}{r_1' r_2'} \left[\frac{r_1' - r_2'}{r_1 - r_2}\right].} \tag{8.85}$$

8.9 Concluding Remarks

The topics discussed in this chapter constitute the fundamental physics governing radiation detectors whose signal formation is based on current induction. The reader is referred to the references for sources with more detailed discussions on electricity and magnetism. It should be noted there are circumstances, not covered in the present chapter, that can alter detector performance. For instance, current induction in gas-filled ion chambers may depend mainly upon the motion of electrons, and in other gas-filled detectors the current induction may depend mainly on positive ion motion. Semiconductor detectors, based on current induction, may have imperfections that cause an exponential decrease of the charge carrier density with time, thereby causing the current induction to be a function of time, charge carrier velocity, and interaction position. Such alterations in detector response are described in the chapters on gas-filled and semiconductor detectors. Further, unique detector electrode designs can be used to change the current induction contributions of electrons and positive ions as a function of position, as shown here for the cylindrical and spherical devices. In the absence of space charge, the weighting and operating potentials of two-terminal devices have essentially the same shape, the difference being the former is normalized and the latter is not. In the presence of space charge, the shapes of the weighting and operating potentials can be significantly different.

PROBLEMS

1. A charge of 2.5×10^{-8} C is placed in an upwardly directed electric field with magnitude 5×10^4 N C^{-1}. Determine the work performed for the following three cases: (a) the charge is moved 24 cm to the right, (b) the charge is moved 24 cm downward, and (c) the charge is moved 34 cm at a downward 45° angle.

2. A 5.5 MeV alpha particle has a direct head-on collision with a Au nucleus at rest. What is the minimum distance achieved between the two particles?

3. There are two point charges placed 1 cm apart, where

$$Q_1 = +q_e N_1 = q_e(10^4) \qquad \text{and} \qquad Q_2 = -q_e N_2 = -q_e(5 \times 10^3).$$

Determine: (a) the potential halfway between the two charges, (b) the potential at a point exactly 6 mm from Q_1 and 8 mm from Q_2, and (c) the work performed moving the charge from the location of B to the location of A.

4. Consider an evacuated parallel plate chamber with 1000 volts applied between the contacts spaced 3 cm apart. Simultaneously, an electron is released from the cathode and a He 2+ ion is released from the anode. (a) At what distance from the positive electrode do the particles pass each other? (b) What are the particle speeds when they arrive at their respective collection electrodes? (c) What are the particle energies when they arrive at their respective collection electrodes?

5. For a cylindrical capacitor with dielectric constant ϵ_s, inner conductor radius r_a and outer conductor radius r_b, (a) derive an expression for the capacitance per unit length. (b) Derive an expression for the total capacitance of a hemispherical capacitor.

6. Consider the diagram below (Fig. 8.17). An electron is released from electrode C and travels through electrode B to electrode A at constant speed. (a) Sketch the output pulse from the electron if measured from electrode A. (b) Sketch the output pulse from the electron if measured from electrode C. (c) Sketch the output pulse from the electron if measured from electrode B.

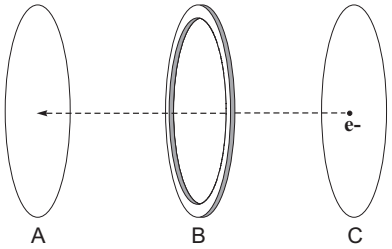

Figure 8.17. Diagram for problem 6.

7. You have a coaxial detector filled with 1 atm Ar and with inner electrode radius of 25 microns and outer electrode radius of 1.25 cm. A potential of 1000 volts is applied. A radiation interaction occurs at radius $r = 0.625$ cm, producing 50,000 electron-ion pairs. Sketch the pulse shape as a function of time for: (a) positive voltage applied to the inner electrode and (b) negative voltage applied to the inner electrode.

Chapter 9

Gas-Filled Detectors: Ion Chambers

Gases are distinguished from other forms of matter, not only by their power of indefinite expansion so as to fill any vessel, however large, and by the great effect heat has in dilating them, but by the uniformity and simplicity of the laws which regulate these changes.

James Clerk Maxwell

In 1908, Ernest Rutherford and Hans Geiger constructed the first gas-filled radiation detector from a metallic cylinder with a thin axially positioned wire inside [Rutherford and Geiger 1908]. The gas medium in this case was air. When a voltage was applied between the cylinder and wire, a current was measured with an electrometer when alpha particles entered the device. They also noticed that the behavior of the detector changed with increasing voltage, namely, that alpha particles could be detected at much lower applied voltages than beta particles. This ability to discriminate between the two radiations became known as *proportional* counting. Experiments conducted later with the gas-filled detectors clearly showed distinctive regions of operation, as shown in Fig. 9.1.

The physical principle behind a gas-filled detector is quite simple. Radiation interacts in either the chamber gas or the chamber walls, thereby liberating electrons from parent nuclei. These electrons (and ions in the gas) produce additional ionization in the detector gas, which creates a charge "cloud" composed of electrons and positive ions. A voltage placed across electrodes in the gas chamber causes the electrons and ions to drift apart in opposite directions, with electrons drifting towards the anode and the positive ions drifting towards the cathode. In some cases, electron attachment to a neutral atom produces negative ions. As these gas ions and electrons, or *charge carriers*, move through the chamber, they induce a current to flow in an external circuit connected to the chamber. This current, or change in current, can then be measured as an indication that a radiation interaction occurred in the chamber.

9.1 General Operation

Gas detectors can be operated in either a *pulse mode* or *current mode*. Pulse mode is generally used in low to moderate radiation fields. In this case, a single radiation particle, such as an alpha particle, beta particle, or gamma ray, interacts in the chamber volume, producing a charge cloud around the interaction site. The charge carriers then drift apart and induce current between the device terminals. A charging circuit, usually consisting of a preamplifier and feedback circuit, time-integrates the current and records a voltage pulse. This voltage pulse is treated as a *single* event, i.e, a single radiation particle has been detected. The preamplifier circuit is subsequently discharged and reset, so as to allow the device to detect the next radiation-interaction event. Hence, each voltage pulse from the detector indicates a radiation interaction event. Although extremely useful, there are drawbacks to pulse-mode operation. Should another radiation interaction occur while the detector is integrating or discharging the current from a previous interaction

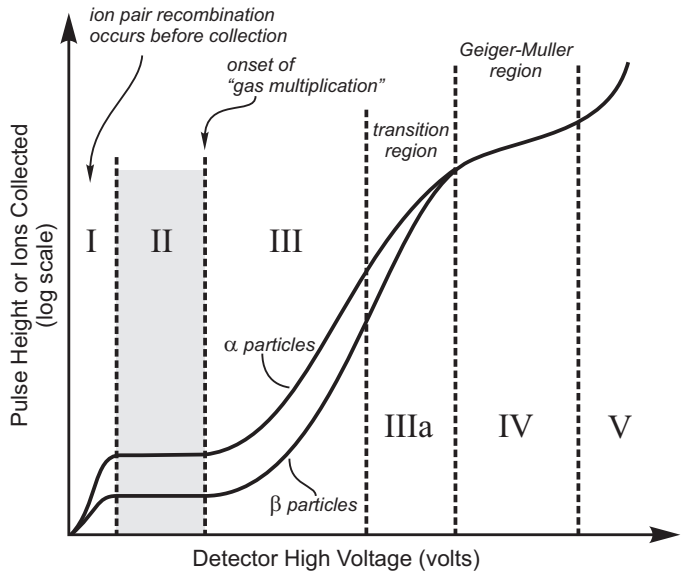

Figure 9.1. The observed output pulse height versus the applied high voltage for a gas-filled detector. Several different regions can be seen: (I) recombination, (II) ion chamber, (III) proportional, (IIIa) transition region, (IV) Geiger-Müller, and (V) continuous discharge.

event, the detector may not, and usually does not, record the new interaction, a condition referred to as *pulse pile up*. The time interval in which a new pulse is not recorded is the detector *recovery time*, also referred to as *dead time* (see Ch. 7). A pulse-mode detector operated in low radiation fields has little problem with dead time; however, a detector operated in high radiation fields may have significant dead time losses, thereby yielding an incorrect measurement of the radiation intensity.

For high radiation fields, gas detectors are commonly operated in current mode, in which the radiation induced current is measured with a current meter. Under such conditions, many interactions can occur in the device in very short periods of time, and the current observed increases with radiation exposure. Hence, current mode can be used to measure high radiation fields in which the magnitude of the current is a measure of the radiation induced ionization rate in the detector. The output current is then proportional to the intensity of the radiation field at the detector location. The drawback to pulse-mode operation is that it does not distinguish between individual radiation interactions.

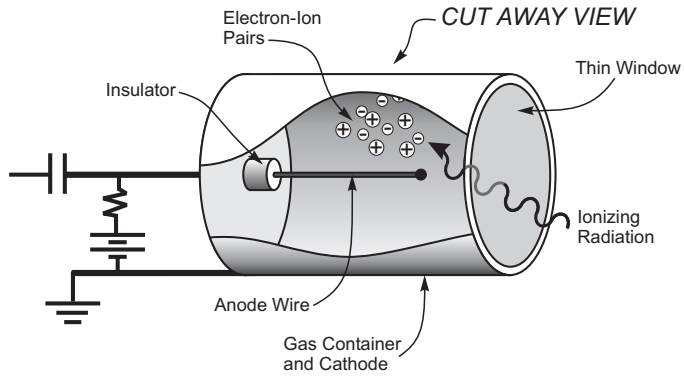

Figure 9.2. Shown is a coaxial gas detector, which is commonly used for Geiger-Müller tubes, and sometimes used for proportional counters. High voltage is applied to the central wire anode, while the outer cylinder wall, the cathode, is held at ground.

Consider a gas-filled detector as shown in Fig. 9.2, similar to the device first devised by Geiger and Rutherford, in which α-particles and β-particles enter through a thin window. These particles can interact in the gas (or tube wall) depositing some or all of their energy in the tube gas and, in the process, generate a miniature cloud of free electrons and positive ions, referred to as *electron-ion pairs*. As required for any radiation detector, there is an absorber (the fill gas), and an observable (the electron-ion pairs). To complete the detector, a method is needed to measure the amount of ionization. Suppose the detector is connected to a simple electrometer so as to measure the current produced by the motion of the electron-ion pairs. Without an applied voltage, the electron-ion pairs diffuse randomly *in all directions* and eventually recombine. As a result, the net current measured by the electrometer is zero. However, if a small positive voltage is applied to the central thin wire (anode) of the device, the free electrons (negative charges) drift towards the anode and the free ions (positive charges) drift towards the detector wall. At low voltages, some measurable current is observed, yet considerable recombination will still occur, the expected result within Region I, the *recombination region*, as

shown in Fig. 9.1. As the voltage is increased, electron-ion pair separation is more rapid until practically no recombination occurs. Hence, the current measured is a measure of the total number of electron-ion pairs formed. This is Region II, and is referred to as the *ionization chamber region*.

As the voltage is increased further, the electrons gain enough kinetic energy from the electric field to create more electron-ion pairs through impact ionization, thereby providing a mechanism for signal gain, often referred to as *gas multiplication*. As a result, the observed current increases as the voltage increases, but the amount of ionization is still proportional to the energy deposited in the gas by the original radiation particle. This is Region III, the *proportional region*. Still further increasing the applied voltage causes disproportional current increases to form, labeled in Fig. 9.1 as the transition region IIIa, beyond which, in Region IV, all currents, regardless of origin, radiation species or energies, have the same magnitude. Region IV is the *Geiger-Müller region*. Finally excessive voltage drives the detector into region V where the voltage causes sporadic arcing and other spontaneous electron emissions to occur, causing *continuous discharging* in the detector. Because of possible equipment damage and the loss of meaningful signals, gas detectors should not be operated in the continuous discharge region. In the following chapter, detector operation in Regions I and II is described.

9.2 Electrons and Ions in Gas

Radiation interactions in gas can cause excitation and ionization. Excitation is a process in which the energy transferred to a gas atom or molecule is less than the ionization energy. Hence, electrons are elevated to a higher energy level, but are still bound to the nucleus. Energy transferred to electrons greater than their ionization energy causes ionization, so that the electrons and positive ions become separate charge carriers. An electric field applied to the gas volume separates these charge carriers and, in the process, produces an induced current, as described in Chapter 8. The electrons, with a mass more than a thousand times less than that of the positive ions, also have quite different transport properties than heavy ions. Also, negative ions, formed from electron attachment to neutral atoms, have different transport characteristics than positive ions (although similar). Detector and gas properties that affect the charge transport for electrons and ions include mobility, electric field, ionization potential, charge transfer, electron attachment, and recombination. In the following chapter on gas-filled ion chambers, pertinent information on charge transport and ion behavior in gases is presented. Exhaustive studies dedicated to the complexities of electron and ion motion in gases have been published in far more detail than presented here. See, for example, [Loeb 1939, 1960; Huxley and Crompton 1974; Sitar et al. 1993].

9.2.1 Ionization

Directly ionizing radiation with energy above the minimum ionizing energy I_0 of a gas will produce electron-ion pairs (eip) along their trajectories. Due to competing energy loss mechanisms, such as atomic excitation and bremsstrahlung production, the average energy w required to produce an electron-ion pair is typically much greater than I_0. As the ionizing particle passes through the detector gas, it produces a continuous chain of electron-ion pairs. The *total* number of electron-ion pairs produced per unit distance of travel by the charged particle is

$$n_t \simeq \frac{dE}{dx}\frac{1}{w}. \tag{9.1}$$

Note that, although Eq. (9.1) may be used to estimate the density of ion pairs per unit path length, the stopping power dE/dx for heavy ions (alpha particles, for instance) is not constant. The values for n_t and dE/dx in Table 9.1 are listed for *minimum ionizing particles* (MIPs), i.e., beta particles with energies above

Table 9.1. Useful properties of various gases at 293 K and 760 torr. From [Sauli 1977].

Gas	Z	A	ρ_o (1 atm) g/cm^3	I_o eV	w eV/eip*	$(dE/dx)/\rho_o$ MeV g^{-1} cm^2	dE/dx keV/cm	n_p eip*/cm	n_t eip*/cm

* eip = electron-ion pair

1 MeV.[1] The total number N_T of electron-ion pairs produced by a beta particle can then be estimated with the measured data listed in Table 9.1 as

$$N_T \simeq \frac{\Delta E}{w}, \tag{9.2}$$

where ΔE is the energy deposited in the gas. The initial ionizing particle creates n_p *primary* electron-ion pairs per unit length as it passes through the detector gas and deposits ΔE of energy. If $\Delta E \gg I_0$, the energetic free electrons and positive ions can have sufficient kinetic energy to produce more electron-ion pairs through secondary ionization (delta rays). By summing contributions from primary and secondary ionization, the *total* density of electron-ion pairs per unit pathlength, n_t, can be found. Values of n_p and n_t for several common detector gases are listed in Table 9.1. For mixtures of different gases, a general rule often used to describe the total number of ion pairs created is

$$N_T \simeq \sum_{i=1}^{K} \frac{f_i \Delta E}{w_i}, \tag{9.3}$$

where f_i is the concentration fraction of each gas constituent. The total ionization, per unit path length of travel, for MIPs is

$$n_t \simeq \sum_{i=1}^{K} f_i n_t^i \frac{\rho}{\rho_\circ}, \tag{9.4}$$

where $\rho_\circ$ is the gas density at 1 atm, ρ is the gas density at the operating pressure, and n_t^i is n_t for gas species i. Similarly, the primary ionization per unit path length for MIPs is

$$n_p \simeq \sum_{i=1}^{K} f_i n_p^i \frac{\rho}{\rho_\circ}. \tag{9.5}$$

[1] From Fig. 4.20 the collisional stopping power for electrons is nearly constant for energies above about 1 MeV.

9.2.2 Diffusion Effects

Following the creation of the electron-ion pairs, the ions and electrons begin to diffuse to regions with lower charge densities according to Fick's law of diffusion. Also the initial high concentration of electrons and positive ions promotes recombination losses. Because the electron mass is much less than that of a positive ion, the electrons diffuse much faster than the positive ions. This phenomenon has a significant effect on detector operation and performance.

Diffusion of Electrons in a Gas

After the initial ionization event, the electrons and ions rapidly come into thermal equilibrium with the gas and assume a Maxwellian distribution of speeds ω_e and ω_{ion}. The number density for the electron thermal speed ω_e distribution in a charge cloud is given by

$$n_e(\omega_e) = 4\pi \left(\frac{m_e}{2\pi kT}\right)^{3/2} \omega_e^2 \exp\left(-\frac{m_e \omega_e^2}{2kT}\right), \tag{9.6}$$

where m_e is the electron mass. The average electron thermal speed $\overline{\omega}_e$ is

$$\overline{\omega}_e = \int_0^\infty \omega_e n(\omega_e)\, d\omega_e \Big/ \int_0^\infty n(\omega_e)\, d\omega_e = \sqrt{\frac{8kT}{m_e \pi}}. \tag{9.7}$$

In terms of energy, the number density for the electron energy distribution in a charge cloud is

$$n_e(E) = 2\pi \left(\frac{1}{\pi kT}\right)^{3/2} \sqrt{E} \exp\left(-\frac{E}{kT}\right), \tag{9.8}$$

and the average electron energy is[2]

$$\overline{E}_e = \int_0^\infty E\, n(E)\, dE \Big/ \int_0^\infty n(E) dE = \frac{3kT}{2}. \tag{9.9}$$

The diffusion rate of the electrons and ions, to a first approximation, can be evaluated with Fick's law, namely,

$$\frac{dn_e(r,t)}{dt} = D_e \nabla^2 n_e(r,t), \quad \text{for electrons,} \tag{9.10}$$

$$\frac{dn_{ion}(r,t)}{dt} = D_{ion} \nabla^2 n_{ion}(r,t), \quad \text{for ions.} \tag{9.11}$$

Here D_e and D_{ion} are the diffusion coefficients for electrons and ions with units of cm^2/s, and $n_e(r,t)$ and $n_{ion}(r,t)$ are the charge carrier concentrations. Also, r is the distance from the center of the initial charge cloud whose size is negligible compared to volume of the gas tube. Thus, all charges are assumed to begin to diffuse radially outwards from $r = 0$. In this spherically symmetric coordinate system Eq. (9.10) can be written as

$$\frac{\partial n_e(r,t)}{\partial t} = D_e \frac{1}{r^2} \frac{\partial}{\partial r}\left(r^2 \frac{\partial n_e(r,t)}{\partial r}\right) = D_e \left(\frac{2}{r}\frac{\partial n_e(r,t)}{\partial r} + \frac{\partial^2 n_e(r,t)}{\partial r^2}\right). \tag{9.12}$$

The solution for $n_e(r,t)$ in three dimensions in an infinite gas medium is

$$n_e(r,t) = \frac{n_0}{(4\pi D_e t)^{3/2}} \exp\left(\frac{-r^2}{4D_e t}\right), \tag{9.13}$$

[2] Note that $\frac{1}{2} m_e \overline{\omega}_e^2 \neq \overline{E}_e$.

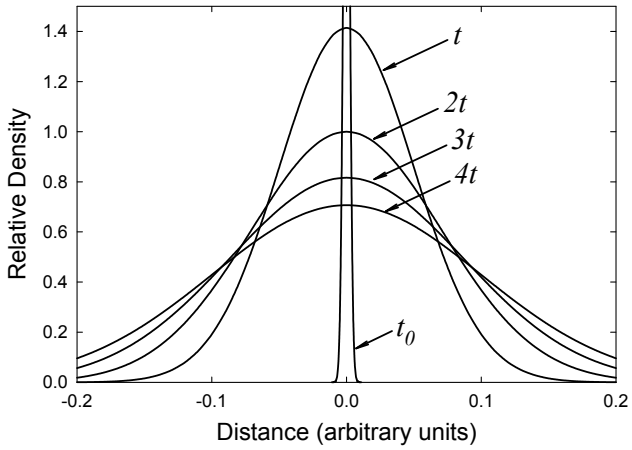

Figure 9.3. Diffusion of an electron cloud based upon Eq. (9.15).

where n_0 is the initial number of electrons. The mean distance squared $\overline{r^2}$ is

$$\overline{r^2} = \int_0^\infty n_e(r,t)\, r^2\, dV \Big/ \int_0^\infty n_e\, dV = 6D_e t. \tag{9.14}$$

Often a simpler one-dimensional diffusion model is used in which electrons diffuse away from a plane of electrons created at $t = 0$ containing n_0 electrons cm^{-2}. Then in Eq. (9.10) $\nabla^2 \rightarrow d^2/dx^2$ where x is the perpendicular distance from the plane source. The solution in an infinite homogeneous gas medium is

$$n_e(x,t) = \frac{n_0}{\sqrt{4\pi D_e t}} \exp\left(\frac{-x^2}{4D_e t}\right), \tag{9.15}$$

which is recognized as a normal (Gaussian) distribution function with mean $x = 0$ and variance $2D_e t$. The diffusion of electrons as a function of time in a gas, according to Eq. (9.15), is illustrated in Fig. 9.3.

The Diffusion Coefficient $\mathbf{D_e}$

The momentum-transfer cross section for electrons is defined as [Buckman and Elford 2000]

$$\sigma_m(E) = 2\pi \int_0^\pi \frac{d\sigma}{d\Omega}\left(1 - \frac{v}{v_0}\cos\theta\right)\sin\theta\ d\theta, \tag{9.16}$$

where $d\sigma/d\Omega$ is the differential scattering cross section, v_0 is the initial electron speed, and v is the electron speed after scattering. The momentum-transfer cross sections for several gases used in radiation detectors are shown in Fig. 9.4. There is a notable decrease in the cross section for Ar, Kr, and Xe gases between the energies of 0.1 eV to 1 eV, known as the Ramsauer-Townsend effect, a consequence of the quantum mechanical wave nature of low-energy electrons and their resonant transmission through the potentials of select gases. The differential scattering cross section is defined as the fraction of electrons of energy E that scatter at angle θ into differential solid angle $d\Omega$, where $d\Omega = 2\pi \sin\theta d\theta$. The electron diffusion coefficient is given by [Rice-Evans 1974]

$$D_e = \frac{\overline{\omega}_e}{3n_a\sigma_m}, \tag{9.17}$$

where n_a is the molecular density at temperature T (absolute) and pressure P (torr) and is found from

$$n_a = n_L \frac{P}{P_0}\frac{T_0}{T}. \tag{9.18}$$

Here n_L is the Loschmidt constant,[3] defined as

$$n_L = \frac{P_0}{kT_0} = \frac{P_0 N_A}{RT_0}, \tag{9.19}$$

[3]The Loschmidt constant is the atomic or molecular density for an ideal gas, quoted as 2.6867774×10^{19} cm^{-3} at 0°C at 760 torr.

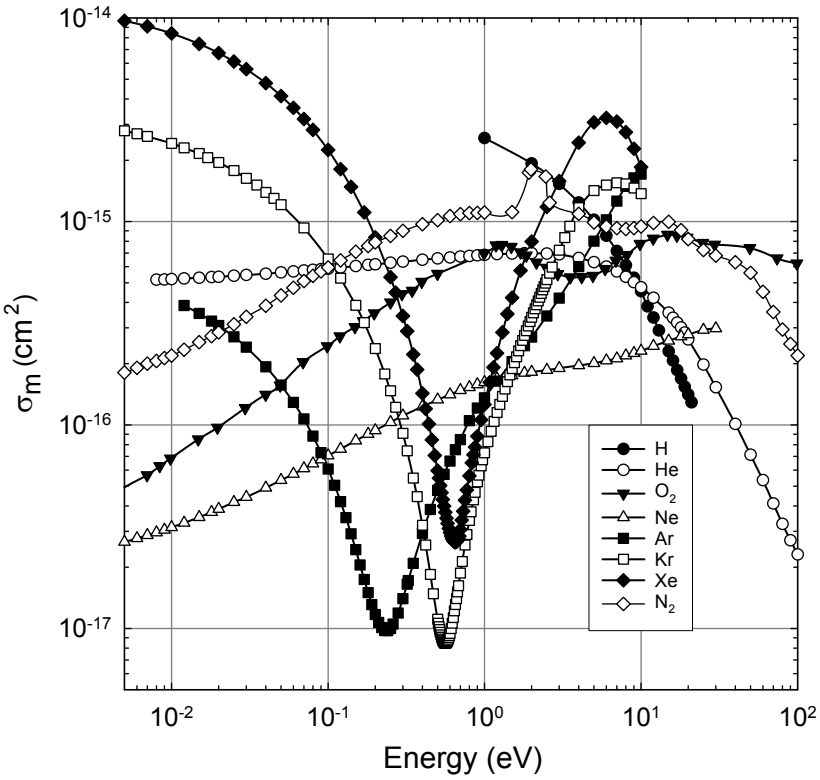

Figure 9.4. The measured momentum transfer cross section of electrons in various gases. From [Phelps 1985; Buckman and Elford 2000; Itikawa 2006].

where $P_0 = 760$ torr, $T_0 = 273$K, N_A is Avogadro's number, R is the gas constant,[4] and k is Boltzmann's constant. The frequency between collisions is [Sitar et al. 1993]

$$\nu_e = n_a \overline{\omega}_e \sigma_e = \tau_e^{-1}, \tag{9.20}$$

where σ_e is the elastic scattering cross section for electrons, $\overline{\omega}_e$ is the average electron thermal speed and τ_e is the average collision time. Note that $\sigma_e = \sigma_m$ for isotropic scattering; hence, the mean free path between collisions is

$$\lambda_e = \frac{1}{n_a \sigma_m} = \frac{kT}{P\sigma_m}. \tag{9.21}$$

Substitution of Eq. (9.7) and Eq. (9.21) into Eq. (9.17), the diffusion coefficient for the average electron energy is

$$D_e = \frac{\overline{\omega}_e \lambda_e}{3} = \frac{(2kT)^{3/2}}{\sqrt{m_e \pi}} \frac{1}{3P\sigma_m}. \tag{9.22}$$

The diffusion of electrons in a gaseous medium is largely governed by the concentration gradient and the diffusion coefficient. However, Coulombic attraction and repulsion between ions and electrons can alter the motion of electrons in the gas from the ideal diffusion model for neutral particles.

[4] $R = 8.3144621 \frac{\text{J}}{\text{mol K}}$.

Different mixtures and concentrations of gases can be used to alter the diffusion properties. For instance, adding gases that have low σ_m values increases D_e and, consequently, increases the electron diffusion. Likewise, diffusion can be hindered by adding gases that have large σ_m values. An estimate of the diffusion coefficient can be found with [Sitar et al. 1993] as

$$D_e = \left[\sum_{i=1} \frac{P_i}{D_i}\right]^{-1}, \tag{9.23}$$

where P_i is the relative partial pressure of each gas and D_i is the diffusion coefficient of each gas.

Diffusion of Ions in a Gas

The equations developed for electron diffusion in a gas hold true for ion diffusion. Hence, the one-dimensional solution of Eq. (9.15) gives

$$n_{ion}(x,t) = \frac{n_0}{\sqrt{4\pi D_{ion} t}} \exp\left(\frac{-x^2}{4D_{ion}t}\right), \tag{9.24}$$

where the mean squared distance $\overline{r^2} = 2D_{ion}t$, which is also the variance of the normal distribution of Eq. (9.24). The diffusion coefficient is

$$D_{ion} = \frac{\overline{\omega}_{ion}\lambda_{ion}}{3} = \frac{(2kT)^{3/2}}{\sqrt{m_{ion}\pi}} \frac{1}{3P\sigma_{ion}}, \tag{9.25}$$

where λ_{ion}, $\overline{\omega}_{ion}$, and m_{ion} are the ion counterparts of λ_e, $\overline{\omega}_e$ and m_e, respectively. Note that the diffusion coefficient is inversely proportional to the square root of the ion mass. For this reason the diffusion coefficients for ions are significantly smaller than that for electrons, as can be seen from Table 9.2. Consequently, the diffusion speed of ions can be over 1000 times less than that of electrons.

9.2.3 Electron and Ion Transport

As explained in Chapter 8, it is the motion of charges in some preferred direction that induces current flow in an electronically operated detector. However, if both negative and positive charges are moving equally in all directions, as occurs in the diffusion of both electrons and ions, then the net induction current must be zero. Although there is no induced current, the diffusion process still causes the electrons and ions to separate because the ions diffuse much more slowly than do the electrons.

But with the application of an electric field to the chamber, the electrons and ions further separate and begin to drift in opposite directions. This motion in a preferred direction then induces a current, whose measurement indicates that an ionizing event has occurred in the detector.

Influence of an Electric Field

The average kinetic energy of thermal electrons in a gas at 20°C is given by the Boltzmann distribution

$$\overline{E}_e = \frac{3kT}{2} = 0.038\text{eV}. \tag{9.26}$$

This average energy corresponds to a speed of $\omega_e = 4.2 \times 10^7$ cm/s. Yet, these randomly oriented trajectories produce no induced current in the detector.

The application of an electric field $\mathcal{E}$ exerts a force on the diffusing electrons and ions causing the electrons to drift preferentially towards the anode and the ions to drift preferentially towards the cathode. However, the drift speeds are typically very much less than the thermal motion speeds. For electrons the drift speeds

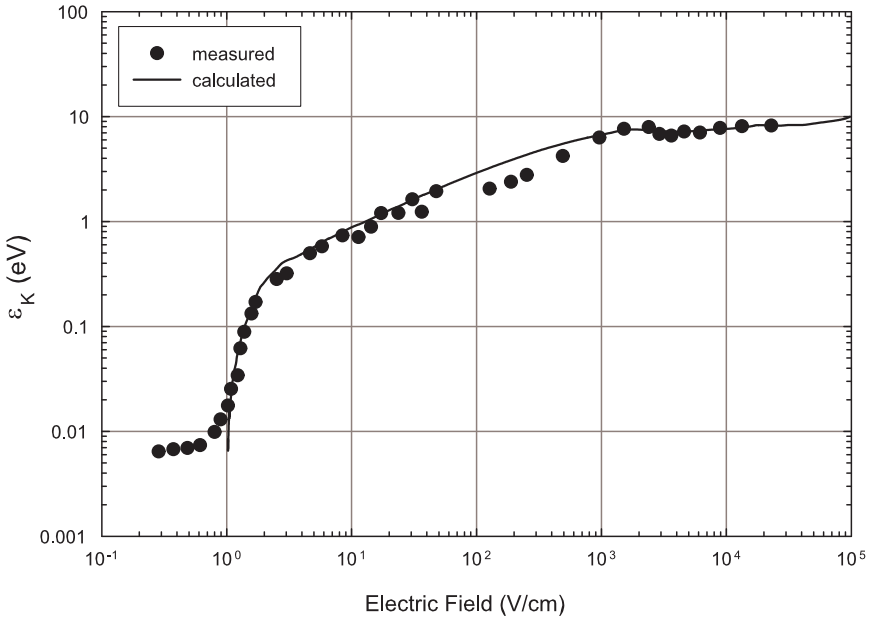

Figure 9.5. The characteristic energy as a function of electric field for Ar gas at 1 ATM. After [Palladino and Sadoulet 1975].

are on the order of 10^5 to 10^6 cm/s. The average electron drift speed v_e of the electrons in the direction of the applied electric field is approximated by Palladino and Sadoulet [1975] as

$$v_e = \frac{q_e \mathcal{E}}{m_e} \frac{\lambda_e}{\overline{\omega}_e}, \tag{9.27}$$

where q_e is the unit electronic charge. A measurable quantity, referred to as the *electronic characteristic energy*, ϵ_K, is a function of the diffusion coefficient and the electric field, namely, [Rice-Evans 1974]

$$\epsilon_K = \frac{q_e D_e \mathcal{E}}{v_e} = \frac{q_e D_e}{\mu_e}. \tag{9.28}$$

and D_e is given by Eq. (9.22). The electronic characteristic energy is the effective kinetic energy of the free electron in an electric field. It is much greater than that for electrons undergoing only thermal diffusion. Measured and calculated values of ϵ_K for pure Ar are shown in Fig. 9.5. Theoretical and measured values of ϵ_K as a function of reduced electric field $(\mathcal{E}/P)$ for many gases can be found in the literature [Christophorou 1971; Schultz and Gresser 1978; Peisert and Sauli 1984]. The quantity

$$\mu_e = \frac{q_e \lambda_e}{m_e \overline{\omega}_e}, \tag{9.29}$$

is commonly referred to as the electron *charge carrier mobility*.[5]

[5]Loeb [1960] reviews alternative, but similar, expressions for electron mobility.

From Eq. (9.27) and Eq. (9.29), the drift speed in the presence of an electric field is thus given by the simple relation

$$v_e = \mu_e \mathcal{E}, \tag{9.30}$$

in which the charge carrier mobility is a function of gas pressure, namely,

$$\mu_e = \frac{P_0\ \mu_0}{P}, \tag{9.31}$$

where μ_0 is the mobility in units of $\text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$ at 1 atm (760 torr) pressure, $P_0 = 760$ torr, $\mathcal{E}$ is the electric field, and P is the gas pressure in torr.

The mobility is related to the diffusion coefficient by[6]

$$\frac{D_e}{\mu_e} = \frac{kT}{q_e} \tag{9.32}$$

where D_e is the electron diffusion coefficient, q_e is the unit charge of an electron, k is Boltzmann's constant and T is the absolute temperature. Equation (9.30) is valid up to a saturation electric field $\mathcal{E}_{sat}$, beyond which charged particle scattering becomes the determining factor for the drift speed. At low fields, the electron drift speed is linear with respect to the applied field; however, this region of linearity is usually below a reduced electric field value of 0.3 $\text{V cm}^{-1}\ \text{torr}^{-1}$ for many important detector gases. As electrons gain energy under higher electric fields, their small mass allows high speeds to be reached with moderately low voltages. Electron collisions with other electrons in the gas can cause more ionization, referred to as *impact ionization*, which increases the number of electron-ion pairs in the gas, but such collisions reduce the mean free path of the electrons. As a result, electrons reach a saturation speed v_{sat} at electric fields approaching $\mathcal{E}_{sat}$.

Consider the ratio ξ between the characteristic energy (for any value D_e and associated μ_e) and the average thermal energy, namely

$$\xi = \frac{\epsilon_K}{\overline{E}_e} = \frac{2q_e D_e}{3\mu_e kT}. \tag{9.33}$$

Substitution of Eq. (9.32) into Eq. (9.33) and rearrangement gives

$$\frac{D_e}{\mu_e} = \xi \frac{3kT}{2q_e}. \tag{9.34}$$

The electron drift speed, for the same reduced electric field, varies among detector gases and gas mixtures. In argon, a common detector gas, electrons reach a fairly constant saturation speed of approximately 0.37 cm μs^{-1} at a reduced electric field of 0.2 $\text{V cm}^{-1}\ \text{torr}^{-1}$, as can be seen from Fig. 9.6. However, the small addition of 0.2% nitrogen increases the saturation speed above 1.0 cm μs^{-1} (at 0.6 $\text{V cm}^{-1}\ \text{torr}^{-1}$). From the data shown in Fig. 9.6, the mean drift speed for electrons in pure argon gas can be approximated by

$$v_e = \frac{3.64(\mathcal{E}/P) + 114.6(\mathcal{E}/P)^2}{1 + 12.7(\mathcal{E}/P) + 304.33(\mathcal{E}/P)^2}\ \text{cm}/\mu\text{s}, \tag{9.35}$$

[6] Eq. (9.32) is commonly called the Einstein relation because it appeared in his 1905 paper in *Annalen der Physik*. On rare occasion, Eq. (9.32) has been called the Einstein-Smoluchowski relation because it was published later by Smoluchowski [1906] (also in *Annalen der Physik* with reference to Einstein's 1905 paper). However, as pointed out by Huxley [1974], Nernst [1888] published the relation for electrolytic ions in 1888. Townsend [1900] applied a form of Eq. (9.32) to gases and published it in 1900 in *Philosophical Transactions A*, although in a considerably less recognizable form. Regardless, it has been suggested by Huxley [1974] that the proper name for Eq. (9.32) should be the Nernst-Townsend relation due to their prior publications.

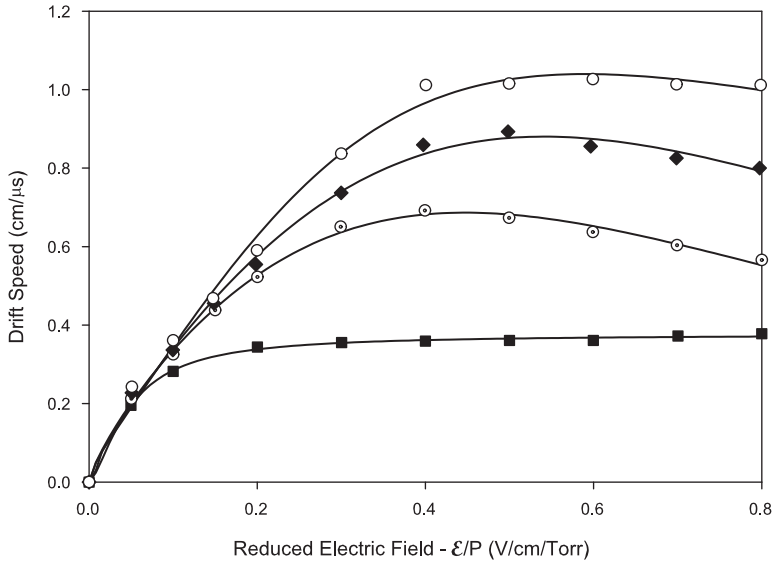

Figure 9.6. The measured drift speed of electrons in argon/nitrogen mixtures as a function of reduced electric field ($\mathcal{E}/\mathcal{P}$) and nitrogen concentration; ■ pure argon; ⊙ 0.05% N_2 ; ♦ 0.1% N_2; ○ 0.2% N_2. After [Bortner et al. 1957].

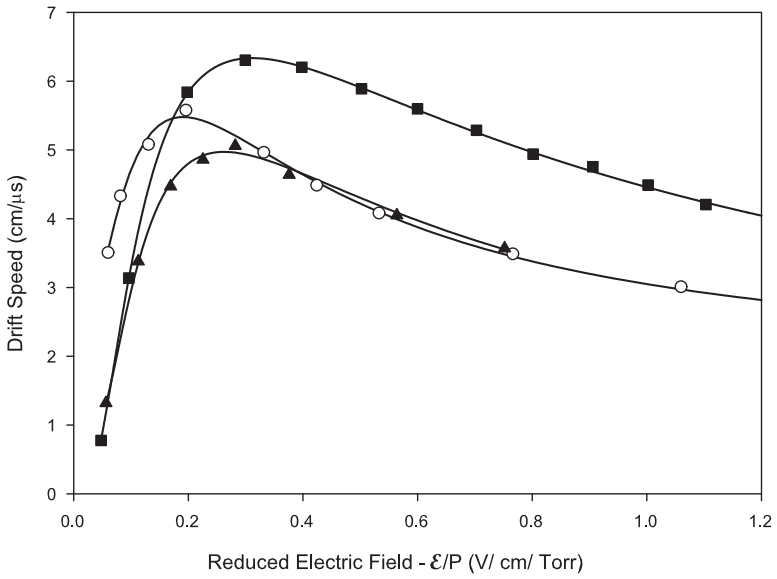

Figure 9.7. The measured drift speed of electrons in P-10 gas (90% argon, 10% methane) as a function of reduced electric field (E/P). Data from ■ [Bortner et al. 1957]; ○ [Mattern 1988]; ▲ [Ferreira et al. 2005]. Discrepancies between measured values may be due to impurity contamination in the gas samples.

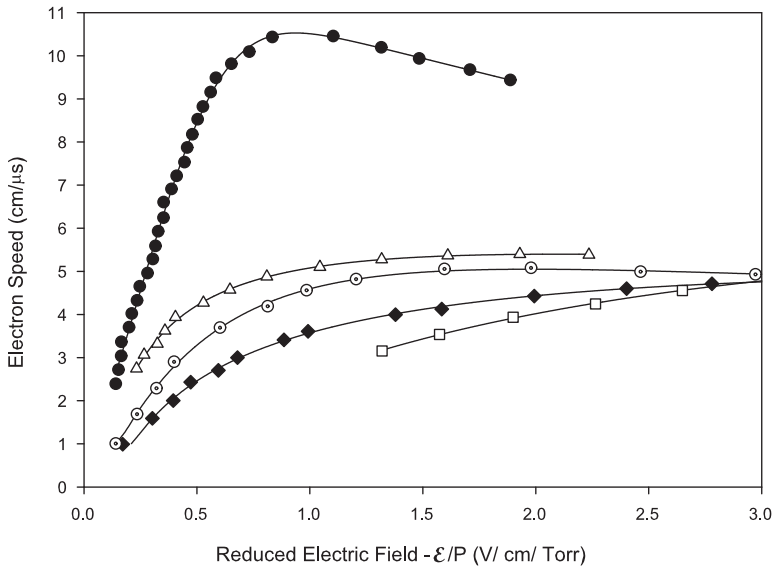

Figure 9.8. The measured drift speed of electrons in various organic polyatomic gases as a function of reduced electric field (E/P); • CH_4; △ C_2H_6 ; ⊙ C_2H_4; ♦ C_3H_8; and □ C_2H_2. After [Cottrell and Walker 1965].

where $\mathcal{E}/P \leq 0.8$ V cm^{-1} torr^{-1}.

Another common detector gas is a mixture of 90% Ar and 10% CH_4, generally referred to as *P-10* gas. Electrons reach a maximum speed at reduced electric fields between 0.2 and 0.3 V cm^{-1} torr^{-1}, beyond which electron scattering causes the speed to drastically decrease as can be seen in Fig. 9.7. With the data of Fig. 9.7, the mean drift speed for electrons in P-10 gas can be approximated by

$$v_e = \frac{6.852\sqrt{\mathcal{E}/P} + 4.626(\mathcal{E}/P)}{1 - 3.306\sqrt{\mathcal{E}/P} + 6.059(\mathcal{E}/P)} \text{ cm}/\mu\text{s}, \tag{9.36}$$

where $\mathcal{E}/P \leq 1.4$ V cm^{-1} torr^{-1}.

Drift speeds of many other organic gases used in gas-filled detectors are shown in Fig. 9.8. Note that CH_4 has a similar electron drift speed characteristic as P-10 gas, with a maximum of approximately 10.5 cm μs^{-1}, whereas the other organic gases shown in Fig. 9.8 do not show this trend, but instead gradually approach a saturation speed.

The drift speed of ions, having much smaller mobilities than electrons because of their much larger masses, typically follow Eq. (9.30) for electric fields commonly used in ion chambers (or other gas-filled detectors). Measured ion mobilities (μ_0) for several gases, as reported by different sources, are listed in Table 9.2.

The motion of charge carriers within an electric field is influenced by the combined effects of diffusion

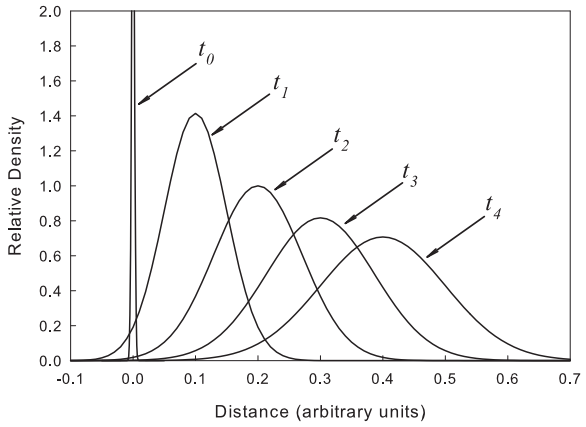

Figure 9.9. Diffusion and drift of an electron cloud based upon Eq. (9.37).

Table 9.2. Transport properties of various ions in the same gas at 1 atm. Data are from [Loeb 1929; Rossi and Staub 1949; Staub 1953; Sharpe, 1964; Huxley 1974; and Sauli 1977].

Gas	λ_{ion} cm	$\overline{\omega}_{ion}$ cm s^{-1}	D^+_{ion} cm^2 s^{-1}	μ^+_{ion} cm^2 V^{-1} s^{-1}	D^-_{ion} cm^2 s^{-1}	μ^-_{ion} cm^2 V^{-1} s^{-1}

and drift. The distribution of electrons or ions as a function of electric field and time is

$$n_i(x,t,\mathcal{E}) = \frac{n_0}{(4\pi D_i t)^{1/2}} \exp\left(\frac{-(x-\mu_i \mathcal{E} t)^2}{4D_i t}\right), \tag{9.37}$$

where the subscript i refers to electrons or ions, $\overline{v}_i = \mu_i \mathcal{E} \leq v_{sat}$. The diffusion and drift of electrons in a gas as a function of time, according to Eq. (9.37), is illustrated in Fig. 9.9.

9.2.4 Charge Transfer

Heavy positive ions colliding with neutral molecules (or atoms) can exchange charge, i.e., a singly charged positive gas ion accepts an electron from a neutral gas component, thereby becoming neutralized while ionizing the previously neutral molecule. For ions moving in the same host gas, for instance Ar^+ moving through Ar, an electron can be transferred from a neutral gas atom to a positively charged gas ion, referred to as symmetric resonance charge transfer [Sitar et al. 1993],

$$X^+ + X \rightarrow X + X^+, \tag{9.38}$$

with a cross section on the order of 10^{-15} to 10^{-14} cm^2. This form of charge transfer effectively reduces the mobility of positive ions in the same neutral gas, quoted as being on the order of 7.5% reduction in mobility from that of the neutral gas atom [Wilkinson 1950].

In many cases, a second gas is purposely introduced in with the main detector gas to alter the ion transport characteristics. The ability for a positive ion to pick up an electron in a collision is strongly dependent upon the separate ionization potentials. If the ionization potential of the host gas is higher than that of the added neutral gas atoms or molecules, then charge transfer from host gas ions colliding with neutral gas molecules (atoms) of the second component is possible, whereas the reverse electron exchange is not. This type of charge transfer is referred to as asymmetric non-resonance charge transfer [Sitar et al. 1993] and is written as

$$X^+ + Y \rightarrow X + Y^+ + \Delta\epsilon, \tag{9.39}$$

where $\Delta\epsilon$ is the difference in ionization energies ($I_{0X} - I_{0Y}$), and has a charge transfer cross section of about 10^{-15} cm^2. For instance, the introduction of CH_4 ($I_0 = 13.1$ eV) into Ar ($I_0 = 15.8$ eV) permits charge

transfer to occur between Ar^+ and CH_4, but not the reverse exchange. Hence,

$$Ar^+ + CH_4 \rightarrow Ar + CH_4^+ + 2.7 \text{ eV}. \tag{9.40}$$

In the next chapter on proportional counters, this reaction is seen to be a very important charge transfer reaction. If the detector gas is a mixture of both Ar and CH_4, ionizing radiation creates a cloud of both Ar^+ and CH_4^+ ions. However, within a short period of time, ion exchange causes virtually all Ar atoms to become neutralized, having transferred their charge to the CH_4 molecules.

9.2.5 Electron Attachment

After the initial charge cloud has been formed, the electric field separates the positive ions and electrons. Electrons, having significantly higher mobility than ions, rapidly drift towards the detector anode, while the positive ions slowly drift towards the cathode. There is a possibility of the formation of negative heavy ions in the chamber, a process in which electrons become attached to a neutral gas atoms or molecules. The consequence of such electron attachment is the formation of slow moving negative ions, thereby altering the speed and shape of the signal formation.

The mechanisms of electron attachment, described by Bloch and Bradbury [1935] and Herzenberg [1969], and summarized by Huk et al. [1988], constitute a basic two-step process. Electrons come into contact with an electro-negative molecule to form an excited negative ion

$$Y + e^- \rightarrow Y^{-*}, \tag{9.41}$$

where Y represents the electro-negative gas molecule. The excited electro-negative molecule may then deexcite through re-emission of the electron

$$Y^{-*} \rightarrow Y + e^-, \tag{9.42}$$

or become stabilized by emission of photon

$$Y^{-*} \rightarrow Y^- + \gamma. \tag{9.43}$$

If the excited gas molecule releases the electron, the effect of electron attachment is basically nullified. However, if the gas molecule becomes stabilized, then the electron charge carrier is converted into a slow moving negative ion, with a decreased mobility by three or more orders of magnitude. Often, these parasitic gases are contaminants in the host detection gas X. The negative ion in the excited state may instead collide with the host detection gas such that

$$Y^{-*} + X \rightarrow Y + X + e^-, \tag{9.44}$$

or become stabilized by,

$$Y^{-*} + X \rightarrow Y^- + X^*. \tag{9.45}$$

The average probability of forming negative ions is a function of the electron *attachment coefficient* C_a [Compton and Langmuir 1930], which is the average probability that a single collision causes an electron to attach to an atom or molecule and can be expressed as

$$C_a = \lambda_e f_V N \overline{\sigma}_{at}. \tag{9.46}$$

Here N is the atomic density of the gas for the species being considered, f_V is the volume fraction of that gas in the chamber gas, and $\overline{\sigma}_{at}$ is the average electron capture cross section. Unfortunately, there appears

Table 9.3. Electron attachment coefficients C_a in various gases. From [Korff 1946; Loeb 1929]. Gases that have practically zero values for C_a include He, Ne, Ar, Kr, Xe, H_2, N_2 and CH_4 [Loeb 1929, 1939].

Gas	C_a	Gas	C_a	Gas	C_a
Air	5.0×10^{-6}	C_2H_6	4.0×10^{-7}	H_2O	2.5×10^{-5}
BF_3	1.24×10^{-8}	CO	6.25×10^{-9}	N_2O	1.64×10^{-6}
C_2H_2	1.28×10^{-7}	CO_2	6.2×10^{-9}	NH_3	1.01×10^{-8}
C_2H_4	2.13×10^{-8}	Cl_2	$> 5.0 \times 10^{-4}$	O_2	2.5×10^{-5}

Table 9.4. Electron attachment rate coefficients α_I for O_2 in various Ar/CH_4 gas mixtures as measured by Huk et al. [1988]. The samples had 200 ppm O_2 added and the measurements were conducted at a pressure of 4 bar.

Ar/CH_4 – 90%/10%			Ar/CH_4 – 80%/20%		
$\mathcal{E}/\mathcal{P}$ V cm^{-1} bar^{-1}	v_e cm/μs	α_I μs^{-1}	$\mathcal{E}/\mathcal{P}$ V cm^{-1} bar^{-1}	v_e cm/μs	α_I μs^{-1}
100	5.36	0.048 ± 0.003	100	5.54	0.103 ± 0.006
138	5.45	0.034 ± 0.003	138	6.61	0.098 ± 0.007
163	5.32	0.029 ± 0.003	163	6.91	0.089 ± 0.007
200	5.07	0.024 ± 0.003	200	7.08	0.074 ± 0.007
250	4.70	0.019 ± 0.003	250	7.10	0.069 ± 0.007

to be some discrepancy regarding this simple definition, because the designation of "attachment coefficient" has been assigned to various dimensioned numbers in the literature [Huk et al. 1988; Sitar et al. 1993]. In the present work, the *interaction coefficient* ψ_I is defined as a function of the attachment coefficient, such that [Sitar et al. 1993]

$$\psi_I \equiv \frac{f_V N \overline{\sigma}_{at} \overline{\omega}_e}{v_e} = \frac{C_a \overline{\omega}_e}{\lambda_e v_e} = \frac{f_V N C_a \overline{\omega}_e \sigma_m}{v_e}, \tag{9.47}$$

in which the last result is obtained from Eq. (9.21).

The *attachment rate coefficient* is defined as the rate at which electrons are attached to gas molecules (atoms), per unit time, and is a function of gas pressure and electric field. It is defined as

$$\alpha_I = \psi_I v_e = \frac{C_a \overline{\omega}_e}{\lambda_e}. \tag{9.48}$$

In Table 9.3 values of the attachment coefficient are given, and in Table 9.4 attachment rate coefficients for Ar/CH_4 are listed for several reduced potentials.

Consider a cloud of electron-ion pairs produced with density N_p at some location x from the anode within a planar gas chamber of width d. Under bias, the electrons drift towards the anode and the positive ions towards the cathode. To be collected, the electrons must drift a distance x over the time $t = x/v_e$ and the positive ions must drift a distance $d - x$ over the time $(d - x)/v_{ion}$. As the electrons drift, they are lost to electron attachment described by

$$N_e(x) = N_p e^{-\psi_I x}, \tag{9.49}$$

or, equivalently,

$$N_e(t) = N_p e^{-\alpha_I t}. \tag{9.50}$$

Common detector gases, such as Ar and CH_4, have relatively low values for C_a, and Staub [1953] states that Ar, CO_2, H_2, He and N_2 have attachment coefficients that are very small, a statement supported in part by data [Loeb 1929]. However, contamination in the detection gas from O_2 or water vapor can increase electron attachment and compromise performance [Staub 1953; O'Kelly et al. 1960; Huk et al. 1988]. Overall, it is usually best to avoid using gases, or gas mixtures, in which a constituent has a fairly high value of C_a. Further, care should be taken to ensure that the detector gas does not become contaminated with impurities having large values of C_a, such as O_2 or water vapor.

Example 9.1: In the operation of a Ar-filled ion chamber, operated with an electric field of 300 V cm^{-1}, it was discovered that the chamber is contaminated with 1% O_2. The chamber is operated at 20°C with pressure of 1 atm. What is the expected electron attachment fraction per unit differential travel distance in the chamber?

Solution:

From Fig. 9.5 the interpolated value (from the data) of the characteristic energy ϵ_K is 3.0 eV, and is the effective kinetic energy of free electrons in the electric field. From Eq. (9.35) (or Fig. 9.6) the drift speed is 3.6×10^5 cm s^{-1}, and from Fig. 9.4, the momentum transfer cross section is 4.2×10^{-16} cm^2. Also, from Table 9.3, the capture coefficient for O_2 is C_a is 2.5×10^{-5}, while that for Ar is essentially zero ($C_a \simeq 0$). The average thermal speed is

$$\overline{\omega}_e = \sqrt{\frac{2\epsilon_K}{m_e}} = \sqrt{\frac{2(3 \text{ eV})(1.6 \times 10^{-19} \text{ J/eV})}{9.1 \times 10^{-31} \text{ kg}}}$$
$$= 1.027 \times 10^6 \text{ m s}^{-1} = 1.027 \times 10^8 \text{ cm s}^{-1}$$

The molecular density of O_2 in the chamber is $fN_{O_2} = f\rho_{O_2}N_a/A_{O_2}$. From Table 9.1, $\rho_{O_2} = 1.33$ mg/cm^3 at 293 K and 760 torr. Thus,

$$f_V N_{O_2} = (0.01)(1.33 \times 10^{-3} \text{ g cm}^{-3})\frac{(6.022 \times 10^{23} \text{ mol}^{-1})}{32 \text{ g/mol}} = 2.50 \times 10^{17} \text{ cm}^{-3}.$$

Then from Eq. (9.47) the interaction coefficient is

$$\psi_I = \frac{f_V N_{O_2} C_a \overline{\omega}_e \sigma_m}{v_e}$$
$$= \frac{(2.50 \times 10^{17} \text{ cm}^{-3})(2.5 \times 10^{-5})(1.027 \times 10^8 \text{ cm s}^{-1})(4.2 \times 10^{-16} \text{ cm}^2)}{(3.6 \times 10^5 \text{ cm/s})}$$
$$= 0.7497 \text{ cm}^{-1}.$$

Hence

$$1 - \frac{N_e(x)}{N_p} = 1 - e^{-\psi_I x} = 1 - e^{-(0.7497 \text{ cm}^{-1})(1 \text{ cm})} = 0.5275.$$

This results means that for every centimeter traveled by the electrons in the chamber gas, 52.75% of the electrons become attached to the O_2 molecules.

Although the average number of collisions per electron in a gas chamber varies with chamber size, gas pressure, and applied electric field, Korff [1946] quotes the average number of collisions per electron per detection event as approximately 10^5. The average probability for electron attachment can be estimated by multiplying the number of collisions by C_a. Hence, for those gases with $C_a < 10^{-5}$, the probability of electron attachment is minimal. However, for gases with $C_a > 10^{-5}$, electron attachment can occur, thereby slowing and distorting the electrical signal from the detector. The number of collisions expected for a single

electron traversing a chamber can be estimated from published values [Staub 1953], with the mean free path generally ranges between 0.5 μm to 3.0 μm. Some halogen gases have relatively high values for C_a, as do O_2 and water vapor.

9.3 Recombination

After the formation of electron-ion pairs, it is possible that some electrons recombine with positive ions before they are separated by drift and diffusion. There are three basic types of recombination described in the literature [Wilkinson 1950], namely *columnar* recombination, *volumetric* recombination, and *preferential* recombination.[7] Columnar recombination occurs from the localized formation of a relatively dense cloud of ion pairs around the trajectory of, for instance, an alpha particle in the detector gas. Electrons recombine with positive ions, but generally not with their original parent atoms. Volumetric recombination is the recombination of positive and negative ions produced by unrelated ionizing interactions. Preferential recombination occurs when an electron attaches to a neutral atom and, subsequently, recombines with the parent positive ion from whence the electron came, or, less probably, the electron recombines immediately with its original parent atom.[8]

Note that recombination occurs only if the electrons and positive ions are locally close enough to enable the process to occur. The product $n^- n^+$ is the combined localized charge carrier concentration within the gas chamber. The larger this concentration, the greater is the rate of recombination. Even under low electric field conditions, the diffusion of electrons is much higher than that of positive ions, and rapid separation can be expected; hence, the effect of electron-ion recombination is typically minor. Recombination is less prevalent in gases that have small electron interaction coefficients than found with electro-negative gases. However, in gases that form heavy negative ions, through electron attachment for instance, recombination may cause significant charge carrier losses.

9.3.1 Columnar Recombination

Columnar recombination is of most concern for gas-filled detectors operated in pulse mode, because the background or interaction rate under most situations is usually not high enough to cause appreciable volumetric recombination. Columnar recombination is almost entirely caused by the recombination of positive and negative heavy ions; therefore, those detector gases that do not suffer from electron attachment have minimal columnar recombination. However, gases that have components that do have large electron attachment coefficients, such as air, alcohols, or contaminated gases, can have appreciable columnar recombination.

Jaffé [1913] developed a theory for columnar recombination based on gases that have appreciable electron attachment coefficients, in which the fraction of ions escaping recombination is described by

$$F(\mathcal{E}) = \frac{N_\infty}{N_o} = \frac{1}{1 + \frac{\beta N_o}{8\pi D_{ion}} \sqrt{\frac{\pi}{z}} S(z)}. \tag{9.51}$$

Here β is the recombination coefficient, N_o is the initial number of electron-ion pairs in the ionization path (eip density), N_∞ is the number of ions that escape recombination, D_{ion} is the ion diffusion coefficient, and

$$S(z) = \sqrt{\frac{1}{\pi}} \int_0^\infty \frac{e^{-S} dS}{\sqrt{S\left(1 + \frac{S}{z}\right)}}. \tag{9.52}$$

[7] Loeb [1939] suggests as many as five types of recombination.

[8] In the strictest sense, preferential recombination is the only true recombination of the many types, in that an electron stripped from an atomic nucleus recombines back with its original parent atom. In the other two cases mentioned, columnar and volumetric recombinations, electrons combine with any random positive ions, other than their original parents.

The substitution

$$f(z) = \sqrt{\frac{\pi}{z}} S(z) = e^{z/2} \left(\frac{i\pi}{2}\right) H_0^{(1)}(\frac{iz}{2}), \tag{9.53}$$

yields

$$F(\mathcal{E}) = \frac{N_\infty}{N_o} = \frac{1}{1 + \frac{\beta N_o}{8\pi D_{ion}} f(z)}. \tag{9.54}$$

where $H_0^{(1)}$ is a Hankel function of the first kind of order zero,[9] listed [Jahnke and Emde 1945] and plotted elsewhere [Zanstra 1935]. The variable z is [Loeb 1939]

$$z = \frac{1}{2}\left(\frac{\mathcal{E}\mu b \sin\theta}{D_{ion}}\right)^2, \tag{9.55}$$

where θ is the angle between the ionization track and the applied electric field, μ is the ion mobility, K_1 is a constant, $\mathcal{E}$ is the applied electric field and P is the gas pressure in atm. With the substitution $z = 2x$ into Eq. (9.53) and Eq. (9.55), Diebner [1931] shows that

$$f(x) = e^x \left(\frac{i\pi}{2}\right) H_0^{(1)}(ix), \tag{9.56}$$

and is approximated by

$$f(x) \approx 2.303 \left[1 + \left(\frac{x}{2}\right)^2\right] e^x \log_{10}\left(\frac{1.122}{x}\right), \tag{9.57}$$

for $x < 0.1$, thereby providing a straightforward method to evaluate Eq. (9.51) as a function of x. However, these equations, Eqs. (9.51) to (9.57), are all very interesting, but, without knowledge of b, F cannot be directly evaluated.[10] The evaluation method developed by Zanstra [1935] expresses Eq. (9.51) as,

$$F(\mathcal{E}) = \frac{N_\infty}{N_o} = \frac{I}{I_o} = \frac{1}{1 + g f(x)}. \tag{9.58}$$

where I is the measured current, I_o is the current without recombination, and

$$g = \frac{\beta N_o}{8\pi D_{ion}}. \tag{9.59}$$

Rearranging terms, Eq. (9.58) can be rewritten as

$$\frac{1}{I} = \frac{1}{I_o} + \frac{g f(x)}{I_o}. \tag{9.60}$$

Zanstra [1931] asserts that, provided g is constant, Eq. (9.60) will yield a linear response. At $f(x) = 0$, the condition $I = I_o$ is satisfied; hence by plotting $1/I$ vs $f(x)$ and extrapolating to the ordinate intercept at $f(x) = 0$ then I_o can be obtained. This method was confirmed with satisfactory results by Clay [1939] and Greening [1964]. For $x > 10$, Eq. (9.56) can be approximated by [Boag 1966]

$$f(x) \approx \sqrt{\frac{\pi}{2x}}. \tag{9.61}$$

[9] Hankel functions are otherwise known as Bessel functions of the third kind (or Weber functions). Here $H_0^{(1)}(z) = J_0(z) + iY_0(z)$, where $J_0(z)$ and $Y_0(z)$ are Bessel functions of the first and second kind, respectively.

[10] An average value of the product $b \sin\theta$ was used for the work [Jaffé 1913].

Substituting Eq. (9.55) and Eq. (9.61) into Eq. (9.58) yields,

$$\frac{N_\infty}{N_o} = \frac{1}{1 + \left(\dfrac{\beta N_o}{8\pi D_{ion}}\right)\left(\dfrac{2D_{ion}}{\mathcal{E}\mu b \sin\theta}\right)\left(\dfrac{\pi}{2}\right)^{1/2}}. \tag{9.62}$$

Rearranging terms yields, and acknowledging that $N_o \propto Q_o$,

$$\frac{1}{N_\infty} = \frac{1}{N_o} + \left(\frac{\beta}{8\pi D_{ion}}\right)\left(\frac{2D_{ion}}{\mathcal{E}\mu b \sin\theta}\right)\left(\frac{\pi}{2}\right)^{1/2} \qquad \text{so that} \qquad \frac{1}{Q} = \frac{1}{Q_o} + \frac{C_1}{V_o}, \tag{9.63}$$

where Q is the measured charge, Q_o is the actual charge liberated, V_o is the applied voltage, and C_1 is constant, resulting in a linear equation identical to that expressed by Attix [2004]. Hence, for relatively high applied voltages, the inverse of the measured charge Q can be plotted against measured values on the right side of Eq. (9.63), as shown in Fig. 9.10. Extrapolating back to the origin where $C_1/V_o = 0$, the actual value of a Q_o can be found.

There are a few trends, perhaps obvious, that can be seen from Eq. (9.51). First, columnar recombination increases with the density of N_o and the recombination coefficient β. Second, the recombination decreases with larger diffusion coefficients D_{ion}. Finally, perhaps not so obvious from Eq. (9.51), but affirmed by Eq. (9.63), columnar recombination decreases as the applied voltage is increased or gas pressure is decreased.

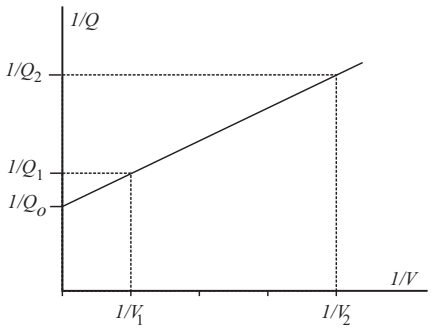

Figure 9.10. Graphic depiction of a method to determine the correct Q_o in the presence of columnar recombination from $1/Q = 1/Q_o + C_1/V_o$.

9.3.2 Volumetric Recombination

Volumetric recombination occurs upon irradiation of a gas medium in high radiation fields, such that negative and positive ions encounter oppositely polarized charge carriers generated from multiple random events. The volumetric rate at which negative charges, with concentration n^-, are recombined with the positive charges, with concentration n^+, thereby reducing both n^- and n^+, is $-\beta n^- n^+$, where β is the recombination coefficient. Loeb [1939] quotes $\beta_e \simeq 2 \times 10^{-10}$ cm^3 s^{-1} for electron-ion pairs in Ar at 1 atm, and Rossi and Staub [1949] makes the claim that β_e is similar for most detector gases. The value of β is much larger if the negative ions are not electrons, but instead negatively charged heavy ions, where β_{ion}^- ranges between 0.9×10^{-6} cm^3 s^{-1} $- 1.7 \times 10^{-6}$ cm^3 s^{-1} at 1 atm [Loeb 1929].

Effects of Diffusion and Recombination in an Ion Chamber

Consider the one-dimensional ion chamber shown in Fig. 9.11 whose gas is uniformly and constantly irradiated such that S_o electron-ion pairs are created per unit volume per unit time. The intensity of the irradiation is sufficiently high that the chamber is operated in the current mode. In this section three cases are considered: (1) no diffusion or recombination effects, (2) only diffusion is important, (3) only recombination is important. In the following analysis the approach taken by Rossi and Staub [1949] is used.

Case (1): No Diffusion or Recombination Effects

The positive and negative current densities $\mathbf{j}^\pm$ formed, respectively, by the positive and negative ion drift velocities $\mathbf{v}^\pm$ caused by the electric field are given by

$$\boldsymbol{\nabla} \bullet \mathbf{j}^\pm = \pm q_e S_o. \tag{9.64}$$

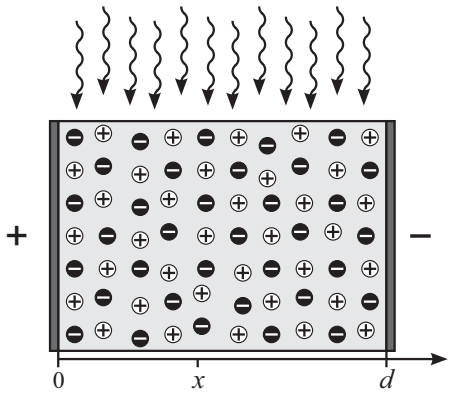

Figure 9.11. Uniform irradiation of a planar configuration gas-filled ion chamber. Volumetric recombination increases as the source term $S_\circ$, the production of electron-ion pairs, is increased.

Equivalently, in terms of the ion concentrations

$$\mathbf{j}^{\pm} = \pm q_e n^{\pm} \mathbf{v}^{\pm}. \tag{9.65}$$

For the one-dimensional case of Fig. 9.11, the ion speeds are

$$\mathbf{v}^{\pm} = \pm \mathbf{i} v^{\pm}, \tag{9.66}$$

and the current densities are

$$\mathbf{j}^{\pm} = \mathbf{i} j^{\pm}, \tag{9.67}$$

where $j^{\pm}$ and $v^{\pm}$ are the absolute values, respectively. Substitution of Eq. (9.65) into Eq. (9.64) and use of the magnitudes $v^{\pm}$ yields the following differential equations for the steady-state ion concentrations

$$v^{\pm} \frac{dn^{\pm}(x)}{dx} = \pm S_o. \tag{9.68}$$

The general solution of these equations is

$$n^{\pm}(x) = \pm \frac{S_o}{v^{\pm}} x + C^{\pm}, \tag{9.69}$$

where $C^{\pm}$ are arbitrary constants that can be determined from the boundary conditions $n^{+}(0) = 0$ and $n^{-}(d) = 0$. In this manner, the concentration profiles are found to be

$$n^{+}(x) = \frac{S_o}{v^{+}} x \qquad \text{and} \qquad n^{-}(x) = \frac{S_o}{v^{-}} (d - x). \tag{9.70}$$

In terms of the magnitudes $v^{\pm}$ and $j^{\pm}$ the current densities for the geometry of Fig. 9.11 are

$$j^{\pm} = q_e n^{\pm}(x) v^{\pm}, \tag{9.71}$$

so that

$$j = j^{+} + j^{-} = q_e [v^{+} n^{+}(x) + v^{-} n^{-}(x)] = q_e S_o d \tag{9.72}$$

Finally, multiplication of j by the area A of the electrodes gives the steady-state *saturation* induced current

$$I_s = q_e S_o A d. \tag{9.73}$$

Case (2): Ion Drift with Diffusion

When diffusion caused by thermal agitation becomes appreciable, some ions near the electrode of the same sign reach that electrode and are neutralized. This reduces the number ions that drift towards their collecting electrode and, hence, reduces the induced current.

To quantify this effect, add diffusion to the previous analysis. Equation (9.64) still holds but Eqs. (9.65) become

$$\mathbf{j}^{+} = q_e n^{+} \mathbf{v}^{+} - q_e D^{+} \boldsymbol{\nabla} n^{+} \qquad \text{and} \qquad \mathbf{j}^{-} = -q_e n^{-} \mathbf{v}^{-} + q_e D^{-} \boldsymbol{\nabla} n^{-}. \tag{9.74}$$

For the one-dimensional case of Fig. 9.11 and use of absolute values these equations yields

$$j^{+}(x) = q_e n^{+}(x) v^{+} - q_e D^{+} \frac{dn^{+}(x)}{dx} \quad \text{and} \quad j^{-}(x) = q_e n^{-}(x) v^{-} + q_e D^{-} \frac{dn^{-}(x)}{dx}. \tag{9.75}$$

Equation (9.64), as before, gives

$$\frac{dj^{\pm}(x)}{dx} = \pm q_e S_o \qquad \text{or} \qquad j^{\pm}(x) = \pm q_e S_o x + C_1^{\pm}. \tag{9.76}$$

where $C_1^{\pm}$ are constants of integration. Equating the right-hand sides of Eqs. (9.75) and (9.76) gives, after rearrangement,

$$\frac{dn^{+}(x)}{dx} = \frac{v^{+}}{D^{+}} n^{+}(x) - \frac{S_o}{D^{+}} x + \widetilde{C}_1^{+}, \tag{9.77}$$

$$\frac{dn^{-}(x)}{dx} = -\frac{v^{-}}{D^{-}} n^{-}(x) - \frac{S_o}{D^{-}} x + \widetilde{C}_1^{-}, \tag{9.78}$$

where $\widetilde{C}_1^{\pm} = C_1^{\pm}/D^{\pm}$.

The most general solutions of Eqs. (9.77) and (9.78) are

$$n^{+}(x) = C_2^{+} e^{v^{+}x/D^{+}} + \frac{S_o x}{v^{+}} + C_3^{+}, \tag{9.79}$$

$$n^{-}(x) = C_2^{-} e^{-v^{-}x/D^{-}} - \frac{S_o x}{v^{-}} + C_3^{-}, \tag{9.80}$$

where $C_2^{\pm}$ and $C_3^{\pm}$ are arbitrary constants. To evaluate these four constants, use the four boundary conditions $n^{\pm}(0) = 0$ and $n^{\pm}(d) = 0$. With these conditions the concentration profiles are found to be

$$n^{+}(x) = \frac{S_o}{v^{+}} x - \frac{S_o d}{v^{+}} \left[\frac{1 - e^{v^{+}x/D^{+}}}{1 - e^{v^{+}d/D^{+}}} \right], \tag{9.81}$$

$$n^{-}(x) = -\frac{S_o}{v^{-}} x + \frac{S_o d}{v^{-}} \left[\frac{1 - e^{-v^{-}x/D^{-}}}{1 - e^{-v^{-}d/D^{-}}} \right]. \tag{9.82}$$

For most practical ion chambers $v^{\pm}d/D^{\pm}$ are large numbers so that Eqs. (9.81) and (9.82) can be approximated as

$$n^{+}(x) \simeq \frac{S_o}{v^{+}} x - \frac{S_o d}{v^{+}} e^{-v^{+}(d-x)/D^{+}}, \tag{9.83}$$

$$n^{-}(x) \simeq \frac{S_o}{v^{-}} (d - x) - \frac{S_o d}{v^{-}} e^{-v^{-}x/D^{-}}. \tag{9.84}$$

To obtain the current densities, substitute Eqs. (9.83) and (9.84) into Eqs. (9.75) to obtain

$$j^{+}(x) \simeq q_e S_o x - q_e \frac{D^{+}}{v^{+}} S_o \qquad \text{and} \qquad j^{-}(x) \simeq q_e S_o (d - x) - q_e \frac{D^{-}}{v^{-}} S_o. \tag{9.85}$$

Finally, the induced current is seen to be

$$I = A(j^{+} + j^{-}) \simeq q_e S_o A d - q_e S_o A \left[\frac{D^{+}}{v^{+}} + \frac{D^{-}}{v^{-}} \right]. \tag{9.86}$$

Thus, the decrease in the saturation current I_s due to diffusion effects is

$$-\frac{\delta I_s}{I_s}\bigg|_{\text{diffusion}} \simeq \left[\frac{D^{+}}{v^{+} d} + \frac{D^{-}}{v^{-} d} \right]. \tag{9.87}$$

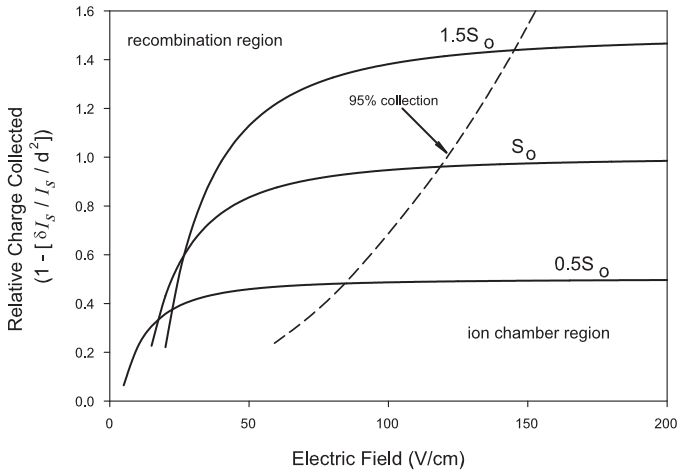

Figure 9.12. The relative charge collection $1-(\beta RS_o)/(6v^+v^-)$ for air as a function of the electric field. Here the distance d between electrodes is in cm and $q_eS_o = 1$ nA cm^{-3}. Values of the other variables are calculated in Example 9.2.

Substitution of Eq. (9.34) into Eq. (9.87), which also applies to ions, gives

$$-\left.\frac{\delta I_s}{I_s}\right|_{\text{diffusion}} \simeq \frac{3kT}{2q_eV}\left(\xi^+ + \xi^-\right), \tag{9.88}$$

where V is the applied voltage. For heavy ions, the difference between the characteristic energy and the thermal energy is small, hence for both negative and positive heavy ions $\xi \simeq 1$, and

$$-\left.\frac{\delta I_s}{I_s}\right|_{\text{diffusion}} \simeq \frac{3kT}{q_eV}, \tag{9.89}$$

from which it is seen that diffusion losses are negligible for high voltages. However, for electrons, the value of ξ can be considerably higher, on the order of 200 or more for typical electric fields employed in ion chamber operation. In this case

$$-\left.\frac{\delta I_s}{I_s}\right|_{\text{diffusion}} \simeq \frac{3kT}{2q_eV}\left(\xi_e^- + 1\right). \tag{9.90}$$

This result shows that there can be electron losses from diffusion if the operating voltage is on the order of only a few hundred volts. Raising the operating voltage minimizes diffusion losses.

Case (3): Effect of Recombination

Assume that diffusion losses are negligible so that the ion concentration profiles are given by Eqs. (9.70). The induced current, with recombination effects, is thus

$$I = I_s - \delta I_s = q_eS_oAd - q_eA\int_0^d \beta n^+(x)n^-(x)R\,dx, \tag{9.91}$$

where R is the fraction of free electrons that produce heavy negative ions through electron attachment. Substitution of Eqs. (9.70) into this result yields

$$-\left.\frac{\delta I_s}{I_s}\right|_{\text{recombination}} = \frac{\beta R}{S_od}\int_0^d \frac{S_o^2x(d-x)}{v^+v^-}dx = \frac{\beta R}{6}\frac{S_od^2}{v^+v^-}. \tag{9.92}$$

From Eq. (9.87) it is seen that losses from diffusion decrease with increasing electrode spacing while, from Eq. (9.92), losses from recombination are seen to increase with electrode spacing. Equation (9.87) also indicates that diffusion losses are independent of the source term S_o, and are inversely proportional to the ion drift speeds, which are proportional to the applied electric field. Equation (9.92) indicates that recombination losses increase proportionally to the source term S_o and inversely to the drift speeds of the charge carriers (or applied voltage). The electric field required to move the operation of the detector from the recombination region into the ion chamber region increases with radiation exposure, i.e., with S_o, as depicted in Fig. 9.12. For gases with negligible electron attachment and, consequently, relatively small recombination losses, the recombination region spans a small range of voltages. Examples of such gases with little to no recombination losses include Ar, CH_4, P-10 and diatomic forms of halogens. However, contamination from electronegative gases, such as O_2, O, NO, OH, and Cl, can cause considerable recombination, thereby extending the range of the recombination region. Equation (9.92) indicates that the recombination region increases as the volumetric ionization increases, as shown in Fig. 9.12. Hence, as S_o increases, the applied electric field must also be increased to transition from the recombination region into the ion chamber region.

Example 9.2: An open air ion chamber is irradiated with 662-keV gamma rays to produce $q_e S_o = 1$ nA cm^{-3}. The ion chamber's aperture is 2.5 cm × 2.5 cm and the electrode spacing is 2.5 cm. The electrodes are designed as squares, each being 2.5 cm × 2.5 cm. The chamber is operated at 300 volts. The saturation speed of electrons in air at 760 torr is $v_e = 6.58 \times 10^5$ cm s^{-1}. What is the fractional loss of saturation current due to recombination?

Solution:

The electric field across the chamber is $\mathcal{E} = 300$ V/2.5 cm = 120 V/cm. For energies below 0.2 eV, there is an unfortunate lack of data for the ratio D/μ (or ϵ_K) for oxygen, although it can be assumed from available measurements that $\epsilon_K \lesssim 0.2$ eV [Huxley and Crompton 1974; Peisert and Sauli 1984]. Instead, assume that $\xi = 1$ so that $\epsilon_K = \overline{E}_e$, thereby giving as a first approximation the average thermal electron energy as $3kT/2$. The characteristic energy is then

$$\epsilon_K = \frac{q_e D_e}{\mu_e} = \frac{2\overline{E}_e}{3} = kT \simeq .026 \text{ eV},$$

which can be interpreted as the minimum thermal energy.[11] From Fig. 9.4, the momentum transfer cross section σ_m for O_2 is $\simeq 7 \times 10^{-16}$ cm^2. Also, from Table 9.3, the capture coefficient for O_2 is C_a is 2.5×10^{-5}. The capture coefficient for N_2 is essentially zero ($C_a \simeq 0$).

$$\overline{\omega}_e = \sqrt{\frac{2\epsilon_K}{m_e}} = \sqrt{\frac{2(0.026 \text{ eV})(1.6 \times 10^{-19} \text{ J/eV})}{9.1 \times 10^{-31} \text{ kg}}} = 9.56 \times 10^4 \text{ m s}^{-1} = 9.56 \times 10^6 \text{ cm s}^{-1}$$

The mean free path λ_e between scatters with O_2 is estimated as a function of O_2 density, namely $\lambda_e = 1/(fN\sigma_m)$, where $n_a = fN$. From Eq. (9.47),

$$\psi_I = \frac{C_a \overline{\omega}_e}{\lambda_e v_e} = \frac{C_a \overline{\omega}_e \sigma_m f N}{v_e} = \frac{(2.5 \times 10^{-5})(9.56 \times 10^6 \text{ cm s}^{-1})(7 \times 10^{-16} \text{cm}^2)}{6.58 \times 10^5 \text{ cm s}^{-1}}$$
$$\times (0.21)(2.7 \times 10^{19} \text{cm}^{-3}) \frac{273\text{K}}{293\text{K}} = 1.34 \text{ cm}^{-1}. \tag{9.93}$$

If, instead, $\epsilon_K = 0.2$ eV is used, then $\psi_I = 3.72$ cm^{-1}. Hence, it can be assumed that the interaction coefficient lies between the two extremes, i.e., 1.34 cm$^{-1} \leq \psi_I \leq 3.72$ cm^{-1}. With such a high interaction

[11] Typically, the characteristic energy is much higher than the minimum thermal energy. Use of the minimum thermal energy serves to provide the minimum thermal speed $\overline{\omega}_e$.

coefficient, essentially all electrons become attached to an ion within 1 to 2 cm of air; hence $R \simeq 1$. Now assume that direct electron-ion recombination is negligible, leaving only heavy ion recombination between negative and positive heavy ions. From Table 9.2, the positive ion and negative ion speeds are

$$v^+ = \frac{760\mu^+_{air}\mathcal{E}}{P} = \frac{1.36 \text{ cm}^2}{\text{V s}}\frac{300\text{V}}{2.5\text{cm}} = 163.2 \text{ cm s}^{-1},$$
$$v^- = \frac{760\mu^-_{air}\mathcal{E}}{P} = \frac{1.87 \text{ cm}^2}{\text{V s}}\frac{300\text{V}}{2.5\text{cm}} = 224.4 \text{ cm s}^{-1}$$

For $q_e S_o = 10^{-9}$ A cm^{-3}, the number of electron-ion pairs S_o produced per unit volume per unit time is 6.25×10^9 cm^{-3} s^{-1}. Finally, assume a high recombination coefficient of 1.7×10^{-6} cm^3 ion^{-1} s^{-1} [see data from Loeb 1929]. Thus,

$$-\frac{\delta I_s}{I_s} = \frac{\beta S_o d^2}{6v^-v^+} = \frac{(1.7 \times 10^{-6}\text{cm}^3 \text{ ion}^{-1} \text{ s}^{-1})(6.25 \times 10^9 \text{ ion pairs cm}^{-3}\text{s}^{-1})((2.5 \text{ cm})^2)}{6(224.4 \text{ cm s}^{-1})(163.2 \text{ cm s}^{-1})} = 0.3022.$$

This result means that approximately 30% of the charge carriers are lost to recombination.

Equation (9.92) is at times written as a collection efficiency [Boag 1966]

$$f = \frac{Q}{Q_o} = 1 - \frac{\beta R}{6}\frac{S_o d^2}{v^+v^-} = 1 - \frac{\beta R}{6}\frac{Q^*_o d^4}{q_e\mu^+\mu^- V_o^2} = 1 - \frac{1}{6}\zeta^2, \tag{9.94}$$

where Q^*_o is the true ionization rate (esu cm^{-3} s^{-1}), q_e is the unit electric charge (in esu),[12] and V_o is the applied voltage across electrode separation d, and

$$\zeta = \sqrt{\frac{\beta R}{q_e\mu^-\mu^+}}\left(\frac{d^2\sqrt{Q^*_o}}{V_o}\right) = k^*\left(\frac{d^2\sqrt{Q^*_o}}{V_o}\right), \tag{9.95}$$

where k^* is a constant. Through comparisons of experimental observations, an accepted average value of k^* is 36.7 ± 2.2 V s$^{1/2}$ cm$^{1/2}$ esu$^{1/2}$ for air at STP [Greening 1964]. Other terms in Eq. (9.95) are defined as follows [Attix 2004]: d is the plate separation (cm), $Q^*_o = qN_o/v_l t$ (esu/cm^3 s), q_e the unit electrical charge (esu) $= 4.8032 \times 10^{-10}$ esu, N_o the number of ion pairs produced in the chamber volume, v_l the chamber volume (cm^3), t the irradiation duration (s), V_o the applied potential (volts), β the recombination coefficient (cm^3/ion s), μ^- the mobility of negative ions (cm^3/V s), μ^+ the mobility of positive ions (cm^3/V s), and R the fraction of negative ions from electron attachment. It is assumed the irradiation time t is long by comparison to the ion-transit time across the detector (~ 1 ms). The solution Eq. (9.92), and also Eq. (9.94), are based on the charge density distributions described by Eq. (9.70), which ideally form a linear dependence with position. Boag [1966] points out that the solutions Eq. (9.92) and Eq. (9.94) overestimate the recombination in an ion chamber and offer a correction altering Eq. (9.70) with the charge carrier collection efficiencies,

$$n^+(x) = \frac{fS_o}{v^+}x \qquad \text{and} \qquad n^-(x) = \frac{fS_o}{v^-}(d - x). \tag{9.96}$$

Substitution into Eq. (9.91) yields

$$f = 1 - \frac{f^2\zeta^2}{6}, \tag{9.97}$$

[12] The esu, or statcouloumb, is a nearly defunct unit in the cgs system, with a conversion to the SI system, 1 C $= 2.9979 \times 10^9$ statC or 1 statC $= 3.3357 \times 10^{-10}$ C.

which actually underestimates the recombination losses. The derivations by Mie [1904] and Greening [1964] produce a geometric average between the two derivations of Eq. (9.92) and Eq. (9.97), namely,

$$f = 1 - \frac{f\zeta^2}{6}, \qquad \text{or} \tag{9.98}$$

$$f = \frac{1}{1 + \dfrac{\zeta^2}{6}}. \tag{9.99}$$

Eq. (9.99) is accurate for d between 0.5 cm up to 8 cm provided that $f \geq 0.7$. Rearranging terms with the substitution $q_e N_o / v_l t = Q_o^*$, Eq. (9.99) reduces to the linear equation

$$\frac{1}{Q} = \frac{1}{q_e N_o} + \frac{k^{*2} d^4}{6 v_l t V_o^2} = \frac{1}{Q_o} + \frac{C_1}{V_o^2}, \tag{9.100}$$

where $C_1 = k^{*2} d^4 / 6 v_l t$ is constant. Eq. (9.99) can be plotted to determine the true charge collection efficiency f, or the true value of Q_o, as shown in Fig. 9.13. Hence, by measuring the current, or charge, at two different operating voltages, a line can be projected through the ordinate at $1/V^2 = 0$ to determine the value $1/Q_o$.

Equation (9.100) also holds true for cylindrical and spherical ion chambers, although the device dimensions, and therefore ζ, must be altered. For cylindrical detectors, in which a is the inner electrode wire radius (usually the anode) and b is the outer wall electrode radius (usually the cathode), one has

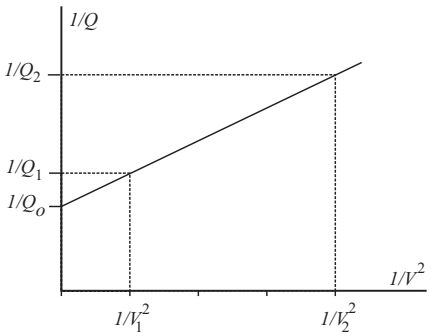

Figure 9.13. Graphic depiction of a method to determine the correct Q_o in the presence of volumetric recombination from $1/Q = 1/Q_o + C_1/V_o^2$.

$$\zeta_{cyl} = k^* \frac{[(b-a)\kappa_{cyl}]^2 \sqrt{Q_o^*}}{V_o} \tag{9.101}$$

where

$$\kappa_{cyl} = \left[\left(\frac{b+a}{2(b-a)} \right) \ln \left(\frac{b}{a} \right) \right]^{1/2}. \tag{9.102}$$

For spherical detectors, in which a is the inner electrode wire radius and b is the outer wall electrode radius, *zeta* is given by

$$\zeta_{sph} = k^* \frac{[(b-a)\kappa_{sph}]^2 \sqrt{Q_o^*}}{V_o} \tag{9.103}$$

where

$$\kappa_{sph} = \left[\frac{1}{3} \left(\frac{b}{a} + 1 + \frac{a}{b} \right) \right]^{1/2}. \tag{9.104}$$

9.3.3 Preferential Recombination

Preferential recombination occurs when a liberated electron recombines with its original parent ion. The process can occur when a heavy negative ion, formed through electron attachment, remains in close proximity of the positive parent ion. The probability that preferential recombination occurs is [Onsager 1938]

$$P_{pr} = 1 - \exp \left[\frac{-q_e^2}{4\pi\epsilon_o d_s k T} \right], \tag{9.105}$$

where d_s is the distance between the negative and positive ions. Preferential recombination occurs when the electrostatic attractive forces of the negative and positive ions overcome the thermal Brownian motion of the ion-pair, i.e., when

$$\frac{q_e^2}{4\pi\epsilon_o d_s} \gtrsim \frac{3}{2}kT. \tag{9.106}$$

Wilkinson (1950) points out that preferential recombination is generally unimportant for ion chambers operated under typical gas pressures. Regardless, the effect of preferential recombination is to remove charge carriers from the signal formation process, the same as columnar and volumetric recombination. Hence, its effect is nearly indistinguishable from other forms of recombination, except, perhaps, at high gas pressures where $D^{\pm}$ becomes small. Loeb [1939] suggests that gases with high attachment coefficients, such as O_2, Cl_2, SO_2, and CO_2, may experience preferential recombination for pressures above 5 to 10 atm.

9.4 Ion Chamber Operation

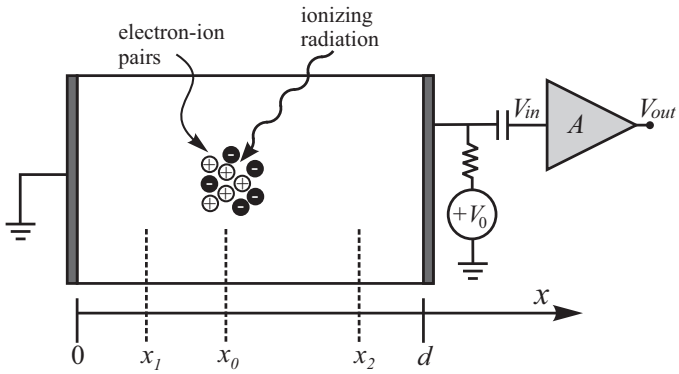

Figure 9.14. Depiction of an ion chamber of planar design.

Perhaps the simplest gas-filled detector is the *ion chamber*. There are many configurations of ion chambers, and they are operated in Region II of the gas curve. The detection method is simple. Ionizing radiation, such as charged particles or energetic photons, enter a region filled with a gas, such as Ar or air. The chamber has electrodes across which a voltage is applied. As the radiation interacts with the gas, electron-ion pairs are created, depicted in Fig. 9.14, whose number is proportional to the radiation energy absorbed. The voltage applied across the electrodes causes the negative electrons to separate from the positive ions and drift across the chamber volume. Electrons or negative ions drift towards the anode, and positive ions drift towards the cathode. Such charge motion *induces* current to flow in the external circuit.

Typically, this induced current is sensed by either directly measuring the current or by first storing the charge in a capacitor and then measuring the resulting voltage across the capacitor. The first case is referred to as *current mode* operation and the second case is *pulse mode* operation. Current mode operation is used in high radiation fields, and the magnitude of the current measured gives a relative measure of the radiation field. Pulse mode is used for lower radiation fields, and allows each radiation particle interacting in the chamber to be counted. The voltage produced by the ion chamber detector is the input voltage to the amplification circuitry, and hence, is referred to as V_{in}. The shaped voltage pulse exiting the accompanying amplification circuits is referred to as the output voltage V_{out}.

Ion chambers come in many forms: they can be used for reactor power measurements, in which the radiation field is very high, and for small personnel dosimeters, in which the radiation levels are typically very low. Although simple in concept, two main problems occur when the ion chamber is operated in pulse mode, namely, (1) the measured signal is small due to relatively few electron-ion pairs produced by a single radiation particle and (2) the time to form a signal can be relatively long due to the slow motion of the heavy positive ions. To ameliorate this second problem, an RC circuit is often connected to an ion chamber to reduce the time constant of the system, thereby reducing the time response. Consequently, the capacitor usually discharges *before* all of the ions are collected.

9.4.1 Planar Ion Chambers

A planar ion chamber of the design shown in Fig. 9.14 is operated with positive potential V_0 applied across the electrodes separated by distance d. A radiation particle deposits energy at location x_0 in the chamber and creates a cloud of electron-ion pairs. The number of electron-ion pairs produced is proportional to the energy deposited within the detector gas by the radiation particle.

Current Mode Operation

A simple current mode arrangement for measuring radiation interactions is shown in Fig. 9.15. Radiation interactions in the chamber create electron-ion pairs, which are drifted across the chamber to their respective collecting electrodes by the applied voltage.

One method used to measure the energy deposited by radiation interactions within an ion chamber is to directly measure the current. This action can be accomplished by inserting a current meter into the circuit, as depicted in Fig. 9.15. Because electron speeds are much higher than ions, the current is highest while electrons are in motion. The measured current is defined as

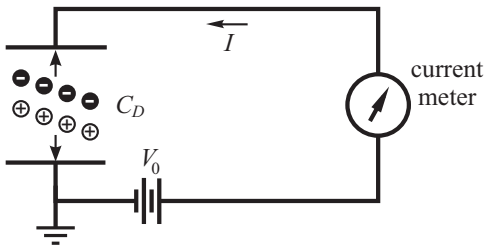

Figure 9.15. Current mode operation of an ion chamber.

$$I = \frac{Q}{t} = \frac{q_e E v_e}{w \Delta x_e} + \frac{q_e E v_{ion}}{w \Delta x_{ion}} = \frac{q_e E}{w t_e} + \frac{q_e E}{w t_{ion}}, \quad 0 < t \leq t_e. \tag{9.107}$$

and

$$I = \frac{q_e E}{w t_{ion}}, \quad t_e < t \leq t_{ion}, \tag{9.108}$$

where E is the energy deposited in the detector, w is the average energy the radiation particle must deposit in the gas to produce an electron-ion pair, and t_e and t_{ion} are the electron and ion extraction or sweep-out times, respectively.

Example 9.3: Calculate the initial instantaneous current measured from an energy deposition of 1 MeV by a radiation particle in an ion chamber operated with pure Ar gas at 1 atm. The distance d between the electrodes is 2 cm with an applied bias of 200 volts. The interaction occurs at $x_0 = 0.5d$.

Solution:

From Table 9.1, the average energy required to produce a electron-ion pair in Ar is 26 eV. For an electric field of 200 V, the reduced electric field at 1 atm (760 torr) is

$$\frac{\mathcal{E}}{P} = \frac{200 \text{ V}}{(2 \text{ cm})(760 \text{ torr})} = 0.132 \text{ V cm}^{-1} \text{ torr}^{-1},$$

From Eq. (9.35), the electron drift speed in argon is

$$\begin{aligned} v_e &= \frac{3.64(\mathcal{E}/P) + 114.6(\mathcal{E}/P)^2}{1 + 12.7(\mathcal{E}/P) + 304.33(\mathcal{E}/P)^2} \\ &= \frac{3.64(0.132 \text{ V cm}^{-1} \text{ torr}^{-1}) + 114.6(0.132 \text{ V cm}^{-1} \text{ torr}^{-1})^2}{1 + 12.7(0.132 \text{ V cm}^{-1} \text{ torr}^{-1}) + 304.33(0.132 \text{ V cm}^{-1} \text{ torr}^{-1})^2} \\ &= 0.364 \text{ cm}/\mu\text{s} = 3.64 \times 10^5 \text{ cm/s}. \end{aligned} \tag{9.109}$$

From Table 9.2, the positive ion mobility is 1.7 cm^2 V^{-1} s^{-1}, and from Eq. (9.30)

$$v_{ion}^{+} = \mu_{ion}^{+} \mathcal{E} = (1.7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1})(100 \text{ V cm}^{-1}) = 170 \text{ cm/s}.$$

The initial current is mainly from electron motion; hence, the extraction time over distance $d - x_0 = 1$ cm is

$$t = \frac{1 \text{ cm}}{3.64 \times 10^5 \text{ cm s}^{-1}} = 2.75 \ \mu\text{s}.$$

Thus, the initial current is

$$I = \frac{Q}{t} \simeq \frac{(10^6 \text{ eV})(1.6 \times 10^{-19} \text{ Coulombs})}{(26 \text{ eV/e-ion pair})(2.75 \times 10^{-6} \text{ seconds})} = 2.24 \text{ nA}.$$

After the electrons are collected, the positive ions are collected with an extraction time of (1 cm)/(170 cm s^{-1})= 5.88 ms. Thus the current decreases to

$$I = \frac{(10^6 \text{ eV})(1.6 \times 10^{-19} \text{ Coulombs})}{(26 \text{ eV/e-ion pair})(5.88 \times 10^{-3} \text{ s})} = 1.05 \text{ pA},$$

decreasing to zero after all ions are collected.

Ion chambers are frequently used in high radiation environments in which pulse processing is not possible because of unacceptable pulse pile-up and dead time losses. However, under low irradiation conditions, the induced currents can be very small and difficult to measure. Thus under these conditions it is more practical to employ pulse processing methods and to operate the detector in pulse mode.

Pulse Mode Operation

A planar ion chamber is operated with positive potential V_0 applied across the electrodes separated by distance d as shown in Fig. 9.14. As before, a radiation particle deposits energy at location x_0 in the chamber and creates a cloud of electron-ion pairs. The motion of these mobile charges induces current to flow across a coupling capacitor in which the charge is stored and measured as a voltage $V = Q/C$. The pulse shape provided by the detector V_{in} is determined by several physical parameters, including the type of gas, chamber, line and coupling capacitances, and the detector load resistor. Three operating cases are considered in the following analyses.

Case 1: No Electron Attachment Here it is assumed that the gases chosen for the ion chamber have negligible electron attachment coefficients; hence, the charge carriers are restricted to electrons and positive ions. The solution for current and charge induction for a planar detector was developed in Chapter 8, where it was found (see Eq. (8.43))

$$\Delta Q = q_e N_o \left[\frac{x_0 - x_1}{d}\bigg|_{ions^+} + \frac{x_2 - x_0}{d}\bigg|_{e^-} \right]. \tag{9.110}$$

Because the mobility of electrons in gas far surpasses that of the heavy ions, the saturation drift speed of electrons $v_e = \mu_e \mathcal{E}$ is always much higher than the drift speeds of ions $v_{ion} = \mu_{ion} \mathcal{E}$, i.e., $v_e \gg v_{ion}$. Consequently, the electron sweep-out time $t_e = (x_2 - x_0)/v_e$ is much smaller than the ion sweep-out time $t_{ion} = (x_0 - x_1)/v_{ion}$, i.e., $t_e \ll t_{ion}$.

If t is measured from the time of the ionizing event, the induced charge changes in time as the charge carriers are swept out of the chamber. From Eq. (9.111) the induced charge is first seen to vary as

$$\Delta Q(t) = \frac{q_e N_o t}{d} \left[v_{ion} + v_e \right], \qquad 0 < t \leq t_e. \tag{9.111}$$

Regardless of the location of x_0, the total charge induced at time t_e is

$$\Delta Q(t_e) = \frac{q_e N_o t_e}{d} \left[v_{ion} + v_e \right], \tag{9.112}$$

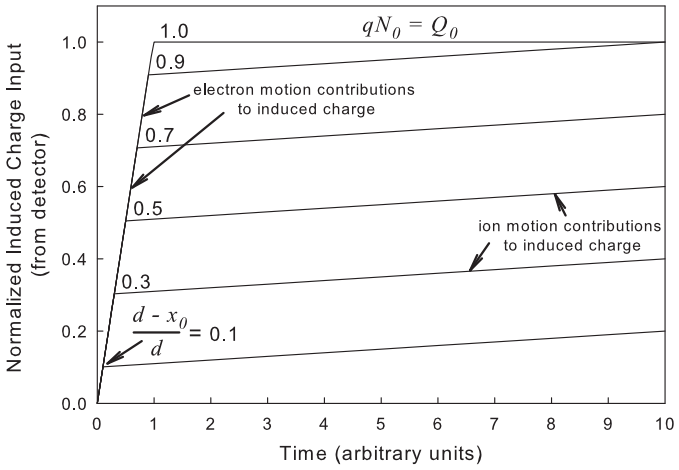

Figure 9.16. Normalized induced charge input from a planar ion chamber as a function of interaction location $d - x_0$. Depicted is the case in which $v_e = 100 v_{ion}$.

which, because $v_e \gg v_{ion}$, can be approximated as

$$\Delta Q(t_e) \simeq q_e N_o \frac{v_e t_e}{d} = q_e N_o \frac{d - x_0}{d}. \tag{9.113}$$

After the electrons are rapidly collected, the positive ions continue to drift across the chamber at a much lower speed, so the collected charge is

$$\Delta Q(t) = q_e N_o \left[\frac{v_{ion} t}{d} + \frac{d - x_0}{d} \right], \qquad t_e < t \leq t_{ion}. \tag{9.114}$$

Finally, for $t > t_{ion}$ all the charge has been collected and ΔQ remains constant at

$$\Delta Q(t) = q_e N_o \left[\frac{x_0}{d} + \frac{d - x_0}{d} \right] = q_e N_o, \qquad t > t_{ion}. \tag{9.115}$$

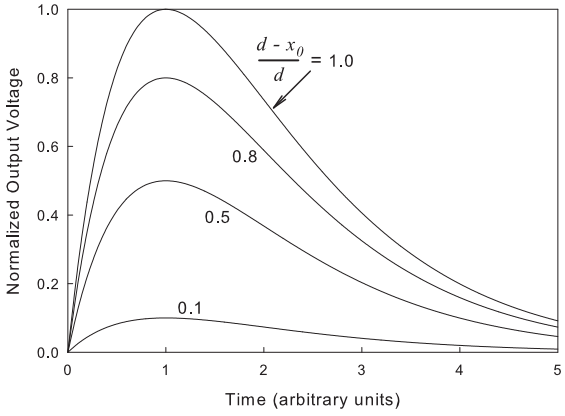

Figure 9.17. Normalized output voltage V_{out} for various interaction locations $d - x_0$ in a planar ion chamber.

The induced charge input for a planar device is shown in Fig. 9.16. Typically, v_{ion} for normal operating voltages of an ion chamber is much too slow for pulse mode operation, and the system RC network discharges the stored charge before all of the ions are collected. Consequently, the induced charge applied to the detector shaping electronics is best described by Eq. (9.113), in which the contribution of positive ions is mostly neglected. Also, the pulse height described by Eq. (9.113) is dependent upon the initial location of the ionization cloud, i.e., the pulses are *position dependent*. The electronic signals from ion chambers operated with gases having low electron attachment coefficients are dominated by electron motion. As a result, ion chambers generate signals that are strongly dependent upon the interaction location within the detector. Recall from Chapter 8 that $V = Q/C$. The time dependent

rise in voltage from an ion chamber with intrinsic capacitance C is, thus,

$$V_{in}(t) = \frac{\Delta Q}{C} = \frac{q_e N_o t}{Cd}\left[v_{ion} + v_e\right] \simeq \frac{q_e N_o t}{Cd} v_e. \tag{9.116}$$

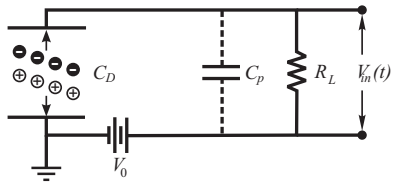

Figure 9.18. Equivalent circuit model for the time variant input voltage from an ion chamber.

The ideal voltage output from a planar ion chamber, for an input voltage V_{in} to the electronic circuitry, is depicted in Fig. 9.17. However, the ion chamber capacitance C_D, line and stray capacitances C_p, and the load resistor R_L connected to the voltage supply form an RC network that introduces a time constant τ intrinsic to the detector. The equivalent circuit for the time dependent input from a planar ion chamber is depicted in Fig. 9.18, that, as discussed in Chapter 22, forms a high pass differentiator circuit. The load resistor provides a leakage path to drain charge from the coupling capacitor between the detector and the preamplifier circuit, without which the coupling capacitor would eventually saturate. If R_L is too small, current from the detector is drained too quickly and the resulting voltage is small. If R_L is too large, τ becomes large, causing pulse pile-up from consecutive radiation interactions and, eventually, causing the coupling capacitor to saturate. The time dependent voltage from an ion chamber with intrinsic capacitance C and load resistance R_L is

$$V_{in}(t) \simeq \frac{q_e N_o}{Cd}\left[v_{ion} + v_e\right] t \exp\left[-\frac{t}{RC}\right], \tag{9.117}$$

Typically, the load resistor is chosen such that the time constant is much greater than the longest possible electron collection time, while remaining shorter than the ion collection time, or $t_{ion} \gg RC \gg t_e$. As a result, the intrinsic differentiator circuit has little discharge effect upon the electron induced current, yet causes the coupling capacitance to discharge before the ions are collected. The effect of the RC time constant upon $V_{in}(t)$ is depicted in Fig. 9.19. The combined effects of position dependent charge collection and the intrinsic system RC time constant lower the voltage pulse height from the ideal maximum. This difference in the expected value is called the *pulse height deficit*, an example of which is shown in Fig. 9.19. The magnitude of the pulse height deficit is a function of the RC time constant and the radiation interaction location in the ion chamber.

Example 9.4: An ion chamber filled with pure argon at 1 atm is operated with the following parameters: $V_0 = 200$ volts; $R_L = 5$ MΩ; $C = 65$ pF; $d = 5$ cm; $x_0 = 2$ cm from the anode; deposition energy $E = 5.5$ MeV. What is the maximum input voltage pulse after the radiation interaction? Compare the answer to that of an interaction occurring at $x_0 = 5$ cm from the anode. Determine the pulse height deficit for both cases.

Solution:
The time constant is $\tau = RC = 300$ μs. From Table 9.1 the average energy to produce an electron-ion pair in Ar is 26 eV, so that the total number of electron-ion pairs produced is

$$N_0 = \frac{5.5 \times 10^6 \text{ eV}}{26 \text{ eV/e-ion pair}} = 211538 \text{ eip.}$$

For $\tau \to \infty$, the expected input voltage is from Eq. (9.115)

$$V_{in} = \frac{\Delta Q}{C} = \frac{q_e N_0}{C} = \frac{(1.6 \times 10^{-19} \text{ C})(211538 \text{ e-ion pairs})}{65 \times 10^{-12} \text{ F}} = 0.5207 \text{ mV}.$$

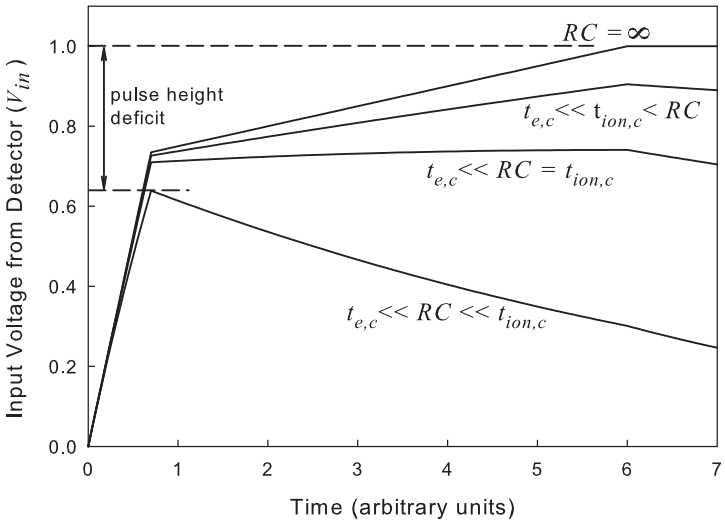

Figure 9.19. Normalized input voltage V_{in} from a planar ion chamber, where $(d - x_0)/d = 0.7$ and $v_e = 10v_{ion}$. Comparison between systems with different RC time constants is shown.

With an electric field of 200 V/ 5 cm = 40 V/cm, the reduced electric field at 1 atm (760 torr) is

$$\frac{\mathcal{E}}{P} = \frac{200 \text{ V}}{(5 \text{ cm})(760 \text{ torr})} = 0.0526 \text{ V cm}^{-1} \text{ torr}^{-1}.$$

From Eq. (9.35), the electron speed in argon is

$$v_e = \frac{3.64(\mathcal{E}/P) + 114.6(\mathcal{E}/P)^2}{1 + 12.7(\mathcal{E}/P) + 304.33(\mathcal{E}/P)^2}$$
$$= \frac{3.64(0.0526 \text{ V cm}^{-1} \text{ torr}^{-1}) + 114.6(0.0526 \text{ V cm}^{-1} \text{ torr}^{-1})^2}{1 + 12.7(0.0526 \text{ V cm}^{-1} \text{ torr}^{-1}) + 304.33(0.0526 \text{ V cm}^{-1} \text{ torr}^{-1})^2} = 0.203 \text{ cm}/\mu\text{s} = 2.03 \times 10^5 \text{ cm/s}$$

From Table 9.2, the positive ion mobility is 1.7 cm^2 V^{-1} s^{-1}, and from Eq. (9.30)

$$v_{ion}^+ = \mu_{ion}^+ \mathcal{E} = (1.7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1})(40 \text{ V/cm}) = 68 \text{ cm/s}.$$

The electron extraction time is

$$t_e = \frac{x_0}{v_e} = \frac{2 \text{ cm}}{2.03 \times 10^5 \text{ cm/s}} = 9.85 \times 10^{-6} \text{ s},$$

and the ion extraction time is

$$t_{ion} = \frac{d - x_0}{v_{ion}} = \frac{2 \text{ cm}}{68 \text{ cm/s}} = 44.12 \times 10^{-3} \text{ s}.$$

Because $t_e \ll \tau \ll t_{ion}$, the maximum input voltage is estimated from Eq. (9.117) at t_e as

$$V_{in}(t_e) \simeq -\frac{q_e N_o}{dC} [v_{ion} + v_e] t_e \exp\left[-\frac{t_e}{RC}\right],$$
$$= -\frac{(1.6 \times 10^{-19} \text{ C})(211,538 \text{ e-ion pairs})}{(5 \text{ cm})(65 \times 10^{-12} \text{ F})}$$
$$\times \left[68 \text{ cm/s} + 2.03 \times 10^5 \text{ cm/s}\right] (9.85 \times 10^{-6} \text{ s}) \exp\left[-\frac{9.85 \times 10^{-6} \text{ s}}{300 \times 10^{-6} \text{ s}}\right] = 0.2016 \text{ mV}.$$

The pulse height deficit is 0.5207 mV − 0.2016 mV = 0.3191 mV. By comparison, if the interaction occurred at $x_0 = d$, then the induced current is produced entirely from electron motion and $t_e = 2.46 \times 10^{-5}$ s. The input voltage in this case is

$$V_{in}(t_e) \simeq -\frac{q_e N_o}{dC} v_e t_e \exp\left[-\frac{t_e}{RC}\right],$$
$$= -\frac{(1.6 \times 10^{-19}\ \text{C})(211,538\ \text{e-ion pairs})}{(65 \times 10^{-12}\ \text{F})} \exp\left[-\frac{2.46 \times 10^{-5}\ \text{s}}{300 \times 10^{-6}\ \text{s}}\right] = 0.4797\ \text{mV}.$$

The pulse height deficit is 0.5207 mV − 0.4797 mV = 0.041 mV.

Although discussions on nuclear electronics are reserved for Chapter 22, to illustrate the consequence of slow positive ion speeds, the following exposition is offered. The input voltage $V_{in}(t)$ from a ion chamber is commonly applied to a CR-RC preamplifier. The preamplifier consists of (1) a low-pass integrating/shaping circuit that has an R_iC_i time constant τ_i, and (2) a high-pass differentiating/shaping circuit that has an R_oC_o time constant of τ_o. If it is assumed that the collection time for electrons is much less than the time constant ($t_e \ll \tau$), and the time constant is much less than the collection time for the ions ($\tau \ll t_{ion}$), then Eq. (9.113) can be approximated as a step input to the electronic circuitry. The observed output voltage from the preamplifier circuit for a step input is,

$$V_{out}(t) \simeq V_{in}(t) \frac{\tau_o}{\tau_o - \tau_i} \left(e^{-t/\tau_o} - e^{-t/\tau_i}\right), \tag{9.118}$$

Often, the time constant for input and output are equal, i.e., $\tau_o = \tau_i$. Substitution of Eq. (9.113) and use of L'Hôpital's rule[13] yields

$$V_{out}(t) \simeq \frac{q_e N_o v_e t_e}{Cd} \frac{t}{\tau} e^{-t/\tau} \qquad t > t_e, \tag{9.119}$$

where it is assumed that t_e is relatively small such that the input appears as a step input, and

$$V_{out}(t) \simeq \frac{q_e N_o (d - x_0)}{Cd} \frac{t}{\tau} e^{-t/\tau}. \tag{9.120}$$

The normalized output voltages V_{out} as a function of interaction location $d - x_0$ for monoenergetic ionizing radiation particles are shown in Fig. 9.17, from which the responses are seen to be overwhelmingly position dependent. As a result, a monoenergetic ionizing radiation source produces a continuous spectrum of signals with varying amplitudes, thus, precluding the use of a planar ion chamber as an energy spectrometer.

Case 2: High Electron Attachment Consider the case in which the gas in the ion chamber has high electronegativity; in other words, the electrons become attached to neutral molecules almost immediately after liberation. The induced charge now becomes

$$\Delta Q = -\frac{q_e N_o t}{d} \left[v_{ion}^{+} + v_{ion}^{-}\right] = -\frac{q_e N_o t \mathcal{E}}{d} \left[\mu_{ion}^{+} + \mu_{ion}^{-}\right]. \tag{9.121}$$

The time dependent input voltage from the detector is

$$V_{in}(t) = \frac{\Delta Q}{C} = -\frac{q_e N_o t}{Cd} \left[v_{ion}^{+} + v_{ion}^{-}\right]. \tag{9.122}$$

[13] Although named after Guillaume François Antoine Marquis de L'Hôpital, evidently it was his tutor Johann Bernoulli who discovered the rule (for pay), as indicated by communications between the two mathematicians [Dunn and Shultis 2012].

Because mobilities for positive and negative ions are only slightly different, the pulse mode signals produced are small for typical operating voltages applied to ion chambers; however, they are much more consistent in magnitude than the case in which electrons dominate. Nevertheless, there is some dependence of the pulse magnitude on the energy deposited and the resulting induced signal formed from the drifting ions. Background and electronic noise further degrade the spectroscopic performance. Consequently the ion chamber typically cannot be used for energy spectroscopy. However, these detectors can be used in current mode to measure high radiation fields.

Case 3: Moderate Electron Attachment If the ion chamber is contaminated with an electronegative gas, the electrons are lost by electron attachment according to Eq. (9.49) and Eq. (9.50). In pulse mode operation, the positive ions and electrons are rapidly separated; hence, it is assumed that recombination is minimal. Electrons lost from attachment to neutral molecules become slow moving negative ions. But if electrons are the main contributor to the current, the instantaneous current produced at time t is

$$I = \frac{dQ}{dt} = -\frac{q_e N_o}{d}\left[v_e e^{-\alpha_I t}\right], \qquad t \le \frac{d - x_0}{v_e} = t_e, \tag{9.123}$$

where α_I is the electron interaction rate coefficient. Integration of Eq. (9.123) yields the time dependent input voltage from the detector as

$$V_{in}(t) \simeq -\int_0^t \frac{q_e N_o}{Cd}\left[v_e e^{-\alpha_I t'}\right] dt' = -\frac{q_e N_o}{Cd}\left[\frac{v_e}{\alpha_I}(1 - e^{-\alpha_I t})\right], \quad t \le t_e. \tag{9.124}$$

Within the electron collection time t_e, the electrons have either attached to neutral molecules or have been collected. The induced signal is position dependent, dominated by electron motion (unless α_I is very large). The observed slope of the time dependent signal decreases with t, thereby reducing the output signal below that expressed by Eq. (9.116).

After the electrons have been collected, the positive ions continue to drift and produce an induced voltage described by

$$V_{in}^{+}(t) = -\frac{q_e N_o t}{Cd}\left[\mu_{ion}^{+}\mathcal{E}\right], \qquad t \le \frac{x_0}{\mu_{ion}^{+}\mathcal{E}} = t_{ion}. \tag{9.125}$$

The heavy negative ions produced from electron attachment also continue to drift. Assuming that $v_e \gg v_{ion}^{-}$, the input voltage produced by the heavy negative ions is found to be (see Exercise Problem 9.7)

$$V_{in}^{-}(t) = -\frac{q_e N_o v_e}{Cd}\left\{\frac{\mu_{ion}^{-}\mathcal{E}}{v_e}t + \frac{e^{-\alpha_I t_e}}{\alpha_I}\left[1 - \exp\left(\frac{\alpha_I t \mu_{ion}^{-}\mathcal{E}}{v_e}\right)\right]\right\}, \quad t \le \frac{d - x_0}{\mu_{ion}^{-}\mathcal{E}}. \tag{9.126}$$

The total input voltage from the detector with moderate electron attachment is found by summing Eq. (9.124), Eq. (9.125), and Eq. (9.126). An example is shown in Fig. 9.20.

9.4.2 Coaxial Ion Chambers

In Chapter 8, it was shown that the charge induction for a coaxial detector was a function of the inner electrode diameter and the outer electrode diameter. The shape of the signal output changes significantly depending upon the bias configuration. Typically, a positive voltage is applied to the inner electrode, as shown in Fig. 9.21. The charge induction for electrons and positive ions is given by Eq. (8.79) which can be written as

$$\Delta Q = q_e N_o \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1}\left\{\ln\left(\frac{r_2'}{r_0}\right) - \ln\left(\frac{r_1'}{r_0}\right)\right\}. \tag{9.127}$$

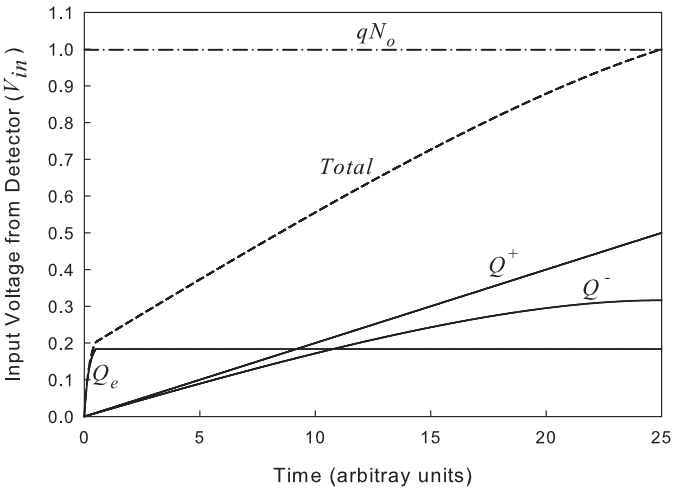

Figure 9.20. Normalized detector input voltage $V_{in}(t)$ for an ion chamber with moderate electron attachment. Shown is the case for $v_e = 50v_{ion}$, $x_o = 0.5d$ and $RC = \infty$. $V(t)$ is the sum of induced voltage from electrons (Q_e/C), positive (Q^+/C), and negative (Q^-/C) ions.

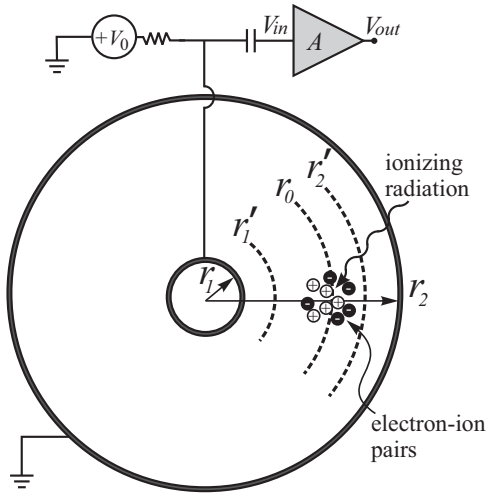

Figure 9.21. Depiction of an ion chamber of cylindrical design.

The electric field for a cylindrical detector is given by Eq. (8.75), namely,

$$\mathcal{E}(r) = \frac{V_0^+}{r} \ln\left[\frac{r_2}{r_1}\right], \tag{9.128}$$

where V_0 is the positive voltage applied to the inner electrode. Because the electric field now varies with r, the drift speeds of the charge carrier are position dependent such that

$$v^{\pm}(r) = \mu^{\pm}\mathcal{E}(r) = \mu^{\pm}\frac{V_0}{r} \ln\left[\frac{r_2}{r_1}\right]. \tag{9.129}$$

The minimum electron speed is at radius r_2, namely,

$$v_{min}^{-} = \mu_e^{-}\frac{V_0}{r_2} \ln\left[\frac{r_2}{r_1}\right]. \tag{9.130}$$

If the electron speed is much higher than the positive ion speed, as is usually the case, then the electrons are swept out much more rapidly than the ions, thereby contributing the most to the induced charge, as was found for the planar case. Just after the electrons have been collected $r_1' = r_1$ and the positive ions have moved little, i.e., $r_2' \simeq r_0$, the induced charge is, from Eq. (9.127),

$$\Delta Q(t_e) = q_e N_o \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \ln\left(\frac{r_0}{r_1}\right) = q_e N_o \left[\ln(R_{21})\right]^{-1} \ln\left(R_{21}\frac{r_0}{r_2}\right), r_0 \geq r_1 \tag{9.131}$$

where R_{21} is the ratio r_2/r_1. Reversal of the bias polarity yields the induced charge just after the electrons

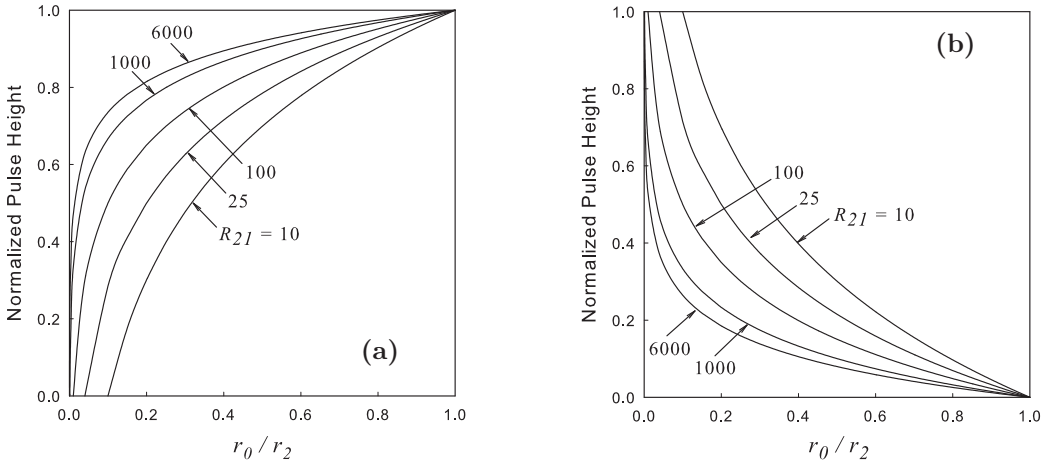

Figure 9.22. The normalized induced charge $\Delta Q/(qN_o)$ just after the electrons have been collected for a cylindrical ion chamber as a function of interaction location r_0 and ratio R_{21}. In (a) positive bias is applied to the inner electrode of radius r_1 and the outer electrode at r_2 is grounded. In (b) negative bias is applied to the inner electrode with outer electrode grounded. Applying positive voltage to the inner electrode has the clear advantage of producing larger signals over much of the detector volume.

have been collected

$$\Delta Q(t_e) = q_e N_o \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \ln\left(\frac{r_2}{r_0}\right) = -q_e N_o \left[\ln(R_{21})\right]^{-1} \ln\left(\frac{r_0}{r_2}\right), r_0 \geq r_1. \tag{9.132}$$

The dependency of $V_{in}(t)$ on radiation interaction location, the ratio r_2/r_1 and the bias voltage polarity is shown in Fig. 9.22.

The predicted electron drift speed is complicated by the fact that low energy (thermal) electrons, with an average energy of $3/2kT$, lose very little energy when colliding with a heavy ion. Hence, as an electric field is applied to a gas, free electrons gain much higher energies than the average thermal energy. The ratio between the electron characteristic energy (ϵ_K) and the thermal energy is denoted by the ratio ξ. As result, the mobility of the electrons is not constant but is a function of the electric field. To develop the expected time-dependent pulse shape from a coaxial ion chamber, the following semi-empirical relation is adopted for the electron speed [Wilkinson 1950], namely,

$$v_e = C_1 \left(\frac{\mathcal{E}}{P}\right)^{1/2}. \tag{9.133}$$

Here C_1 is an experimentally determined constant. This expression is valid for low values of reduced electric fields.

The input pulse into the coupling electronics is

$$V_{in}(t) = \frac{\Delta Q(t)}{C}, \tag{9.134}$$

where C is the combined coupling and detector capacitance. Because the electron drift speeds are much greater than those of the positive ion, the charge induction between $0 \leq t \leq t_e$ is dominated by electron motion. From Eq. (8.44) for $r_2' \simeq r_0$ one has

$$\Delta Q(t) \simeq q_e N_0 \left[\ln\left(R_{21}\right)\right]^{-1} \ln\left(\frac{r_0}{r_e(t)}\right), \tag{9.135}$$

where r_0 is the radial location of the initial ionization event and $r_e(t) = r_1'(t)$ is the electron cloud location at time t. The electron drift speed changes with radial location as

$$v_e(r) = -\frac{dr}{dt} = \frac{C_1}{P^{1/2}}\mathcal{E}(r)^{1/2} = \frac{C_1}{P^{1/2}}\left[\frac{V_0}{r\ln(R_{21})}\right]^{1/2}. \tag{9.136}$$

Integration of this result gives

$$-\int_{r_0}^{r-e(t)} r^{1/2}\,dr = \int_0^t \frac{C_1}{P^{1/2}}\left[\frac{V_0}{\ln(R_{21})}\right]^{1/2} dt \tag{9.137}$$

or

$$\frac{2}{3}\left(r_0^{3/2} - r_e^{3/2}(t)\right) = \frac{C_1}{P^{1/2}}\left[\frac{V_0}{\ln(R_{21})}\right]^{1/2} t. \tag{9.138}$$

The electron sweep out time t_e, i.e., when $r_e(t_e) = r_1$, is found to be

$$t_e = \left(r_0^{3/2} - r_1^{3/2}\right) \Big/ \frac{3}{2}\frac{C_1}{P^{1/2}}\left[\frac{V_0}{\ln(R_{21})}\right]^{1/2}. \tag{9.139}$$

Equation (9.138) can be solved for $r_e(t)$ and combining this result with Eqs. (9.135) and (9.134) yields the pulse height $V_{in}(t)$ as a function of time, namely,

$$V(t) = -\frac{qN_0}{C\ln(R_{21})}\left[\ln r_0 - \ln\left\{r_0^{3/2} - \frac{3}{2}\frac{C_1}{P^{1/2}}\left[\frac{V_0}{\ln(R_{21})}\right]^{1/2} t\right\}^{2/3}\right]. \tag{9.140}$$

The general voltage pulse height time response for coaxial ion chambers, with positive voltage applied to the central wire, is shown in Fig. 9.23. Although the coaxial ion chamber pulses are still dominated by electron motion, the coaxial geometry reduces the problem of widely varying position-dependent pulses that occurs in planar ion chambers.

9.5 Ion Chamber Designs

Ion chambers have been used as radiation detectors from the time of Rutherford's and Geiger's invention of the gas-filled radiation detector. Designs have been improved over the past 100 years to reduce leakage current, stabilize output, and reduce the dependence on the position of the ionizing event. A list of specialized ion chambers would be much too long to cover in the present work, but descriptions for many of these devices can be found in the literature [Rossi and Staub 1949; Staub 1953; Price 1964; Boag 1966, 1986; Attix 2004; Sauli 2014]. Presented here are several common designs encountered in radiation detection and measurement.

The profile of energy deposition in an ion chamber depends on the gas container, the type of gas and the gas pressure. Penetrating radiation, such as gamma-rays, interact readily with the chamber walls, producing energetic electrons (photoelectrons, Compton electrons, or, if $E_\gamma > 1.022$ MeV, electrons and positrons from pair-production). These secondary electrons, if sufficiently energetic, can escape the walls and enter the gas, thereby producing a cloud of electron-ion pairs. The response of the chamber to these secondary electrons can be altered by lining the chamber with materials having of varying Z to change the probability a gamma-ray interacts in the wall and the probability a secondary electron escapes into the gas. Gamma rays can also interact directly with the chamber gas. Increasing gas pressure and the Z number of the detection gas both increase the efficiency of the detector. Because ion chambers are usually designed to measure the electrons produced by ionization, except in special cases, the contribution of the ion motion is minor. Hence, the adverse effects that increasing gas pressure has on ion motion are of little consequence, and the electron speeds remain high.

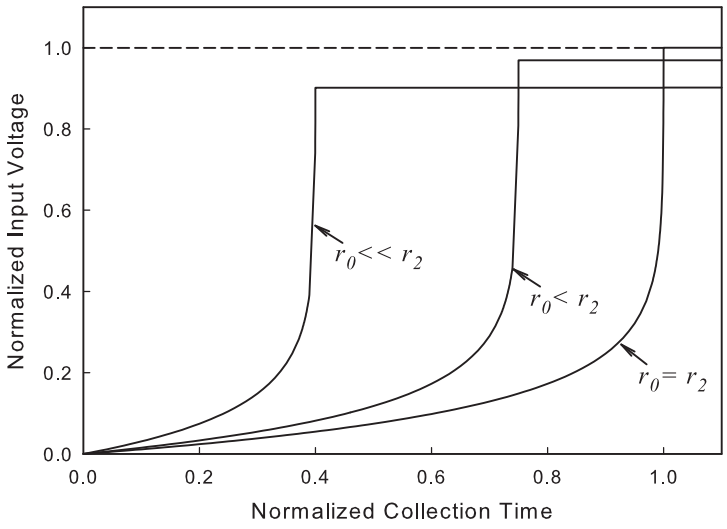

Figure 9.23. Normalized input voltage as a function of normalized time, where $t = 1$ is the drift time between r_2 and r_1 and $R_{21} = 500$. Shown are the cases in which a radiation interaction occurs at the cathode, and at two different locations within the detector where $r_0 < r_2$.

9.5.1 Basic Designs and Characteristics

Although an ion chamber is a simple concept, there are important design details that cannot be overlooked. For instance, the insulators must be selected to reduce leakage current during operation in a radiation field. The resistivity of the feedthroughs must be extremely high to reduce leakage current from moving around the device from anode to cathode.

Planar Ion Chamber Designs

A simple planar ion chamber configuration and its equivalent circuit are shown in Fig. 9.24. A voltage V_0 is applied across the chamber volume and load resistor R_L. Because the actual gas chamber resistance R_C is extremely high, almost all of the voltage is dropped across the chamber and very little across the load resistor. As a result, most of the voltage is also dropped across the insulating feedthroughs and the chamber body. The resistance of the feedthroughs and chamber are represented by R_F, and the leakage current is $I_L = V_0/R_F$. The leakage current can be reduced by using high resistance materials, thereby ensuring that R_F is large and I_L is small.

The detector input voltage becomes contaminated by the leakage current, becoming $V_{in} = (I_C + I_L)R_L$. The leakage current adds white noise and can produce an incorrect assessment of the radiation environment. To illustrate the problem, a common ion chamber operated at the modest voltage of 100 V requires the insulator feedthroughs have a combined resistance of 10^{16} Ω to keep the leakage current below 10^{-14} amp. By comparison, the background current produced by cosmic rays

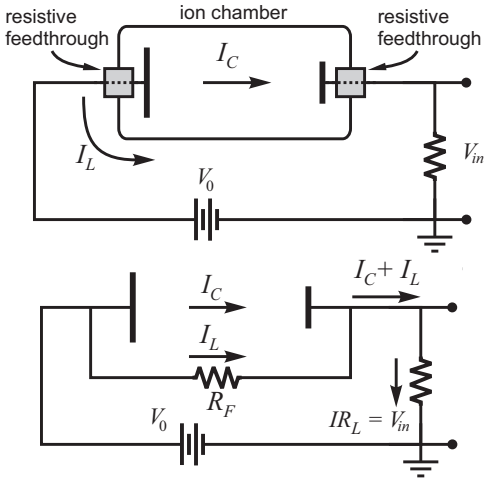

Figure 9.24. (Top) Planar ion chamber. (Bottom) The equivalent circuit model for the planar ion chamber.

is on the order of 10^{-16} amp. Common high resistivity materials used for electrical feedthroughs include Teflon ($\simeq 10^{25}$ Ω cm), quartz ($\simeq 7.5 \times 10^{19}$ Ω cm) and alumina ($\simeq 10^{16}$ Ω cm).

Although the volumetric resistivity of many candidate materials is sufficiently high to serve as feedthroughs, it is usually the surface leakage current that causes problems. The surface leakage is largely dependent on the cleanliness of the surface and the ability of the insulator to absorb moisture. Scratches or other surface damage can also increase surface leakage current. Many attractive high resistivity materials, such as Teflon, undergo resistivity changes as a result of radiation damage. If the ion chamber is to be operated in high radiation fields, materials to be avoided include plastics, Teflon and, under some circumstances, polystyrene. Many ceramic materials, such as alumina and quartz, appear to have much better radiation resistance, and therefore are frequently used as feedthroughs for ion chambers.

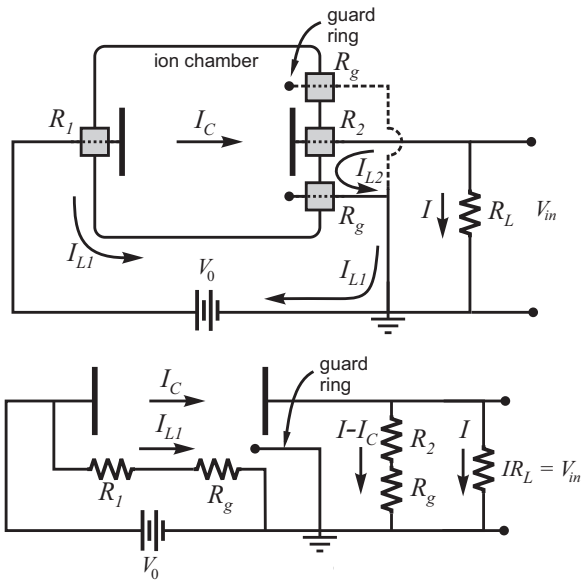

Figure 9.25. (Top) Planar ion chamber with a guard ring. (Bottom) The equivalent circuit model for the planar ion chamber with a guard ring.

An interesting consequence of using plastics and polystyrene, or other soft insulating materials, is the generation of *stress* currents. Stress currents arise from electron migration through the insulator when the material is under high voltage. Although not an issue for systems with detection currents greater than 10^{-13} amp, stress currents can become problematic for chamber currents less than 10^{-14} amp. Thus, the stress current can determine the lower limit of sensitivity for the ion chamber. Dielectric strength is a measure of the electric stress required to abruptly move substantial charge on or through a dielectric. Ceramic materials such as alumina and quartz appear to have low stress currents.

One method to reduce bulk and surface leakage through and around an insulator is to incorporate a guard ring into the detector. A planar ion chamber with a guard ring is depicted in Fig. 9.25, along with the equivalent circuit. The guard ring is placed around the collection electrode and grounded into the detector circuit, as shown in Fig. 9.25. The operating voltage is applied across the chamber, and leakage current I_{L1} flows through (or around) the resistive feedthroughs for the electrode, with resistance R_1, and guard ring, with resistance R_g. This leakage current I_{L1} bypasses the loading resistor R_L and instead returns to ground. Hence, the leakage current I_{L1} does not contribute to V_{in}.

The voltage drop across the guard ring insulator and the collection electrode insulator is determined by leakage current I_{L2}, as depicted in Fig. 9.25. However, because almost all voltage is dropped across the high resistance of the ion chamber, the actual voltage drop between the guard ring and the collection electrode is practically zero; hence, $V_{g-2} = I_{L2}(R_2 + R_g) \simeq 0$, meaning that the leakage current I_{L2} is practically zero as well. As a result, the measured detector current has little contamination from leakage currents.

Guard rings are often employed to define a specific region in the detector that is sensitive to radiation. Electrons and ions collected by the guard ring produce induced current that returns to ground without adding to $IR_L = V_{in}$. As a result, radiation interactions in the electric field region influenced by the guard ring go undetected. The free air ion chamber, discussed in a later section, is one such example of an ion chamber with a sensitive region well defined by a guard ring.

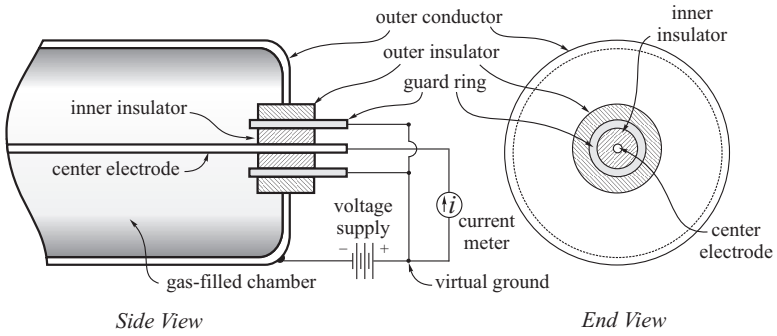

Figure 9.26. Depiction of a coaxial ion chamber with a guard ring.

Coaxial Ion Chamber Designs

Coaxial detectors operate mainly with a positive voltage applied to the central electrode. For different types of detectors, the anode diameter may range between 25 microns to a few hundred microns. Coaxial proportional counters and coaxial Geiger-Müller counters typically have central anodes between 25 to 100 microns in diameter for reasons discussed in Chapters 10 and 11.

Due to the cylindrical geometry, there is a higher probability that gamma rays interact in the larger volume of gas nearest the cathode than in the smaller volume near the anode. This effect is referred to as *geometrical weighting* [McGregor and Rojeski 1999]. As a result the coaxial design reduces the position dependence of the induced signal V_{in} that is transferred to the electronics, as shown in Fig. 9.22(a). Although negative voltage can be applied to the anode, the average voltage signal produced is considerably less, as shown in Fig. 9.22(b).

Guard rings are usually used in coaxial ion chambers as depicted in Fig. 9.26. Just as a guard ring is used in a planar chamber, the guard ring is fashioned so that the leakage current is diverted from adding to the detector signal. Detector leakage currents on the order of only 10^{-16} amp have been successfully realized in designs of coaxial ion chambers. However, variations in the insulator design and other irregularities can blur the edges of the active region in a coaxial ion chamber. Often a second guard ring is placed around the first guard ring, referred to as a *field tube*, to define better the active region of the detector. Because field tubes have a special importance to the operation of proportional counters, a discussion on field tubes is delayed until Chapter 10.

9.5.2 Gamma-Ray Ion Chamber Designs

Gamma-ray ion chambers, operated in the current mode, are stable, have long lives, and they can be fabricated in a variety of sizes and shapes. Large ion chambers are used as area monitors for ionizing radiation, and high-pressure chambers offer a relatively high sensitivity, permitting measurement of exposure rates as low as 1 μR/h. Small chambers with low gas pressures can be operated in radiation fields with exposure rates as great as 10^7 R/h.

Because of the lower energy deposition $(-dE/dx)$ of electrons compared to that of heavy charged particles, electrons produced by gamma-ray interactions in the gas often have ranges greater than the dimensions of an ion chamber. As a result, the energy deposition by electrons is usually less than that for heavy charged particles and, consequently, the resulting input voltage V_{in} is smaller for electrons. Obviously, ion chambers operating at relatively low gas pressures have lower efficiencies than those with higher pressures.

Sensitivity to gamma rays can be enhanced by lining the walls of the chambers with high Z materials to increase the interaction probability. Recall from Chapter 3 that the total interaction coefficient for gamma

rays increases with the Z number. However, the electron range decreases with Z, thereby reducing the sensitive wall thickness for which secondary electrons can escape into the detector gas.

Air-filled ionization chambers vented to atmospheric pressure are often used to measure radiation exposure. After the formation of an electron-ion pair, the electrons and ions begin to move through the gas towards their collecting electrodes. However, the electronegative oxygen atoms quickly capture free electrons to produce heavy negative ions. Because of this electron attachment, most of the free electrons disappear and the chamber current is produced by the motion of both negative and positive heavy ions. This condition is not a problem when a detector is operated in the current mode as long as the potential difference is sufficient to prevent significant charge recombination. However, such a chamber is not suited for pulse-mode operation, because the positive and negative ions move slowly compared to electron speeds in the same electric field, consequently, very few and indistinct pulses are produced.

9.5.3 Neutron-Sensitive Ion Chambers

If an ion chamber is coated with a neutron reactive material with a large neutron cross section or filled with a neutron reactive gas, such that ionizing particles are released from the neutron reactions, the chamber can be used as a neutron detector. Commonly used isotopes for neutron detectors are ^{3}He, ^{10}B, ^{6}Li, and ^{235}U. Neutron sensitive ion chambers are usually filled with $^{10}BF_3$ or ^{3}He gas, or the inside walls of the chamber are coated with ^{10}B, ^{6}LiF, or ^{235}U. These gas-filled neutron detectors can be operated as both ion chambers or proportional counters.

Ion chambers that use ^{235}U are often referred to as fission chambers, since it is the fission fragments from the ^{235}U that ionize the chamber gas. Fission chambers are often used in mixed radiation fields containing large numbers of neutrons and gamma rays. Fission fragments deposit as much as 50 times the energy as do gamma rays in a common fission chamber. Hence, when operated in pulse mode, the voltage pulses formed by fission fragments are much larger than those formed by gamma rays, thereby making it possible to discriminate between the two radiations. Due to pulse pile-up, ion and fission chambers are generally not operated in pulse mode when in high radiation fields, although some special pulse mode designs incorporating ^{235}U are used for in-core nuclear reactor monitoring. Gas-filled neutron detectors are described with more detail in Chapters 17 and 18.

9.5.4 Compensated Ion Chambers

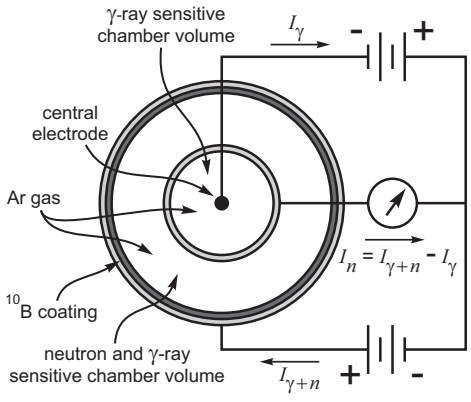

Figure 9.27. Cross section diagram of a concentric compensated ion chamber.

A form of ion chamber frequently used for control of nuclear reactors is known as the *compensated ion chamber*. Ion chambers, when operated in *current mode*, can be used in high radiation environments. If a gas-filled neutron detector is placed near a nuclear reactor, it responds to both neutrons and gamma rays. Yet, current mode operation does not permit pulse-height discrimination between neutron and gamma ray interactions as does pulse mode operation. The compensated ion chamber design is used to distinguish between the two types of radiation in high radiation fields.

Typically the chamber has two concentric electrodes and a central wire electrode. One concentric electrode is coated with a neutron sensitive material such as ^{235}U or a compound containing ^{10}B. The configuration depicted Fig. 9.27 allows both chambers to experience the same radiation field. Differences between the two chambers can be properly calibrated by adjusting

the operating voltages. The ^{10}B (or ^{235}U) coated chamber is referred to as the *working chamber* and the uncoated chamber is referred to as the *compensating chamber*. When exposed to both gamma rays and neutrons, the voltage potential for the working chamber causes current to flow that deflects the current meter in one direction. The voltage potential in the compensating chamber, sensitive only to gamma rays, causes current to flow in the opposite direction. The voltage potentials on the chambers can be adjusted such that the two gamma ray signals exactly cancel. As a result, the compensated chamber produces a net current that is directly proportional to the strength of the (thermal) neutron field. Compensated ion chambers are widely used in nuclear reactors because of their ability to respond to neutron fields that vary up to ten orders of magnitude; i.e., these detectors have a very large *dynamic range*.

9.5.5 Frisch Grid Ion Chambers

An ion chamber design attributed to Otto Frisch [Frisch 1942; Bunemann et al. 1949] practically eliminates the dependence of the output pulse height on the position of the ionizing event in ion chambers, thereby allowing the detector to be used as an energy spectrometer. Shown in Fig. 9.28 is the basic arrangement for a Frisch grid or *gridded* ion chamber design. The gridded ion chamber is separated into two compartments: one is a much larger main chamber and the other is the measurement or detector chamber. The two chambers are separated by a conductive screen. Shielding can be arranged to confine radiation interactions to the main chamber. A voltage is placed across both chambers by use of a resistive divider. The electric field is applied such that the grid is positive with respect to the cathode, and the anode (the collecting electrode in the measurement compartment) is positive with respect to the grid.

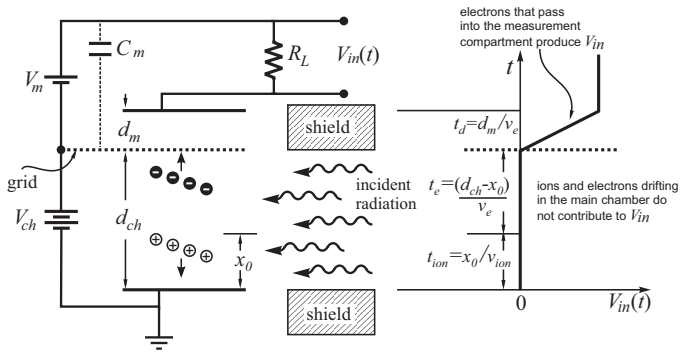

Figure 9.28. Depiction of a Frisch grid ion chamber.

Gamma rays, or other ionizing particles, that interact in the main chamber produce electron-ion pairs just as in any other ion chamber. The positive ions drift toward the cathode and electrons drift toward the grid. However, the main chamber is not connected directly to the input, and the induced current produced in the main chamber does not charge the coupling capacitance. The grid essentially shields the anode from induced current while charges move in the main chamber. As a result, charges moving in the main chamber compartment do not contribute to the voltage signal.

With sufficient speed, the electrons pass through the grid into the measurement compartment, which is connected to the output electronics. As the electrons drift through the measurement compartment, they induce an input voltage $V_{in}(t)$

$$V_{in}(t) = \frac{q_e N_0 v_e t_m}{d_m},$$

where t_m is the drift time across the measurement compartment and d_m is the length of the measurement compartment. If there is no electron attachment, the input voltage reduces to $q_e N_0$ after all electrons are collected. Note that the interaction position dependence has been eliminated from the input voltage. Further, because positive ions do not contribute to the signal, the slow signal component usually observed from ion drift is also eliminated, thereby reducing the effect of pulse height deficit.

9.5.6 Free Air Ion Chambers

A standard instrument used for radiation exposure measurements is the *free air ion chamber*. The traditional radiation exposure unit, the Roentgen, abbreviated R, is defined precisely as the quantity of x or gamma radiation that produces 2.58×10^{-4} coulomb of separated charge of either sign per kilogram of air in the incremental volume where the primary photon interactions occur. The SI exposure unit, the X unit, equals 3881 R, which is defined as the amount of x or gamma radiation that produces 1 Coulomb of charge per kg of air. Hence, by measuring the amount of ionization in air, the radiation exposure field can be determined. This task can be accomplished with a free air ionization chamber.

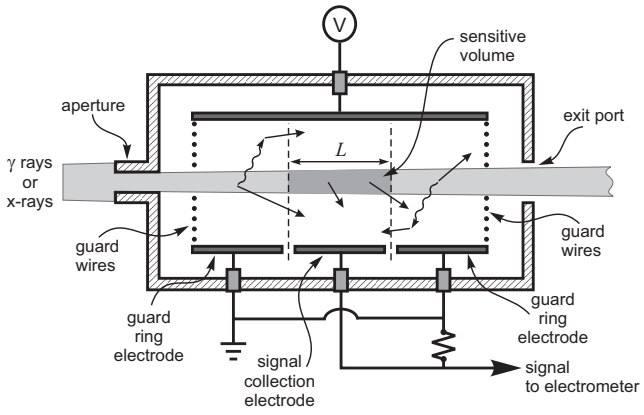

Figure 9.29. Free air ionization chamber configuration.

The chamber is constructed as shown in Fig. 9.29 with one electrode is segmented to form a guard ring structure. The chamber is shielded with lead and is filled only with air at ambient temperature. X or gamma rays enter through an aperture in the box, interact in the air, and whose reaction products then ionize the air. However, only the ionization formed in that region defined by the radiation aperture and the center electrode (of width L) is measured, thereby giving an air volume and the ionization. As a result, the radiation exposure can be determined.

Here the initial assumption is that ion recombination does not significantly affect measured results. However, the high density of O_2 indicates that significant electron attachment will occur in the chamber which can result in recombination losses. To reduce the effect of charge loss to recombination, the ionized volume is kept small, and it is the replenishment of ionized charges in the sensitive volume that indicates the radiation exposure.

Two important design features should be noted. First the interaction rate density along the photon beam inside the chamber must be relatively constant, and second the length of the beam on either side of the central portion of length L must be at least equal to the maximum distance in which ions are produced from the primary photon interaction location. Thus, ions produced outside of L by interactions in L are exactly compensated for by ions produced in L by photon interactions outside of L. This compensation is called *charged particle equilibrium* [Shultis and Faw 2002] and is central to radiation dosimetry.

Because of the need for charge particle equilibrium, the use of the free air ionization chamber is limited to photons with energies less than about 500 keV [Cember 1983]. Although larger units would allow measurements of radiation exposure for higher energy gamma rays, such chambers appear to be impractically large and would require much more extensive shielding.

Example 9.5: A free air ionization chamber is operated at 20°C with air pressure of 750 torr. The chamber aperture diameter is 1 cm and the signal collection electrode is 4 cm in length. At 150 volts operating bias, a current of 12 nA is measured. What is the radiation exposure rate?

Solution:

As discussed earlier, electron attachment is severe in air; hence, almost all electrons undergo electron attachment before collection and, thereby produce heavy negative ions. However, because the exposed volume is small compared to the chamber size, the positive and negative ions are quickly separated so that it is assumed that few ions recombine.

The pressure and temperature must be corrected for the standard conditions of radiation exposure rate. Hence,

$$\frac{dX}{dt} = \frac{I}{\rho_0 V_{ch}} \frac{P_0}{P} \frac{T}{T_0}$$

where V_{ch} is the sensitive volume of the chamber, ρ_0 is the air density, and P_0 and T_0 are the standard pressures (in torr) and absolute temperatures.

The sensitive volume is $V_{ch} = \pi(0.5)^2(4)$ cm^3 = 3.14 cm^3. The density of air at standard conditions is 1.2922×10^{-6} kg/cm^3. The resulting exposure rate is

$$\frac{dX}{dt} = \frac{1.2 \times 10^{-8}\text{A}}{(1.2922 \times 10^{-6}\ \text{kg/cm}^3)(3.14\ \text{cm}^3)} \left(\frac{760\ \text{torr}}{750\ \text{torr}}\right) \left(\frac{293.15\ \text{K}}{273.15\ \text{K}}\right)$$

$$= 3.214 \times 10^{-3}\ \text{X-units/sec} = 12.47\ \text{R/sec}$$

9.5.7 Pocket Ion Chambers

Compact ion chambers, often referred to as *pocket ion chambers*, are a convenient method to measure exposure to radiation. There are fundamentally two types of pocket ion chambers, one is a condenser-type chamber and the other an electroscope chamber, both shown in Fig. 9.30. The condenser-type ion chamber is a form of air-wall ion chamber, in which the air volume is relatively small, usually on the order of 2 cm^3, with walls composed of "air-equivalent" material. The condenser pocket ion chamber operation is quite simple. Coaxial in form, the outer portion is composed of electrically conducting plastic with a gamma-ray response equivalent to pressurized air. A central wire is attached inside the chamber through insulating standoffs, and is positively charged with respect to the outer wall. These chambers are typically backfilled with air. As radiation interactions occur within the chamber walls, the resulting ionization discharges the condenser such that the stored voltage decreases. The decrease in voltage is directly correlated to the energy deposited within the chamber, thereby yielding a measure of the radiation exposure. The condenser pocket ion chamber is conveniently simple, but must be read from a charging device. The sensitivity of common condenser pocket ion chambers ranges from 25 mR to 250 R.

The electroscope pocket ion chamber is closely related to the gold leaf electroscope. These devices are commonly used to measure relative radiation exposure for the wearer. The device consists of a tube approximately 10 cm long and 1 cm in diameter. Inside the tube are two small metal-coated quartz fibers, each approximately 4 microns in diameter. One of the quartz fibers is stationary and the other is hinged, and both are inside an air cavity of the tube. The tube also has viewing optics such that when held up to a light, the observer can see the shadow of the hinged quartz fiber against a display scale. The device is inserted into a power supply and charged so that the two fibers, having like charges, are repulsed apart. This charged-up device can now be worn as a dosimeter. Electrons produced by ionization caused by radiation interactions in the chamber are attracted to the quartz fibers, thereby reducing the net charge and causing the quartz fibers to move closer together. The change in location of the hinged fiber yields the change in exposure to the wearer, which is determined by the change in location of the fiber with respect to the display scale in the tube (maximum scale is usually 200 mR).[14] The clear advantage of the electroscope pocket ion chamber is the convenient method of viewing the exposure. However, interpretation of the exposure is visually left to the user rather than a measuring instrument.

[14] The Federal Civil Defense Administration (FCDA) had millions of pocket ion chambers produced during the 1950s and 1960s for civilian use. By far the most popular pocket ion chamber, the V-742, was read in units of R with a maximum range of 200 R. Some of the units ranged up to 600 R (V-746), although the production run was limited to only a few hundred units.

9.5.8 Cloud Chambers

Cloud chambers are a type of ion chamber, but certainly not in the traditional electronic sense. Developed by Charles Thomson Rees Wilson in 1911 (see [Wilson 1912]), the initial devices operated on the principle of cooling by adiabatic expansion. In the original device, an ionizing radiation source was placed inside an air-filled cylinder outfitted with a tightly sealed plunger. With the plunger in a nearly closed position, the air in the cylinder compartment was saturated with water vapor. When the plunger is rapidly retracted, the rapid decrease in temperature and pressure causes the water vapor to condense, particularly upon ions in the chamber. The condensation upon these ions makes the ionization tracks visible to the eye. The effect is near immediate and quite dramatic. Although the cloud chamber is a simple device, it led to numerous discoveries, including the discovery of the positron (1932), the muon (1936), and the kaon (1947).[15] The cloud chamber works best with electro-negative gas molecules, for which electron attachment is rapid, thereby retarding the diffusion of the negative ions and prolonging the visual effect [Sitar et al. 1993].

Expansion Cloud Chambers

Consider the expansion cloud chamber depicted in Fig. 9.31(a). The chamber is filled with a non-condensible gas that adequately follows the ideal gas law. A vapor, water for instance, is added to the chamber such that it reaches saturation. Initially, the partial pressure of the gas is P_{g1} and the partial pressure of the vapor is P_{v1}. If the total mass of the vapor is m_{v1} at absolute temperature T_1 and chamber volume V_1, then,

$$P_{v1}V_1 = \frac{m_{v1}}{M}RT_1 \tag{9.141}$$

where M is the molecular weight of the vapor molecules and R is a constant. If the piston is rapidly retracted to cause a sudden expansion in the closed system, in which the volume V_1 is expanded to V_2, then the temperature immediately reduces from T_1 to T_2'. For an ideal gas, undergoing a reversible adiabatic

[15] For his invention of the cloud chamber, Charles Thomson Rees Wilson shared the 1927 Nobel prize in physics with Arthur Holly Compton.

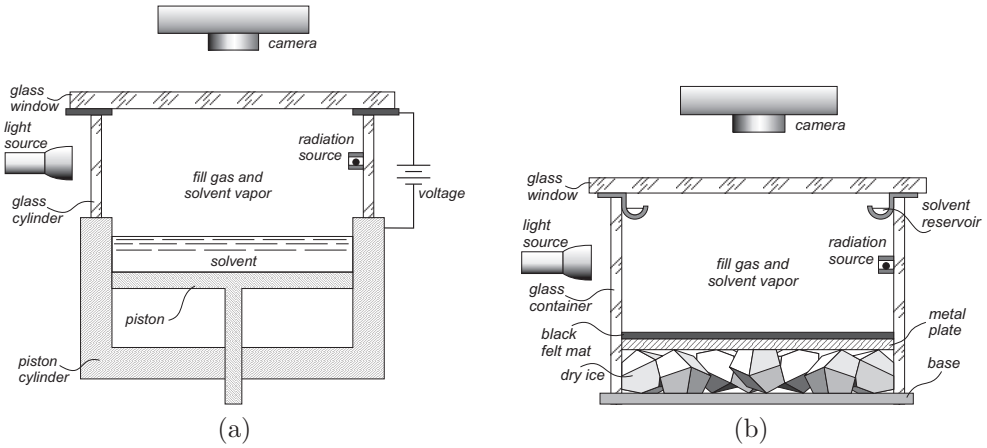

Figure 9.31. (a) Basic components of an expansion cloud chamber and (b) basic components of a diffusion cloud chamber.

process [Das Gupta and Ghosh 1946],

$$\frac{T_1}{T_2'} = \left(\frac{V_2}{V_1}\right)^{\gamma-1}, \tag{9.142}$$

where γ is the adiabatic index[16] for the *gas mixture*

$$\gamma = \frac{C_P}{C_V}. \tag{9.143}$$

Here C_P is the specific heat capacity at constant pressure and C_V is the specific heat capacity at constant volume. Immediately after the expansion, but before condensation takes place, the new vapor partial pressure is

$$P_2' V_2 = \frac{m_{v1}}{M} R T_2', \tag{9.144}$$

where the vapor mass is the same as before, but now distributed over the new volume V_2. Yet, this state is short lived, because the cooling causes part of the water vapor to condense, thereby changing the partial pressure, vapor mass and the temperature (slightly). As equilibrium is reached, the temperature rises slightly from T_2' to T_2, caused by the condensation of vapor. The equilibrium condition is

$$P_2 V_2 = \frac{m_{v2}}{M} R T_2, \tag{9.145}$$

where m_{v2} is the equilibrium vapor mass. The density of the vapor immediately after the piston is retracted is represented by

$$\rho_2' = \frac{m_{v1}}{V_2} \tag{9.146}$$

and after the system has reached equilibrium, the density of the vapor is

$$\rho_2 = \frac{m_2}{V_2}. \tag{9.147}$$

[16] Also called the heat capacity ratio or ratio of specific heats.

The amount of supersaturation can be defined as the ratio of the densities of ρ_2' to ρ_2, i.e.,

$$S = \frac{\rho_2'}{\rho_2} = \frac{m_{v1}}{m_{v2}} = \frac{P_1 V_1 T_2}{P_2 V_2 T_1}. \tag{9.148}$$

Dividing Eq. (9.144) by Eq. (9.145) also yields,

$$S = \frac{P_2'}{P_2}\frac{T_2}{T_2'}. \tag{9.149}$$

If the temperature rise from condensation is small, then $T_2' \simeq T_2$, and with the substitution of Eq. (9.142) into Eq. (9.148) one obtains [Das Gupta and Ghosh 1946]

$$S \simeq \frac{P_1}{P_2}\left(\frac{V_1}{V_2}\right)^{\gamma} = \frac{P_1}{P_2}\left(\frac{1}{F_C}\right)^{\gamma}, \tag{9.150}$$

where F_C is the expansion ratio. Note that the supersaturation is strongly dependent upon γ and the partial vapor pressure P_2. The required expansion ratio to produce a specific amount of supersaturation decreases with increasing γ. Smaller expansion ratios are desirable because the lower amount of volumetric disturbance reduces gas turbulence that can blur the ionization tracks.

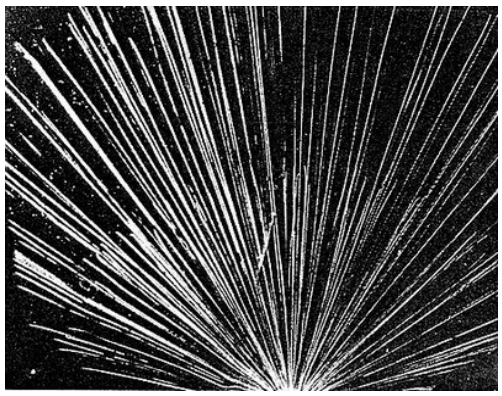

Figure 9.32. Ionization tracks produced by alpha particles in a cloud chamber [http://klarifi.blogspot.com/search/label/nuclear Dec. 2013]

The rapid decrease in gas temperature causes a supersaturation of the water vapor, which enables the water to condense on select surfaces. If the vapor pressure of small water droplets is lower than the supersaturation, the droplets then grow in size, and continue to increase in size until the vapor pressure of the droplets corresponds to the supersaturation condition. As the drops are forming, thermal conduction is heating the chamber gas and reducing the degree of supersaturation, which rapidly returns the gas mixture to the equilibrium condition. The time duration over which the supersaturation conditions permit the formation of visible tracks is relatively short, usually lasting between a few milliseconds to a few seconds.

Viewing is best performed from the top of the chamber through a clear glass window (see Fig. 9.31(a)). Gravity pulls the vapor tracks downward, and diffusion broadens the tracks. Together these two effects serve to blur images if viewed from the side; however, if viewed from the top, blurring from gravity is kept to a minimum, as shown in Fig. 9.32. There is also the possibility of producing turbulence in the gas when the piston is withdrawn, causing additional distortions in the ionization tracks.

Competing condensation surfaces include the chamber walls and foreign matter in the chamber. It can be shown that small particle surfaces have higher vapor pressures than smooth planar surfaces [Staub 1953]; hence operating the system with optimized expansion ratios reduces (or eliminates) surface condensation while permitting condensation on neutral and charged particles. The system can be cycled a few times to reduce the background contamination, such as dust, from the system. Dust particles and other contaminants appear as a faint fog in the chamber when first operated, but eventually drop into the solvent solution from gravity, thereby being cleared from the gas after a few cycles. Tracks formed from ions can be cleared from the system by temporarily applying a voltage across the chamber volume, which resets the system for the next expansion operation.

Diffusion Cloud Chambers

A simpler method of achieving the needed supersaturation condition is used in the diffusion cloud chamber [Wilson 1951]. Depicted in Fig. 9.31(b), the diffusion cloud chamber operates with a temperature gradient from the top to the bottom of the chamber. The chamber bottom is filled with dry ice and covered with a metal plate. Typically a black felt or velvet mat is placed over the metal plate to improve viewing contrast. A reservoir of solvent is placed near the top of the chamber. The entire chamber is covered with a transparent window, usually glass, although modern cloud chambers have plastic lids. Often the lid is slightly warmed to produce a thermal gradient from the lid to the chilled metal plate. The solvent vaporizes and diffuses throughout the chamber, thereby causing the supersaturation condition to appear in the lower temperature region of the chamber.

Diffusion cloud chambers are commonly operated with air as the gas and with either methanol or ethanol as the solvent. These gases and vapors have good electron attachment, facilitating the formation of heavy negative ions, which helps with the formation of visible particle tracks.

Advantages of the diffusion cloud chamber design include the continuous mode of operation and the lack of moving parts, thereby reducing gas turbulence. However, the radiation source must be placed in a location above the region of condensation or condensate coats the source and attenuates the ionizing radiation. For alpha particle sources, the condensate can completely block the alpha particles from emerging into the chamber. Because of its simplicity, diffusion cloud chambers are often used as demonstration devices for classroom instruction.

9.5.9 Smoke Detector Ionization Chambers

A typical form of smoke detector commonly found in a household environment is actually a small free air ionization chamber with an embedded ^{241}Am source that emits alpha particles. It can detect particles of smoke that are too small to be visible. The alpha particles produce ionization in the tiny ion chamber, which consists of an air-filled space between two electrodes, and permits a small, constant current to flow between the electrodes. Smoke entering the chamber absorbs and neutralizes the alpha particles, thereby reducing the alpha-particle induced ionization and current flow. This reduction in current sets off the alarm. Hot air entering the chamber can change the rate of ionization, thereby altering the current and setting off the alarm.

9.6 Summary

There are five distinct regions of operation for a gas-filled detector, the first two appearing at the lowest voltages, identified as the recombination and ion chamber regions. At low applied voltages, charge pairs may recombine, consequently nullifying, at least partially, the charge current induction effect necessary for signal formation. The recombination probability is a strong function of the electron attachment coefficient, the charge carrier diffusion coefficient, the gas density (pressure), and the applied voltage. At high enough voltages, the free charges can be collected at the detector electrodes with reasonably high efficiency. Such voltages are identified as the ionization chamber region of operation. Ion chambers can be operated in current mode or pulse mode. Current mode operation is usually employed for relatively high radiation fields, while pulse mode operation is usually employed for relatively low count rates ($< 5 \times 10^4$ cps). Under pulse mode operation, the signal from a ion chamber is strongly dependent on the electron motion and less so on the heavy ion motion. Ion chambers can be acquired in a variety of configurations and are often application specific.

PROBLEMS

1. A planar ion chamber with spacing between the electrodes of 3 cm is biased at 600 volts. The backfill gas is P-10 filled at 1 atm. Unfortunately, the P-10 is contaminated with 0.04% O_2. Determine the maximum fractional electron losses due to electron attachment for the detector.

2. Verify the general solution of Eqs. (9.79) and (9.80).

3. Use the boundary conditions to obtain solutions of Eqs. (9.81) and (9.82).

4. Verify the approximations of Eqs. (9.83) and (9.84), and then use these results to obtain Eqs. (9.85).

5. An ion chamber backfilled with air at 1 atm is operated at 200 volts. The electrode spacing is 4 cm. The time constant of the detector is much less than the collection time for ions, but much longer than the collection time for electrons. If a 5.5 MeV alpha particle enters into the chamber center parallel to the electrodes and deposits all energy in the gas, what is the total value of free charge measured?

6. A planar ion chamber with electrodes spaced 2 cm apart is backfilled with 1 atm air at 20°C. Both anode and cathode electrodes are square, with area 4 cm^2 each. The chamber is then fully irradiated with a one curie (Ci) 200-keV gamma-ray source at a distance of 25 cm from the detector. At what voltage is the 90% saturation current reached?

7. Given the case in which $v_e \gg v_{ion}^-$, derive Eq. (9.126).

8. A free air ion chamber is operated at 200 volts.

The properties of the chamber include the following:
Electrode separation = 5 cm
Aperture diameter = 1.5 cm
Anode/cathode width = 2.5 cm
The operating conditions include:
Temperature = 82°F
Pressure = 1.05 atm
The operating response = 0.0095 μA
(a) What is the exposure rate from the radiation entering the chamber?
(b) The operator was in the radiation environment for 15 minutes. What is the integrated exposure in X-units and roentgens?

9. The operating voltage of the free air ion chamber in Example 9.5 is increased to 200 volts with a resulting current of 1.3×10^{-8} A. What is the corrected exposure as compared to the result of Example 9.5?

10. A pressurized condenser type pocket ion chamber has a chamber capacitance of 100 pF. When fully charged, the chamber registers a voltage of 100 volts. The volume of the device is 10 cm^3, backfilled with air at a pressure of 3 atm. After a tour of a radiation facility, the wearer of the ion chamber reads a change in voltage of -4 volts. What was the radiation exposure?

Chapter 10

Gas-Filled Detectors: Proportional Counters

I've worked on many detectors, some were very elegant and useless, and didn't have a Nobel Prize, so this one was not the most elegant, but it was useful.

Georges Charpak[1]

10.1 Introduction

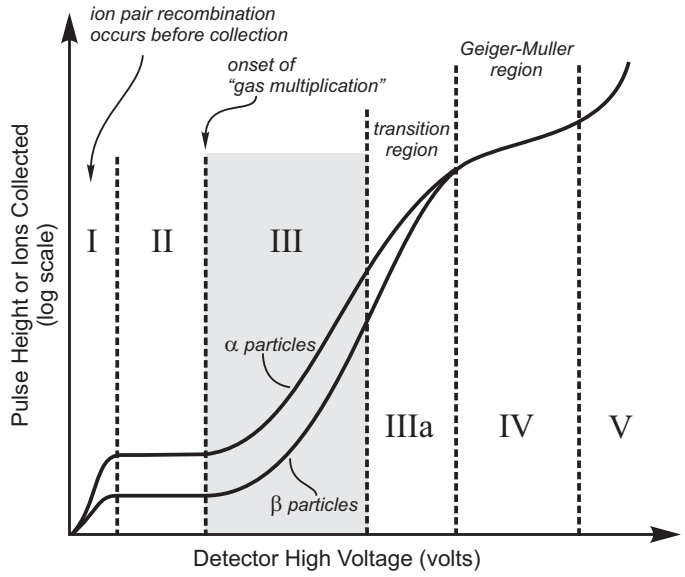

Figure 10.1. Proportional counters are operated in region III of the pulse height curve for gas-filled detectors.

Proportional counters are operated in region III of the pulse height curve for gas detectors (see Fig. 10.1). In this region an electronic pulse produced by ions moving through the detector is proportional to the original energy absorbed in the detector gas by a radiation particle, be they charged particles, neutrons, gamma rays or x rays. Although the gas-flow proportional counter was invented by John A. Simpson, Jr., in the mid 1940s [Simpson 1950a, 1950b], the actual effect of pulse height proportionality was known from those initial experiments conducted by Rutherford and Geiger with their gas-filled chambers. Argon is the most commonly used gas in a proportional counter, although there are many other gases that can be used, such as ^{3}He, Xe, and $^{10}BF_3$.

As with the ion chamber, a radiation particle can interact with the chamber, either directly with the chamber gas or with the chamber walls. If a gamma ray interacts with the chamber wall and a primary or secondary energetic electron escapes into the gas volume, this electron produces a cloud of electron-ion pairs. If the gamma ray interacts directly with the gas, then the energetic electron produced by the interaction also produces a cloud of electron-ion pairs. In either case, a cloud of electron-ion pairs is formed in which the total number of

[1]Received the Nobel Prize in physics in 1992 for inventing the multiwire proportional counter.

electron-ion pairs produced is proportional to the radiation energy deposited in the detector gas. Hence, by measuring the number of electron-ion pairs formed, the amount of energy deposited in the gas can be determined. Application of a voltage across the chamber and measurement of the current produced as the electrons and ions drift through the chamber volume allows the number of electron-ion pairs to be measured. Yet, as with the ion chamber, such a current can be miniscule and hard to measure.

10.2 General Operation

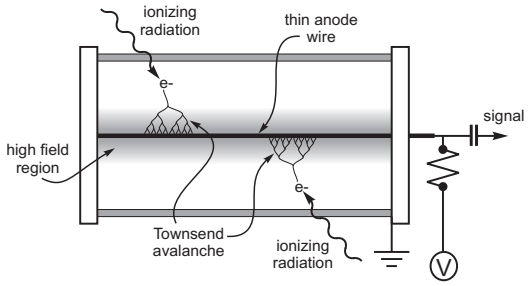

Figure 10.2. With a high electric field near the anode of a gas-filled detector, the signal is amplified by impact or Townsend avalanching, often referred to as "gas multiplication".

At sufficiently high voltages, electrons can gain enough kinetic energy or speed to produce more ionization of the gas, an effect called *impact ionization*. These newly liberated electrons can themselves gain enough energy from the electric field to cause even more ionization (depicted in Fig. 10.2). The process continues until the electrons are collected at the anode. The entire process of generating the impact ionization cloud is called a *Townsend avalanche*, or sometimes *gas multiplication*. There is a threshold electric field, $\mathcal{E}_t$, required for avalanche multiplication, below which the electrons do not gain sufficient energy to cause impact ionization. This threshold defines the difference between Region II and Region III in the gas pulse height curve of Fig. 10.1.

Although parallel plate electrodes work for ion chambers, they are seldom used for proportional counters. The preferred geometry is a coaxial configuration, as depicted in Fig. 10.3. To see why, compare the difference in electric fields between coaxial and parallel plate geometries.

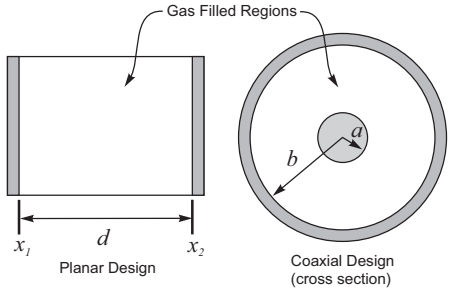

Figure 10.3. Planar and coaxial geometries are often used for gas-filled radiation detectors.

The parallel plate detector configuration is shown in Fig. 10.3. A voltage V_o is applied to the electrode at $x = x_1$ and zero (grounded) at $x = x_2$. The electric field at any position between the electrodes is

$$\mathcal{E}(x) = \frac{V_o}{x_2 - x_1} = \frac{V_o}{d}, \tag{10.1}$$

where d is the width between the parallel electrodes. Notice that the electric field for a planar configuration is constant and, hence, a relatively large voltage is required to reach the threshold $\mathcal{E}_t$ needed to produce avalanching. By contrast consider the coaxial design shown in Fig. 10.3 in which a voltage V_o is applied to the inner anode and the outer electrode is grounded. The electric field at any radius r for $a < r < b$ is, from Eq. (8.75),

$$\mathcal{E}(r) = \frac{V_o}{r \ln(b/a)}, \tag{10.2}$$

where a is the radius of the inner anode and b is the radius of the cathode shell wall. Unlike the planar case, the electric field is not constant for the coaxial case, and the highest electric field is at $r = a$. Suppose the distance between b and a in the cylindrical case is the same as the distance between x_2 and x_1 in the planar case such that $b - a = x_2 - x_1 = d$. The condition is set such that the highest value of the electric field in both cases just barely reaches the threshold electric field $\mathcal{E}_t$,

$$\mathcal{E}_t = \frac{V_o|_{\text{cylindrical}}}{a \ln(b/a)} = \frac{V_o|_{\text{planar}}}{d}. \tag{10.3}$$

or

$$\frac{V_o|_{planar}}{V_o|_{cylindrical}} = \frac{d}{a\ln(b/a)}, \tag{10.4}$$

and, if $a \ll b$ such that $d = b - a \approx b$, then

$$\frac{V_o|_{planar}}{V_o|_{cylindrical}} \approx \frac{b}{a\ln(b/a)}. \tag{10.5}$$

Because $a \ll b$, $b/a > 1$ and the right-hand side of Eq. (10.5) is always greater than unity (usually $\gg 1$). Thus, for similar chamber dimensions it is found that the voltage needed to reach $\mathcal{E}_t$ for the planar device is always greater than that needed for the cylindrical device.

10.3 Townsend Avalanche Multiplication

At a threshold electric field $\mathcal{E}_t$ electrons gain enough kinetic energy to produce impact ionization of neutral gas atoms (or molecules). Although the exact value for $\mathcal{E}_t$ varies with the gas, the threshold electric field required for impact ionization is generally about 10 kV/cm. As the electric field is increased above $\mathcal{E}_t$, the increase dn in the number of electron-ion pairs $n(x)$ over a differential distance dx traveled by the electrons is

$$dn = \alpha_T n(x) dx, \tag{10.6}$$

where α_T is the *first Townsend ionization coefficient* [Townsend 1915]. This coefficient can be interpreted as the probability, per unit differential path length of travel, that an electron causes impact ionization.[2] Also the mean free path between impact ionization events is $1/\alpha_T$.

From Eq. (10.6), the number of new electrons is found to increase exponentially with distance, i.e.,

$$n(x) = n(0)\exp(\alpha_T x), \tag{10.7}$$

where $n(0)$ is the initial number of electron-ion pairs. The *gas gain* or gas multiplication M at distance x from the initial location of the original electron-ion cloud is, therefore,

$$M = \frac{n(x)}{n_0} = e^{\alpha_T x}. \tag{10.8}$$

In Fig. 10.4 the first Townsend ionization coefficient is shown for various gases.

To achieve the necessary electric field threshold for a planar detector, potentials exceeding several thousand volts must be applied across the electrodes. However, coaxial or hemispherical detectors can be operated in region III of the gas pulse height curve with significantly lower voltages, commonly ranging between 200 and 1500 volts.

Consider a coaxial detector of radius b with anode wire of radius a, in which the electric field at the surface of the anode is $\mathcal{E}_t$. Thus, from Eq. (10.2)

$$\mathcal{E}_t(a) \approx 10^4 \text{ volts cm}^{-1} = \frac{V_t}{a\ln(b/a)}, \tag{10.9}$$

or the threshold voltage is approximately,

$$V_t = a\mathcal{E}_t \ln\left(\frac{b}{a}\right) \approx 10^4 a\ln(b/a) \text{ volts}. \tag{10.10}$$

[2] Such a coefficient is analogous to the interaction coefficients for indirectly ionizing radiation discussed in Sec. 4.2.

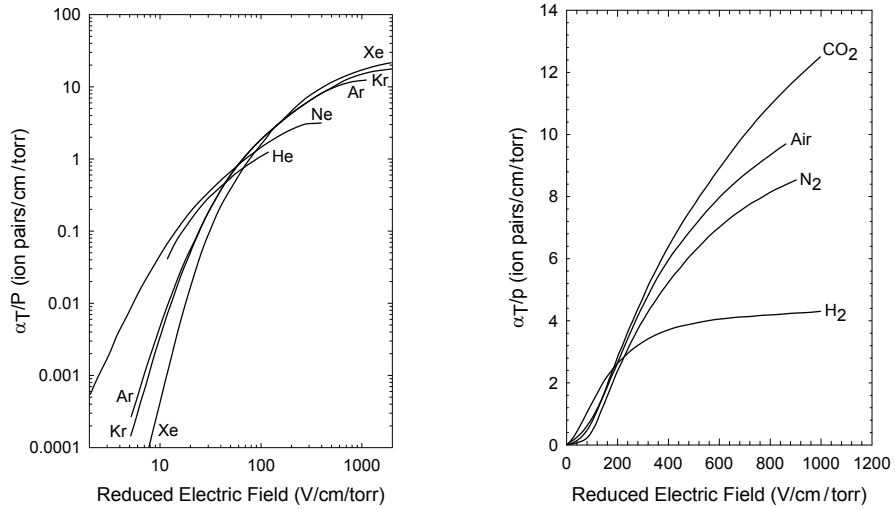

Figure 10.4. The reduced first Townsend coefficient as a function of the reduced electric field for several detector gases. From [Brown 1959].

The critical electric field needed for avalanching can be described in terms of the critical radius r_c at the onset of avalanche multiplication,

$$\mathcal{E}_t = \mathcal{E}(r_c) = \frac{V_0}{r_c \ln(b/a)}. \tag{10.11}$$

Equating Eq. (10.9) with Eq. (10.11) yields,

$$\frac{V_0}{V_t} = \frac{r_c}{a}. \tag{10.12}$$

Example 10.1: Consider a coaxial proportional counter backfilled with argon gas that is 1 inch in diameter with a 25-micron diameter anode wire. Estimate the voltage required to reach the avalanche electric field at the surface of the anode and compare the result to the expected voltage required for a planar detector with a similar electrode spacing.

Solution:

From Eq. (10.9), the threshold voltage for the coaxial detector is,

$$V_t = (10^4)\frac{(25\times 10^{-4}\text{ cm})}{2}\ln\left(\frac{(2)(2.54\text{ cm})}{(2)(25\times 10^{-4}\text{ cm})}\right)\text{ volts} = 86.55\text{ volts}.$$

By comparison, a planar detector with electrode spacing of 1/2 inch would require

$$V_t = (10^4\text{ V/cm})\left(\frac{2.54\text{ cm}}{2}\right) = 12700\text{ volts}.$$

10.3.1 The Rose-Korff Formula for M

A commonly used, but simplistic, expression for the first Townsend coefficient can be derived by first considering the probability that an electron gains enough energy to produce impact ionization [Rice-Evans

1974]. Given an average distance Δx that an electron must traverse to gain enough energy to cause impact ionization, the condition for impact ionization requires

$$q\mathcal{E}\Delta x \geq qI_0 \tag{10.13}$$

where $\mathcal{E}$ is the electric field and I_0 is the ionization potential of the gas. The fraction of electrons with transit paths $\geq \Delta x$ or, equivalently, have energies above E_t needed to cause impact ionization is

$$\frac{n_e(\Delta x)}{n_e(0)} = e^{-\Delta x/\lambda} = e^{-I_0/\lambda\mathcal{E}}, \tag{10.14}$$

where $n_e(0)$ is the initial number of electrons produced from the radiation interaction event, and λ is electron mean free path (for all types of interaction). The first Townsend coefficient is then the probability the electron has $E \geq E_t$ divided by the probability of an interaction in a unit differential distance of travel, namely[3]

$$\alpha_T = \frac{n_e(\Delta x)}{n_e(0)}\frac{1}{\lambda} = \frac{1}{\lambda}e^{-I_0/\lambda\mathcal{E}}. \tag{10.15}$$

The mean free path λ is a function of the gas pressure and can be approximated by

$$\lambda = \frac{1}{AP}, \tag{10.16}$$

where A is an experimentally determined constant and P is the gas pressure. Substitution of Eq. (10.16) into Eq. (10.15), the first Townsend coefficient is thus found to be [Korff 1946],

$$\frac{\alpha_T}{P} = Ae^{-I_0AP/\mathcal{E}} = Ae^{-BP/\mathcal{E}}. \tag{10.17}$$

For a limited range of the reduced electric field $\mathcal{E}/P$, the microscopic cross section for impact ionization σ_i is proportional to the electron energy E_e [Sauli 1977], i.e.,

$$\sigma_i = \overline{z}E_e, \tag{10.18}$$

where $\overline{z}$ is an experimental constant. The mean free path *between impact ionizations* is

$$\lambda_i = 1/\alpha_T = 1/\sigma_i N \tag{10.19}$$

where N is the atomic or molecular density of the chamber gas. Substitution of Eq. (10.18) into Eq. (10.19) yields,

$$\alpha_T = \overline{z}NE_e. \tag{10.20}$$

Measured values for A, B, and $\overline{z}$ for several gases are listed in Table 10.1. From Eq. (10.17) it is seen that α_T increases as the electric field is raised above the avalanche threshold electric field $\mathcal{E}_t$.

[3] Implicit in this derivation of α_T is the assumption that, once $E \geq E_t$, the next interaction is an impact ionization event and not, for example, a scatter.

Table 10.1. Some parameters used to calculate α_T from Eq. (10.17), Eq. (10.18), and Eq. (10.20). A and B are generally useful between 100 - 600 V cm^{-1} torr^{-1}, except H_2 (150 - 600) and He (20 - 150). Data from [Brown 1959; Korff 1946; Rice-Evans 1974].

Gas	A eip cm^{-1} torr^{-1}	B V cm^{-1} torr^{-1}	$\overline{z}$ 10^{17} cm^2 V^{-1}
H_2	5	130	0.46
He	3	34	0.11
N_2	12	342	0.70
Ne	4	100	0.14
Ar	14	180	1.81

Multiplication in a Coaxial Detector If r_c is the *critical radius* at which the electric field reaches the critical electric field necessary for a Townsend avalanche to occur, then the total gain, or multiplication factor, is given by

$$M = \exp\left[\int_a^{r_c} \alpha_T(r)dr\right]. \tag{10.21}$$

The capacitance, per unit length, of a coaxial chamber is

$$C_l = \frac{2\pi\epsilon_0\kappa}{\ln(b/a)}, \tag{10.22}$$

where κ is the dielectric constant of the gas. Recall that the electric field depends upon the radius r, and substitution of Eq. (10.22) into Eq. (10.2) gives this dependence as[4]

$$\mathcal{E}(r) = \frac{V_o}{r\ln(b/a)} = \frac{C_l V_o}{2\pi r\epsilon_o\kappa}, \tag{10.23}$$

and

$$V(r) = \frac{V_o\ln(r/a)}{\ln(b/a)} = \frac{C_l V_o}{2\pi\epsilon_o\kappa}\ln(r/a). \tag{10.24}$$

The average energy gained by electrons between impact ionizing collisions is, by definition,

$$\overline{E}_e = \lambda_i\mathcal{E}(r) = \frac{\mathcal{E}(r)}{\alpha_T}, \tag{10.25}$$

which, when substituted into Eq. (10.20), gives

$$\alpha_T = \sqrt{\overline{z}N\mathcal{E}(r)}. \tag{10.26}$$

Substitution of Eq. (10.26) into Eq. (10.21) and use of Eq. (10.23) allows the gas multiplication to be evaluated as

$$M = \exp\left[\int_a^{r_c}\sqrt{\overline{z}N\frac{C_l V_o}{2\pi r\epsilon_0\kappa}}dr\right] = \exp\left[\sqrt{2\overline{z}N\frac{C_l V_o}{\pi\epsilon_0\kappa}}\left(r_c^{1/2} - a^{1/2}\right)\right] = \exp\left[\sqrt{2a\overline{z}N\frac{C_l V_o}{\pi\epsilon_0\kappa}}\left(\sqrt{\frac{r_c}{a}} - 1\right)\right]. \tag{10.27}$$

[4]Note that from Poisson's equation, $\nabla^2 V = -\nabla\cdot\vec{\mathcal{E}} = -\rho/\kappa\epsilon_0$. Here the authors assume that the initial space charge is negligible and use the magnitudes of the voltage and electric fields to determine M.

Table 10.2. The reduced first Townsend coefficient α_T/P and the gas multiplication factor M as a function of $\ln M/(aPS_a)$ where $S_a \equiv \mathcal{E}_a/P$. Here $S_a \equiv S(a)$ and $\mathcal{E}_a \equiv \mathcal{E}(a)$. Also C_1 to C_{14}, K_1 to K_{10}, m, and d are empirical constants. The formulas are from [Kowalski 1986].

Citation	α_T/P	$\ln M/(aPS_a)$
Rose and Korff [1941]	$\frac{c_1}{2}\sqrt{S}$	$K_1 - \frac{c_1}{\sqrt{S_a}}$
Hristov [1957]	c_2	$K_1 - \frac{c_2}{S_a}$
Diethorn [1956]	$c_3 S$	$c_3(\ln S_a - \ln K_3)$
Townsend [1915] Williams, Sara [1962]	$c_4 \exp\left(\frac{-c_5}{S}\right)$	$\frac{c_4}{c_5}(\exp\frac{-c_5}{S_a} + K_4)$
Ward [1958] Charles [1972]	$c_6 \exp\left(\frac{-c_7}{\sqrt{S}}\right)$	$K_5 + \frac{2c_6}{c_7^2}\left(\frac{c_7}{\sqrt{S_a}} + 1\right)\exp\left(\frac{-c_7}{\sqrt{S_a}}\right)$
Zastawny [1966]	$c_8(S - S_0)$	$K_6 + c_8\left(\ln\frac{S_a}{c_9} + \frac{c_9}{S_a} - 1\right)$
Kowalski [1985]	$\frac{c_{10}S^{1.5}}{2}$	$c_{10}\sqrt{S_a} + K_7$
Aoyama [1985]	$c_{11}S^m \exp\left(\frac{-c_{12}}{S^{1-m}}\right)$	$\frac{c_{11}}{c_{12}}\frac{1}{1-m}\exp\left(-c_{12}S_a^{m-1}\right) + K_8$
Kowalski [1986]	$c_{13}S^d + c_{14}$	$\frac{c_{13}}{d-1}S_a^{d-1} - \frac{c_{14}}{S_a} + K_9$
Kowalski [1986]	$c_{13}S^d$	$\frac{c_{13}}{d-1}S_a^{d-1} + K_{10}$

Finally, substitution of Eq. (10.12) into Eq. (10.27) and use of Eq. (10.23) gives the following two equivalent results

$$\boxed{\begin{aligned} M &= \exp\left[\sqrt{2a\overline{z}N\frac{C_l V_o}{\pi\epsilon_0\kappa}}\left(\sqrt{\frac{V_0}{V_t}} - 1\right)\right] \\ M &= \exp\left[2\sqrt{\frac{a\overline{z}NV_o}{\ln(b/a)}}\left(\sqrt{\frac{V_0}{V_t}} - 1\right)\right] \end{aligned}} \quad . \tag{10.28}$$

Equation (10.28) represents the derived result of at least one formulation of the avalanche coefficient, traditionally named the "Rose-Korff" formula [Rose and Korff 1941]. In the present case, Eq. (10.28) yields acceptable results for many gases for which $10 \leq M \leq 10^3$ [Staub 1953]. However, above this range, the formulation of α_T may need adjustment. Further, several experimental studies indicate that Eq. (10.28) has limited use for many detector gas mixtures, and has limited use over a large range of gas detector design parameters [Diethorn 1956; Kiser 1960; Zastawny 1966; Zastawny and Mizeraczyk, 1966]. Consequently, there are many alternative empirical formulas for M listed in the literature [Kowalski 1986]. A summary of these formulas is given in Table 10.2.

10.3.2 The Diethorn Formula for M

Another commonly used expression for M is the Diethorn formula [Diethorn 1956]. At a constant gas pressure P in the detector chamber under a reduced electric field $S(r) \equiv \mathcal{E}(r)/P$, the distance between successive impact ionizations varies as $1/S$. Also, within a *constant* reduced electric field S, the mean free path between ionizing collisions varies with $1/P$. Hence,

$$\lambda_i \propto \frac{1}{SP} \propto \frac{P}{\mathcal{E}P} \propto \frac{1}{\mathcal{E}}. \tag{10.29}$$

This relation indicates that the distance between ionizing collisions decreases as the electric field increases and is independent of the gas pressure P. The ionization mean free path λ_i can be much greater than the collision mean free path λ. The kinetic energy acquired by an electron between successive ionizing events is,

$$q\Delta V = q\lambda_i\mathcal{E} \tag{10.30}$$

where ΔV is the potential difference that an electron must pass through over a distance λ_i in order to obtain sufficiently kinetic energy to produce an ionizing event. From Eq. (10.29), ΔV must be a constant characteristic of the fill gas. It is therefore assumed that the first Townsend coefficient is linearly related to the electric field, or

$$\frac{\alpha_T}{P} = c\frac{\mathcal{E}}{P}, \tag{10.31}$$

where c is an experimentally determined constant. Also, for any gas pressure P, there is a critical threshold electric field for the onset of avalanche multiplication, or

$$\mathcal{E}_t = KP, \tag{10.32}$$

where K is an empirical constant.

Diethorn [1956] estimates the number of electron collisions producing secondary ionization as $n = V_t/\Delta V$ where V_t is the potential at $\mathcal{E}_t$.[5] Because the first ionization event yields 2 electrons both of which cause subsequent ionization events, thereby doubling their number, and so on, then after n impact ionizations there are 2^n electrons for each initial electron. Thus, the multiplication factor is

$$M = 2^n \qquad \text{or} \qquad \ln M = n\ln 2 = \frac{V_t}{\Delta V}\ln 2. \tag{10.33}$$

For a coaxial detector, the reduced electric field can be described by,

$$S(r) = \frac{\mathcal{E}(r)}{P} = \frac{V_0}{rP\ln(b/a)}. \tag{10.34}$$

with reduced potential distribution

$$U(r) = \frac{V(r)}{P} = \frac{V_0\ln(r/a)}{P\ln(b/a)}. \tag{10.35}$$

Solve Eq. (10.34) for r and evaluate the result at the critical radius r_c to obtain

$$r_c = \frac{V_0}{\mathcal{E}_t \ln\dfrac{b}{a}} \tag{10.36}$$

[5] Diethorn's treatment indicates that a negative potential is applied to the cathode of a coaxial detector with the anode grounded, a case rarely used, if ever. However, the treatment is mathematically correct. If instead a positive potential was applied to the anode with the cathode grounded, the estimated number of ionizing collisions would be $n = (V_0 - V_t)/\Delta V$.

Table 10.3. Constants for different gases used to calculate M from Eq. (10.38).

Gas	ΔV V	K V cm^{-1} torr^{-1}	Citation
95% Xe/5% CO_2	31.4	48.16	Hendricks [1972]
90% Xe/10% CH_4	33.9	47.63	Hendricks [1972]
P-5 (95% Ar/5% CH_4)	21.8 ± 4.4	59.21 ± 5.26	Wolff [1974]
P-10 (90% Ar/10% CH_4)	23.6 ± 5.4	63.16 ± 3.95	Wolff [1974]
CH_4	36.5 ± 5	90.79 ± 6.58	Wolff [1974]
C_3H_8	29.5 ± 2	131.58 ± 5.26	Wolff [1974]

Substitution of Eq. (10.32) and Eq. (10.36) into Eq. (10.35) yields,

$$V_t = \frac{V_0}{\ln \dfrac{b}{a}} \ln \left(\frac{V_0}{aKP \ln \dfrac{b}{a}} \right). \tag{10.37}$$

Finally, substitution of Eq. (10.37) into Eq. (10.33) yields the Diethorn formula [Diethorn 1956],

$$\boxed{\ln M = \frac{V_0}{\ln(b/a)} \frac{\ln 2}{\Delta V} \left(\ln \frac{V_0}{aP \ln(b/a)} - \ln K \right)} \quad , \tag{10.38}$$

or the general form used in Table 10.2,

$$\boxed{\frac{\ln M}{aPS_a} = \frac{\ln 2}{\Delta V} (\ln S_a - \ln K)} \quad , \tag{10.39}$$

where $S_a \equiv S(a)$. Equation (10.38) is particularly useful for CH_4 and many forms of Xe-CH_4 and Ar-CH_4 mixtures. Reported values for constants in Eq. (10.38) are listed in Table 10.3.

10.3.3 The Zastawny Formula for M

However, Eq. (10.38) is less useful for pure Ar, N_2, and CO_2, or for those gas mixtures involving CO_2. To address the problems with Eq. (10.38), Zastawny [1966] developed an alternative solution to the Diethorn equation (also listed in Table 10.2). Differentiation of Eq. (10.34) and evaluation of $S_a = S(a)$ from this equation gives the relation

$$dr = -\frac{aS_a}{S^2(r)} dS. \tag{10.40}$$

With this relation between dr and dS Eq. (10.21) may be expressed as

$$\ln M = aPS_a \int_{S_{r_c}}^{S_a} \frac{\alpha_T(S)}{P} \frac{dS}{S^2(r)}, \tag{10.41}$$

Table 10.4. Constants for different gases used to calculate M from Eq. (10.43).

N_2	$(0.655 \pm 0.03) \times 10^{-3}$	$(18.6 \pm 0.9) \times 10^{-2}$	85 ± 4	Zastawny, Mizeraczyk [1966]
Ar	$(6.25 \pm 0.3) \times 10^{-3}$	$(39.6 \pm 2) \times 10^{-2}$	34 ± 2	Zastawny, Mizeraczyk [1966]
P-10	$(0.5 \pm 0.1) \times 10^{-3}$	$(3.0 \pm 0.03) \times 10^{-2}$	25 ± 1	Zastawny [1967]
Xe/5% CO_2	2.49×10^{-3}	3.01×10^{-3}	32.37	Hendricks [1972]
Xe/10% CH_4	5.45×10^{-3}	2.46×10^{-3}	19.47	Hendricks [1972]

where $S_{r_c} = S(r_c)$ is the reduced electric field at the radial location for the onset of avalanching, and $\alpha_T(S)$ is the first Townsend coefficient as a function of the reduced electric field. Zastawny [1966] proposed

$$\frac{\alpha_T}{P} = c_1(S - c_2), \tag{10.42}$$

which, when substituted into Eq. (10.41) yields,

$$\boxed{\frac{\ln M}{aPS_a} = K + c_1\left(\ln\frac{S_a}{c_2} + \frac{c_2}{S_a} - 1\right)} \quad , \tag{10.43}$$

where K, c_1, and c_2 are experimentally determined constants. Experimental comparisons indicate that Eq. (10.43) works well for Ar, N_2, CO_2, and mixtures of CO_2 gas [Zastawny 1966, 1967; Zastawny and Mizeraczyk 1966]. Reported values of constants in Eq. (10.43) for several gases are listed in Table 10.4.

10.3.4 The Kowalski Formula for M

Kowalski mentions that equations for M listed in Table 10.2 have diverse results when tested with various gases over wide ranges of S. In an attempt to produce a generalized formula for the gas multiplication factor, Kowalski suggests the use of

$$\frac{\alpha_T}{P} = cS^d \tag{10.44}$$

where c and d are experimentally determined constants. Insertion of Eq. (10.44) into Eq. (10.41) yields

$$\boxed{\frac{\ln M}{aPS_a} = \frac{c}{d-1}S_a^{d-1} + K} \tag{10.45}$$

where K is an experimentally determined constant. When fit to data reported by various researchers, Eq. (10.45) appears to have merit for a variety of complex gas mixtures, many of which are listed in Table 10.5.

10.4 Gas Dependence

The ionization potentials and electron mobilities for many detector gases are significantly different, many of which are listed in Tables 9.1 and 9.2. The first Townsend coefficient should also vary among gases because

Table 10.5. Constants for different gases used to calculate M from Eq. (10.45). Data from [Kowalski 1986].

Xe/16.7% Kr/7% H_2	1.80×10^{-4}	2.125	-4.08×10^{-3}

M is strongly dependent on the mean free path length λ_i between ionizing collisions. As a result, gas multiplication can vary significantly for different detector parameters, gases, and gas mixtures. Examples of experimentally measured multiplication factors as a function of operating voltage are shown in Fig. 10.5 and Fig. 10.6.

Electron attachment, discussed in Sec. 9.2.5, can adversely affect the performance of proportional counters. Hence, gases with small electron attachment coefficients are commonly chosen as the gas in a proportional counter and include CH_4, CO_2, and Ar. Extreme care is required to prevent contaminant gases with relatively high electron attachment coefficients, such as O_2, from entering the detector.

Various gas mixtures are often introduced into the detector chamber to improve performance. Gas additives and mixtures can improve electron velocities (see Fig. 9.6 and Fig. 9.7), improve avalanche gain, decrease the required operating voltage, improve energy resolution, and eliminate spurious pulses. These gas mixtures may include Penning mixtures to increase the number of charge carriers per ionizing event, and may include quench gases to prevent successive avalanches from a single event.

10.4.1 Quenching Gas

After an impact collision, the resulting ion is often left in an excited state which can rapidly decay by emitting a photon (usually in the ultraviolet). This photon may then interact photoelectrically with another gas atom or molecule releasing a photoelectron which then causes another avalanche of electrons.

Let δ be the probability that an electron liberated through impact ionization leads to a tertiary electron through photoionization (typically $\delta \ll 1$). The gas multiplication per initial electron-ion pair is then given by

$$M = f + \delta f^2 + \delta^2 f^3 + ... + \delta^{n-1} f^n = \sum_{i=1}^{n} \delta^{i-1} f^i \quad , \tag{10.46}$$

where f is the total number of electrons liberated per primary electron-ion pair and would equal the multiplication factor if there were no photoionization, i represents the consecutive avalanche number (first, second, third, and so on) up to the final avalanche (n). Because δf is strongly dependent upon the applied operating voltage and is generally less than unity, Eq. (10.46) reduces to

$$M = \frac{f}{1 - \delta f} \quad . \tag{10.47}$$

If, in fact, $\delta f > 1$, the avalanching process becomes uncontrollable and the detector develops a self-sustaining discharge, which may occur with too high of voltage (as in Region V). Continuous waves of

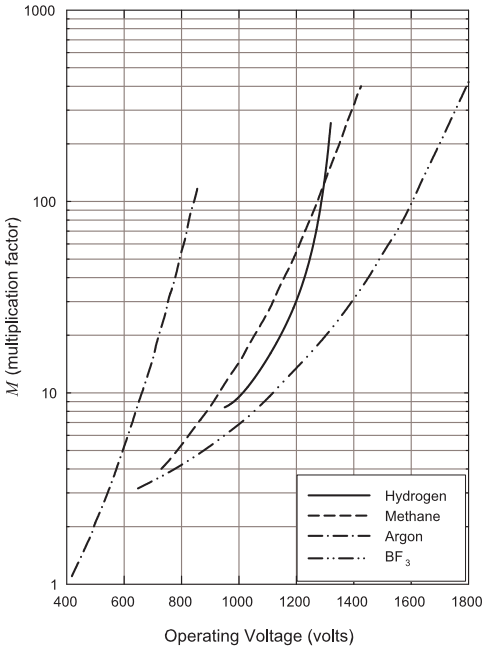

Figure 10.5. The multiplication factor M for several gases each at a pressure of 100 torr. The detectors for H_2, CH_4 and Ar had $a = 127\mu$m and $b = 11.05$ mm. The BF_3 detector had $a = 127\mu$m and $b = 19.05$ mm. From [Staub 1953].

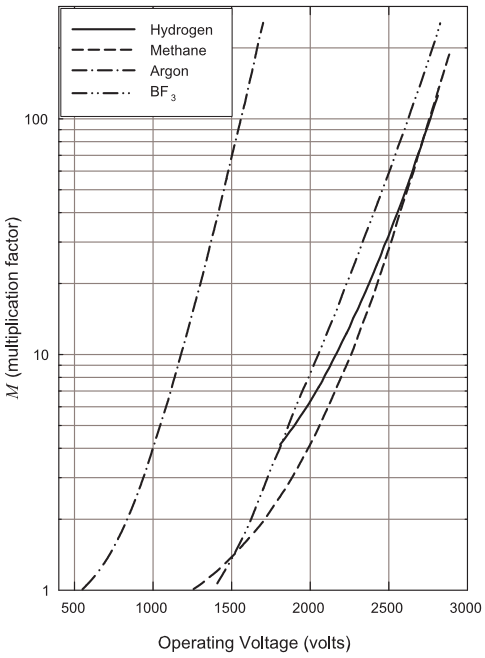

Figure 10.6. The multiplication factor M for several gases and pressures. The detectors for H_2 (550 torr), CH_4 (400 torr) and Ar (400 torr) had $a = 127\mu$m and $b = 11.05$ mm. The BF_3 detector (804 torr) had $a = 127\mu$m and $b = 19.05$ mm. From [Staub 1953].

avalanches can occur if UV light released by excited ions causes photoionization of outer shell electrons in too many more neutral Ar atoms. This is the most probable source of new electrons because of the high opacity of the gas at UV energies. However, UV light striking the cathode may also release photoelectrons from the cathode material. Finally, when a gas ion reaches the cathode wall, more electrons may be released by two different mechanisms. First, the energy difference between the work function of the cathode material and the ionization potential of the ion may be radiated into the tube gas as an ultraviolet photon which may, in turn, interact with a gas atom releasing a photoelectron. Second, the energy difference may liberate an electron directly from the cathode in a radiationless energy transfer. These mechanisms for starting additional avalanches are depicted in Fig. 10.7(a).

To prevent continuous waves of avalanches from occurring in the chamber after a radiation interaction, a small amount of a *quenching gas* is added to the gas mixture, typically a polyatomic molecule. When an ionizing particle enters the detector, it ionizes both the host and the quenching gases. More important, the argon ions, traveling towards the cathode, collide with a quenching gas molecules from which they readily take an electron, thus transferring almost all of the positive charge to quench gas molecules. UV photons can also interact with the quench gas, but the molecules dissociate instead of releasing photoelectrons. These molecules, when reaching the cathode, dissociate rather than liberate electrons, as would an argon ion if it were to strike the wall. In this manner further avalanches are suppressed. These quenching mechanisms are depicted in Fig. 10.7(b).

Quench gases are usually chosen with ionization potentials below that of the host gas, a precaution that allows charge to transfer from the host gas to the quench gas while rendering the reverse process improbable.

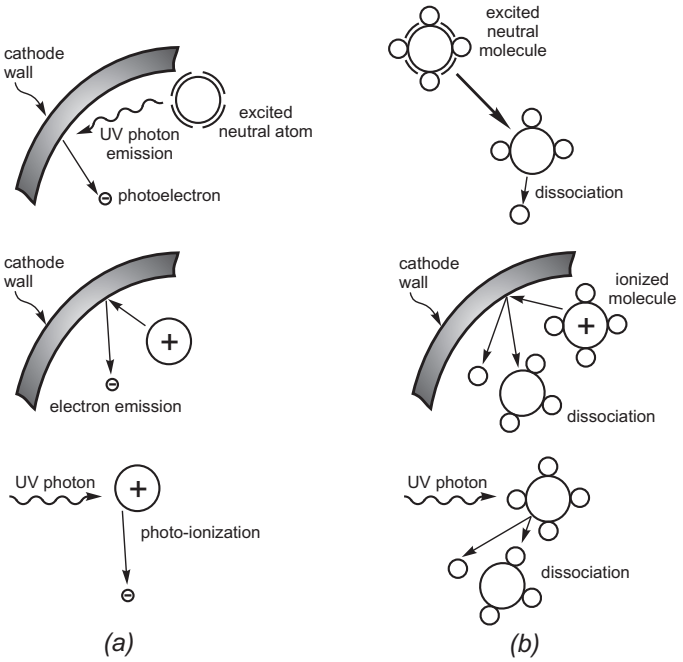

Figure 10.7. A quench gas is used to prevent continuous avalanches in the proportional counter. When a noble gas ion or UV photon strikes the cathode wall or a UV photon is absorbed by a neutral noble gas atom, electrons may be ejected that can start another avalanche, as depicted in *(a)*. The quench gas, usually an organic molecule, dissociates when it strikes the cathode wall or when it absorbs an energetic photon; hence it does not cause the release of an electron that can start a new avalanche, as depicted in *(b)*.

Quench gases should also not be electronegative so they are not prone to electron attachment. Several different organic molecules have been successfully used as quench gases (see Table 10.6). As the host gas ions drift through the chamber, they pass their charge to the quench gas molecules. These charged quench gas ions continue to drift and carry the positive charge to the cathode wall. When a quench gas is either struck by a UV photon or strikes the cathode wall, it dissociates, rather than eject an electron, as illustrated in Fig. 10.7(b). As a result, the quench gas prevents continuous waves of ionization. A common proportional counter gas mixture is *P-10*, which is a mixture of 90% Ar and 10% methane.

10.4.2 Penning Mixtures

Electron collisions in a gas can leave a gas in an excited state, which generally de-excites by the emission of a photon. However, long-lived metastable states can also be formed by electron collisions, in which radiative transitions to the ground state are forbidden. These excited metastable states do not produce ionization and consequently do not add to the induced charge signal. However, if a small amount of gas is added to the gas mixture, in which the added gas has a lower ionization potential than that of the excited metastable state of the host gas, then the energy stored by the metastable state can be transferred through a collision to produce another electron-ion pair,

$$A^* + B \rightarrow A + B^+ + e^-, \tag{10.48}$$

Table 10.6. Common detector host and quench gases with their ionization potentials I_o. From [Christophorou 1971].

Detector Gas	Common Name	I_o (eV)	Detector Gas	Common Name	I_o (eV)
Ar	Argon	15.755	CH_4	Methane	12.98
He	Helium	24.580	CO_2	Carbon Dioxide	13.79
H_2	Hydrogen	15.42	C_2H_2	Acetylene	11.36
O_2	Oxygen	12.08	C_2H_5OH	Ethyl Alcohol	10.50
N_2	Nitrogen	15.6	C_3H_8	Propane	11.08
Ne	Neon	21.559	C_4H_{10}	Isobutane	10.55
Kr	Krypton	13.996	Cl_2	Chlorine	11.48
Xe	Xenon	12.127	Br_2	Bromine	10.55

known as the Penning effect [Penning 1927]. This gas additive is also referred to as a "quench gas", although the effect is quite different than described in the previous subsection. Quite instead, adding a Penning quench gas increases ionization, and thereby increases the charge signal for the primary radiation absorption event. In effect, the average ionization energy of the gas mixture is lower than either individual gas, which works to improve charge collection statistics and improve energy resolution in a proportional counter [Sipilä 1976].

An example of the Penning effect is the small addition of Ar to a host gas of Ne. From Table 10.7, Ne has a metastable state energy of 16.53 eV while Ar has a first ionization energy of 15.76 eV. Hence, the metastable Ne gas atom can transfer sufficient energy to an Ar gas atom to produce an electron-ion pair. Typically, excellent improvement is achieved with only 0.01% Ar added [Druyvesteyn and Penning 1940]. The Penning effect is also observed with numerous polyatomic gases, generally because polyatomic gases have relatively low ionization energies (see Table 10.6). Experimental studies have shown that addition of H_2C_2 (acetylene) to the host gas Ar improves energy resolution for low avalanche gains (≤ 10) [Järvinen and Sipilä 1984; Agrawal et al. 1989]. Studies with gas-filled proportional detectors have shown that $\sim 2\%$ Xe added to Ar does improve performance, providing higher avalanche gains than other mixtures tested in the study [Agrawal et al. 1989], while a gas mixture of $\sim 20\%$ Xe added to Ar produced improved energy resolution ($\approx 7\%$ FWHM at 22 keV) nearly equal to mixtures of Ar/H_2C_2. In a similar study for multiple organic gas additives with Xe as the host gas, a strong Penning effect was observed with trimethylamine ($I_o \approx 8.32$ eV) and dimethylamine ($I_o \approx 8.4$ eV) as additives [Ramsey and Agrawal, 1989], where it is reported that the Penning mixture of Ar + 5% trimethylamine allowed for a 50% reduction in operation voltage while improving energy resolution by $\approx 22\%$.

10.5 Proportional Counter Operation

The creation of a pulse in a proportional counter starts with the initial ionizing event and ends with the collection of the liberated charges at the electrodes (see Fig. 10.8). A radiation particle enters the detector, interacts with the chamber gas, and liberates N_0 electron-ion pairs. The electrons are quickly swept towards the anode at speeds far exceeding those of the positive ions. Hence, the slow moving ions contribute very little to the initial induced charge. Upon entering the avalanche region near the anode, the electrons create numerous electron-ion pairs through impact ionization, equaling approximately $N_0\overline{M}$, where $\overline{M}$ is the average multiplication factor. The dense cloud of electrons is rapidly collected, leaving behind a dense cloud of slow moving positive ions. These positive ions slowly drift towards the cathode. Because of the high weighting potential in the anode region, it is the positive ions drifting from the anode towards the cathode that contribute to nearly all of the input voltage $V_{in}(t)$ to the amplification circuit.

Table 10.7. Ionization and excitation data for several gases. Data from [Christophorou 1971; Rice-Evans 1974].

Gas	First Ionization Energy (eV)	Second Ionization Energy (eV)	First Excited State (eV)	Recombination Coefficient ($cm^3\ s^{-1}$)
He	24.58	54.40	20.9 19.8 meta	10^{-8}
Ne	21.559	41.07	16.68 16.53 meta 16.62 meta	2×10^{-7}
Ar	15.755	27.52	11.56 11.49 meta 11.66 meta	9×10^{-7}

O_2	12.08			4×10^{-7}
I_2	9.0		1.9	1.5×10^{-8}

10.5.1 Pulse Shape

The pulse shape of a coaxial gas-filled detector varies greatly depending on which region of the pulse height gas curve of Fig. 10.1 the chamber is operated. The expected pulse shape for electron dominated voltage

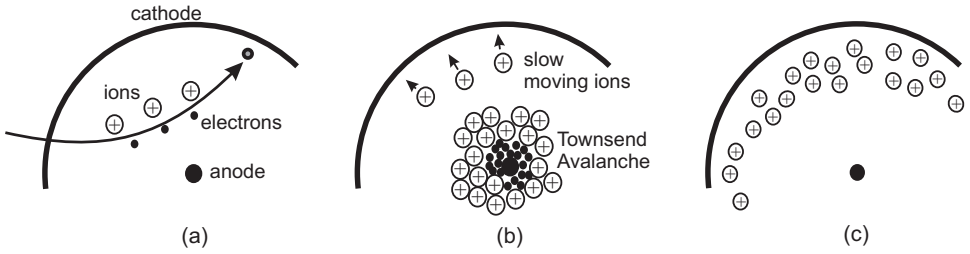

Figure 10.8. Pulse progression for a proportional counter: (a) an ionizing particle enters the detector gas and creates electron-ion pairs, (b) the electrons rapidly drift towards the anode and create an avalanche of electron-ion pairs, (c) the electrons are rapidly collected, whereas the positive ions drift much more slowly towards the cathode. It is the positive ion drift that contributes to most of the input pulse $V(t)$ from a proportional counter.

pulses in a coaxial ion chamber was derived in Sec. 9.4.2. However, operating the same detector in the proportional region causes a significant difference in the input pulse shape $V_{in}(t)$. For simplicity, assume that a radiation interaction creates a localized electron-ion cloud that can be treated as the location of N_0 charged pairs at a single point. Initially, the input voltage induced by drifting electrons is essentially the same as that in an ion chamber. However, once the electrons enter the avalanching region, a huge cloud of electron-ion pairs is produced, mostly within a few microns of the anode. Because the total charge is increased by the gas multiplication factor, most of the electron-ion pairs are produced very close to the anode. Consequently, the drift distance for electron collection is relatively short, and the electron contribution to the input voltage is relatively small. It is the motion of the cloud of positive ions drifting back towards the cathode that is responsible for most the time-dependent input voltage. Hence, the input voltage in proportional counters is *positive ion dominated*, whereas for ion chambers the input voltage is *electron dominated*.

Recall that the time dependent input pulse into the coupling electronics is

$$V_{in}(t) = \frac{\Delta Q(t)}{C} \tag{10.49}$$

where C is the combined coupling and detector capacitance. The expression for $\Delta Q(t)$ for a coaxial detector was derived in Sec. 8.7. Equation (8.80) with the variables used here is

$$\Delta Q(t) = qN_0[\ln(b/a)]^{-1} \ln(r_{ion}(t)/r_e(t)). \tag{10.50}$$

where $r_{ion}(t)$ and $r_e(t)$ are the radial locations of the positive ions and electrons, respectively, at time t. Unlike an ion chamber in which only N_0 electron-ion pairs are collected, in a proportional counter MN_0 pairs are collected The electrons are rapidly collected in time t_e, leaving behind the positive ions to drift toward the cathode. Almost all of the positive ions, save those very few produced in the original ionization event, begin their drift, after all of the electrons are collected, essentially at the anode surface. Thus, for $t > t_e$, Eq. (10.50) becomes

$$\Delta Q(t) \approx qMN_0 \ln(b/a)]^{-1} \ln(r_{ion}(t)/a) \qquad t > t_e \simeq 0. \tag{10.51}$$

The drift speed of the positive ions is given by

$$v_{ion} \equiv \frac{dr_{ion}}{dt} = \frac{P_0\ \mu_{ion}\mathcal{E}(r)}{P} = \frac{P_0\ \mu_{ion}V_0}{rP\ln(b/a)}. \tag{10.52}$$

The ion position $r_{ion}(t)$ is found by integrating Eq. (10.52) as

$$\int_a^{r(t)} r\,dr = \frac{P_0\ \mu_{ion}V_0}{P\ln(b/a)} \int_0^t dt \qquad \text{or} \qquad \frac{r_{ion}^2}{2} - \frac{a^2}{2} = \frac{P_0\ \mu_{ion}V_0}{P\ln(b/a)}t.$$

Rearrangement of this last result yields

$$r_{ion}(t) = \sqrt{\frac{2P_0\ \mu_{ion}V_0t}{P\ln(b/a)} + a^2}. \tag{10.53}$$

Upon substitution of Eq. (10.53) into Eq. (10.50) and use of Eq. (10.49) the input voltage is

$$V_{in}(t) \approx \frac{qMN_0}{C\ln(b/a)} \ln\left(\sqrt{\frac{2P_0\ \mu_{ion}V_0t}{a^2P\ln(b/a)} + 1}\right), \qquad t_e < t < t_{ion}, \tag{10.54}$$

for which the collection time for the positive ions is

$$t_{ion} = \frac{(b^2 - a^2)P\ln(b/a)}{2P_0\ \mu_{ion}V_0}. \qquad (10.55)$$

The maximum input voltage V_{max} is found by evaluating Eq. (10.54) at $t = t_{ion}$. The normalized input voltage $V(t)/V_{max}$ is, thus

$$\frac{V_{in}(t)}{V_{max}} \approx \frac{1}{\ln(b/a)} \ln\left(\sqrt{\frac{2P_0\ \mu_{ion}V_0 t}{a^2 P\ln(b/a)} + 1}\right). \qquad (10.56)$$

The magnitude of $V(t)/V_{max}$ initially rises rapidly, a fortuitous characteristic of the coaxial detector design, and is due to the combined effects of an initially high positive ion speed because of the high electric field near the anode and the enhanced weighting potential near the anode. For example, the time required to reach half the maximum input voltage $V_{max}/2$ is found from Eq. (10.56) as

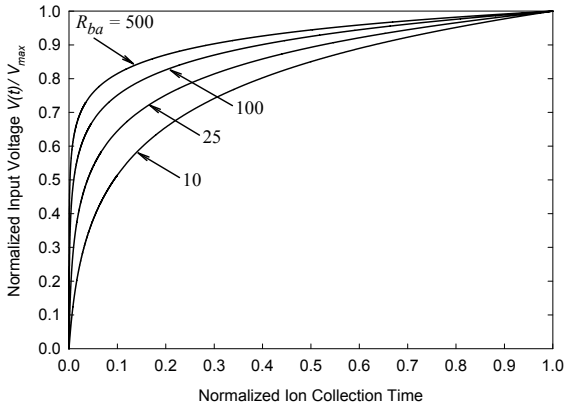

Figure 10.9. The normalized time-dependent input voltage $V(t)/V_{max}$ for a proportional counter as a function of t/t_{ion} for different values of $R_{ba} = b/a$ as given by Eq. (10.56). For the results shown, $b = 1.25$ cm and $a = b/R_{ba}$.

$$t_{V_{max}/2} = \left[\frac{b}{a} - 1\right] \frac{a^2 P\ln(b/a)}{2P_0\ \mu_{ion}V_0}. \qquad (10.57)$$

The normalized time-dependent input voltages $V(t)/V_{max}$ as a function of t/t_{ion} are shown in Fig. 10.9 for different values of $R_{ba} \equiv b/a$.

Example 10.2: A coaxial proportional counter backfilled with argon at 1 atm is operated at 1000 volts. The detector has an anode radius of $a = 25$ microns and cathode radius $b = 1.25$ cm. Exclude the possibility of a time delay caused by space charge. At what time past $t = 0$ does the input voltage $V(t)$ reach 1/2 the maximum possible pulse height? How far have the positive ions drifted in the chamber?

Solution:

From Table 9.2, the mobility μ^+_{ion} at 1 atm for argon is 1.7 cm^2 V^{-1}s^{-1}. The ratio $b/a = 500$. The maximum speed of the positive ions is found from Eq. (10.52) as

$$v_{max} = \frac{P_0\ \mu_{ion}V_0}{aP\ln(b/a)} = \frac{(1\text{ atm})(1.7\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1})(1000\text{ V})}{(25\times^{-4}\text{ cm})(1\text{ atm})\ln(500)} = 0.109\text{ cm}/\mu\text{s}.$$

The highest positive-ion speed is less than the saturation speed shown in Fig. 9.6, thereby validating the use of the ion-speed approximation. From Eq. (10.57)

$$t_{V_{max}/2} = \left[\frac{b}{a} - 1\right] \frac{a^2 P\ln(b/a)}{2P_0\ \mu_{ion}V_0} = [500 - 1]\ \frac{(25\times^{-4}\text{ cm})^2(1\text{ atm})\ln(500)}{2(1\text{ atm})(1.7\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1})1000\text{ V}} = 5.7\times10^{-6}\text{ seconds}.$$

Insertion of this result into Eq. (10.53), the radial location is

$$r(t_{V_{max}/2}) = \sqrt{\frac{2P_0\ \mu_{ion}V_0 t}{P\ln(b/a)} + a^2}$$

$$= \sqrt{\frac{2(1\text{ atm})(1.7\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1})(1000\text{ V})(5.7\times10^{-6}\text{ s})}{(1\text{ atm})\ln(500)} + (25\times^{-4}\text{ cm})^2} = 0.0559\text{ cm} = 559\ \mu\text{m},$$

which indicates that the positive ions have drifted

$$d = (559 - 25)\ \mu\text{m} = 534\ \mu\text{m}.$$

The input voltage $V_{in}(t)$ from a proportional counter is often applied to a preamplifier CR-RC circuit (as is done with an ion chamber). From Eqs. (9.118) and (10.56), the output voltage of the preamplifier is

$$\begin{aligned} V_{out}(t) &= V_{in}(t)\frac{\tau_o}{\tau_o - \tau_i}\left(e^{-t/\tau_o} - e^{-t/\tau_i}\right), \\ &= \frac{qMN_0}{C\ln(b/a)}\ln\left(\sqrt{\frac{2P_0\ \mu_{ion}V_0 t}{a^2 P\ln(b/a)}+1}\right)\frac{\tau_o}{\tau_o-\tau_i}\left(e^{-t/\tau_o} - e^{-t/\tau_i}\right). \end{aligned} \tag{10.58}$$

With the same analysis used to obtain Eq. (9.120) for the case $\tau_o = \tau_i$, Eq. (10.58) reduces to

$$V_{out}(t) = \frac{qMN_0}{C\ln(b/a)}\ln\left(\sqrt{\frac{2P_0\ \mu_{ion}V_0 t}{a^2 P\ln(b/a)}+1}\right)\frac{t}{\tau}e^{-t/\tau}. \tag{10.59}$$

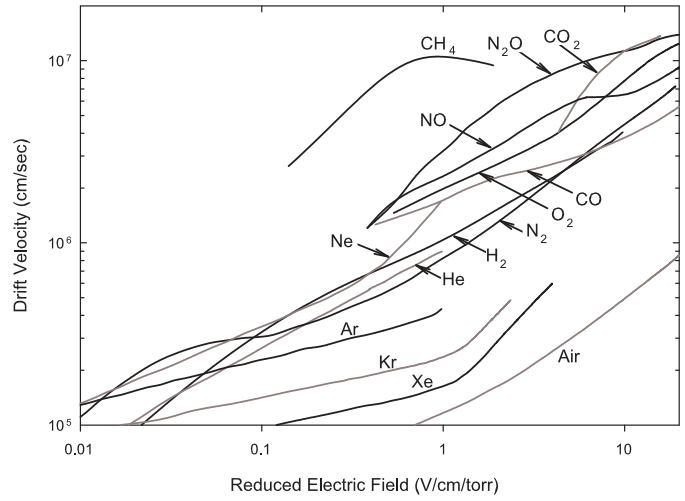

Figure 10.10. Electron drift speeds, measured at room temperature (293–300 K), for several detector gases as a function of reduced electric field. Data from [Bowe 1960; Brown 1959; Cottrell and Walker 1965; Pack and Phelps 1961; Phelps et al. 1960].

Typically the time constant of the circuit is adjusted to be much shorter than the total time required to collect the positive ions; otherwise, the recovery time would result in significant dead time loss. However, because a large portion of the input voltage is induced within the first several microseconds, the time constant can be adjusted to be small while still allowing the induction of large input currents. For monoenergetic events, the proportional counter nearly eliminates the position dependent charge collection issues typical of ion chambers. In principle, proportional counters should be capable of operating as energy spectrometers provided there is strict proportionality, i.e., M does not depend on the primary ionization. This requirement is true if space-charge effects by the positive ions are negligible (see Sec. 10.5.2) and if all the electrons have approximately the same travel distance and produce the same avalanche multiplication. This last requirement is achieved by using a very thin anode wire, typically a few hundred μm in radius. Thus, the high electric fields that cause avalanching are very close to the anode and almost all secondary ionization is in a very small volume around the anode.

Radiation interactions rarely create electron-ion pairs at a point location. Typically, radiation charged particles or charged particle reaction products have paths oriented over all possible directions in the chamber. The situation is further complicated for energetic electrons because they move along very tortuous trajectories (see Fig. 4.22). For instance, a cloud of electron-ion pairs oriented parallel to the central anode wire produces a time-dependent input pulse similar to that described by Eq. (10.54). However, an ion pair

track perpendicular to the anode wire produces an input voltage distorted from those shown in Fig. 10.9. Those electrons liberated nearest the anode start an avalanche at time t_0, whereas those electrons liberated furthest from the anode enter the avalanche region at $t_0 + \Delta t$, where Δt is the time required for all the electrons to drift into the avalanche region. As a result, the rise of $V_{in}(t)$ is further extended over Δt causing a distortion in the shape of the input voltage. Consequently, the input pulses can have different maxima for monoenergetic events, thereby compromising the energy resolution of the proportional counter. This problem of varying pulse heights, with examples, is discussed in the literature [Gott and Charles 1969]. To reduce the effect, it is typical to choose proportional gases with high electron mobilities and low electron attachment coefficients. Recall from Chapter 9 that electron drift speeds in Ar are relatively low. The same is true for other noble gases such as Kr and Xe. However, the average electron speed can be significantly increased by adding small portions of CH_4 or CO_2 into the proportional gas (for example, compare Fig. 9.6 and Fig. 9.7). Shown in Fig. 10.10 are the speed characteristics as a function of reduced electric field for several gases often used in proportional counters.

10.5.2 Space Charge Effects

As detailed by Wilkinson [1950] *space charge* accumulation can affect the gain, and ultimately the energy resolution, of a proportional counter. The buildup of space charge has two basic formation mechanisms, namely, *self-induced* space charge and *cumulative* space charge [Hendricks 1969; Mori and Watanabe 1982].

Self-induced space charge appears as an accumulation of positive charge near the anode as a consequence of the avalanching process. This buildup of positive charge around the anode decreases the electric field in the region nearest the anode wire. This space charge causes the local avalanche region around the anode to decrease in size and causes a slight decrease in gain. The higher the radiation energy deposited in the chamber, or rather, the more initial electron-ion pairs produced, the more avalanche electron-ion pairs are produced. Hence, the space charge effect can introduce a small amount of non-proportionality in the detector response at moderate operating voltages. As the operating voltage is increased, the multiplication factor increases (see Fig. 10.5 and Fig. 10.6) and a larger cloud of space charge is formed. Hence, increasing the operating voltage also increases the non-proportionality response to energy deposition and, generally, causes a decrease in the expected pulse height [Fergason 1966]. Eventually, at sufficiently high voltages, the detector is driven into the *transition region* (region IIIa of Fig. 10.1), in which pulses have limited proportionality to the energy deposited in the detector chamber.

Cumulative space charge appears as a consequence of multiple events contributing to the total number of drifting positive ions. Recall that, for those positive ions originating near the anode, the drifting times required to reach the cathode can be relatively long compared to the electron drift time. During that drifting period of the ions, additional radiation interaction events may occur that create additional clouds of positive ions near the anode and which drift, in sequence, towards the cathode. Although these ions are drifting in a region of low electrical field, the cumulative effect of multiple ion cloud formations causes the total electric field to drop, including that in the avalanching region. Consequently, the induced charge is observed to decrease from that expected from a single event [Burkhalter 1966]. This space charge effect becomes worse with higher count rate, in which the uncertainty in pulse height for monoenergetic radiations increases, and the average spectral shift in pulse height increases [Hendricks 1969]. To reduce the overall effect of space charge within the chamber, it has been recommended that the gas gain M be kept low [Wilkinson 1950; Hendricks 1969].

10.5.3 Counting Curve

It is always a good practice to calibrate gas-filled detectors before conducting measurements. For survey instruments, such a calibration may be performed once per year with sufficient confidence in the measurement

results. However, laboratory instrumentation coupled to modular counting equipment, such as NIM or CAMAC, requires calibration much more often. The reason why, of course, is because of the possible frequent changes in equipment settings made by other users, such as the amplifier gain or the lower level discriminator (LLD) setting, changes which alter the overall detector response. Consequently, before any radiation measurements are conducted, a *counting curve* is usually first created to locate region III of the pulse height curve for the chamber being used and also for the type of radiation particle being measured in the samples.

Ideally, one should use a known source that emits the energy and type of particle to be measured in the samples. For example, suppose the samples were thought to contain a radionuclide that emits an alpha particle of energy E_o. Then with a check source that emits the same alpha particle energy, the lower level discriminator (LLD) is adjusted by observing, with an oscilloscope, the amplitudes of the pulses being sent to the counter. The LLD is set to reject pulses produced by background and other lower amplitude pulses produced by other radiations. In this fashion only the higher amplitude pulses formed by the alpha particle of energy E_o are counted.

Table 10.8. Data for the counting curve of Fig. 10.11.

HV	Counts	HV	Counts	HV	Counts	HV	Counts
0	0	250	560	500	658	750	711
25	0	275	620	525	692	775	707
50	0	300	645	550	698	800	725
75	0	325	669	575	654	825	720
100	10	350	642	600	693	850	754
125	23	375	659	625	703	875	832
150	37	400	685	650	667	900	900
175	65	425	648	675	686	925	1130
200	123	450	671	700	714	950	1342
225	349	475	667	727	683	975	1800

Once the LLD is set, a series of measurements or counts of the radiation source are recorded at incrementally increasing voltages beginning with a very low or zero voltage. Each measurement has the same time duration. As the output pulses triggered by the radiation sources become larger, a direct result of increasing M with applied voltage, they eventually pass through the LLD and are counted. The counts for each measurement are plotted versus the operating voltage used. For a monoenergetic α particle source, as the operating voltage is increased, eventually almost every output pulse from the radiation source exceeds the LLD, and the number of counts per measurement reaches a near constant value over a finite voltage region as shown in Fig. 10.11. As the voltage is increased further, the avalanche gain in the chamber continues to increase until eventually lower energy radiations from the source or background radiations create pulses that also pass through the LLD, at which point the count rate rapidly increases. Usually, the operator selects an operating voltage in the center of the perceived *counting plateau* to conduct the sample measurements.

A measure of the performance of a proportional counter is the slope of counting plateau. To obtain the slope first draw a smooth line through the data points and, somewhat subjectively, determine the voltage V_a at the start of the plateau and the voltage V_b and the end of the plateau. The fractional plateau slope is given by

$$\text{slope} = \left(\frac{\text{Cts}_b - \text{Cts}_a}{V_b - V_a}\right)\left(\frac{2}{\text{Cts}_b + \text{Cts}_a}\right) \tag{10.60}$$

where Cts_a and Cts_b are the measured counts at operating voltages V_a and V_b, respectively.[6]

[6] An alternative expression is

$$\text{slope} = \left(\frac{\text{Cts}_b - \text{Cts}_a}{V_b - V_a}\right)\left(\frac{1}{\text{Cts}_a}\right),$$

where ΔCts is divided by Cts_a. But, because proportional counters are operated in the counting plateau center, and because of the subjective nature of choosing the counting plateau limits, the authors believe that dividing by the average counts offers a better representation of the fractional slope.

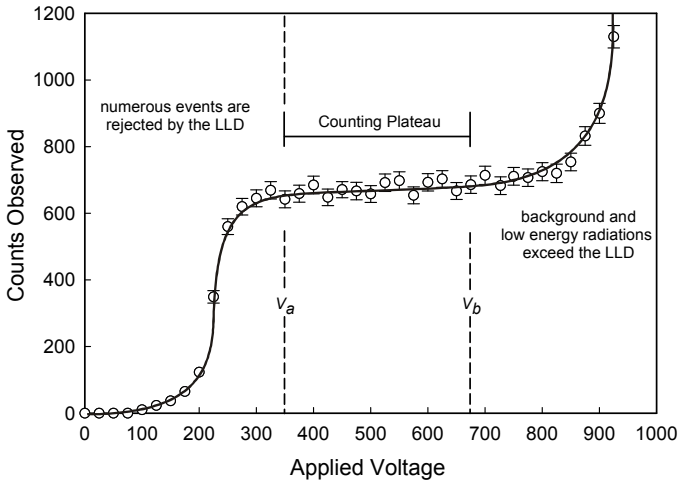

Figure 10.11. A counting curve for a gas-filled proportional counter in which a monoenergetic alpha particle source was used to calibrate the detector counting plateau.

The slope can also be expressed in terms of percent change per 100 volts of operating potential,

$$\%\ \text{slope}|_{100V} = 100\left(\frac{100(\text{Cts}_b - \text{Cts}_a)}{V_b - V_a}\right)\left(\frac{2}{\text{Cts}_b + \text{Cts}_a}\right). \tag{10.61}$$

Example 10.3: Measurements were conducted with a proportional counter with a monoenergetic α-particle source for many operating voltages and yielded the data of Table 10.8. These data were used to construct Fig. 10.11. Determine the % slope of the detector.

Solution:

The limits of the counting plateau are determined to be $V_a = 350$ volts and $V_b = 675$ volts, yielding

$$\begin{aligned}\text{slope} &= \left(\frac{\text{cnts}_b - \text{cnts}_a}{V_b - V_a}\right)\left(\frac{2}{\text{cnts}_b + \text{cnts}_a}\right)\\ &= \left(\frac{686\ \text{cnts} - 642\ \text{cnts}}{675\ \text{volts} - 350\ \text{volts}}\right)\left(\frac{2}{686\ \text{cnts} + 642\ \text{cnts}}\right) = 0.000204\end{aligned}$$

$$\begin{aligned}\%\ \text{slope}|_{100V} &= 100\left(\frac{100(\text{cnts}_b - \text{cnts}_a)}{V_b - V_a}\right)\left(\frac{2}{\text{cnts}_b + \text{cnts}_a}\right)\\ &= 2.04\%\ \text{per 100 volts.}\end{aligned}$$

Source and Detector Effects

Quite often a source may emit several different radiations. Such mixed sources may emit alpha particles, beta particles and gamma-rays of different energies. If performed correctly, the proportional counting can be used to distinguish among the different radiations and their energies. Consider the pulse height histogram of Fig. 10.12, showing the spectral features of a mixed source that emits alpha and beta particles.

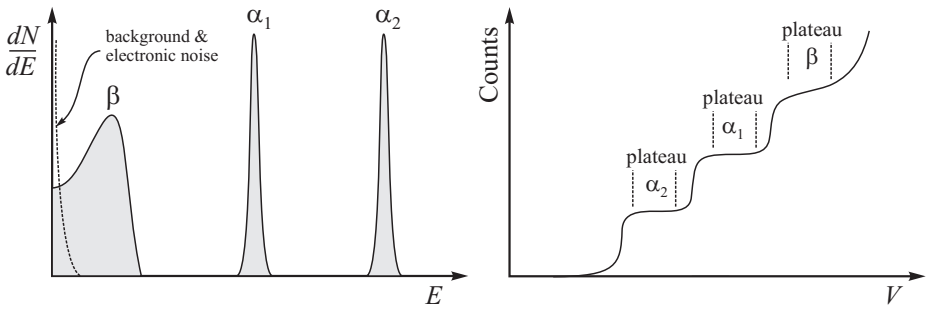

Figure 10.12. Depiction of the differential pulse height spectrum from a mixed α and β particle source and the resulting counting curve for a relatively large volume proportional counter.

For many proportional counter designs, the ranges of the α or β particles are longer than the chamber dimensions. In other words, the particles do not deposit all of their initial energy in the detector. Because the differential energy deposition, or stopping power $-dE/dx$, is much greater for α particles than that for β particles, the density of the ionized charge cloud produced by the α particles is greater than that produced by β particles. Consequently, the operating voltage required to produce pulses exceeding the LLD is lower for α particles than β particles.

As shown in Fig. 10.12, the highest energy α particle yields a counting plateau at the lowest operating voltage. The α particle with the lower energy, α_1, requires a higher operating voltage to produce a counting plateau. Note that the counting plateau for α_1 includes the sum of counts from both α_2 and α_1. At a higher voltage, the β particle source produces its counting plateau.

Because β particles are emitted with a continuum of energies, ranging from zero to E_{max}, the counting plateau for β particles has a much higher increasing slope with increasing operating voltage than do the slopes for the alpha particles. Consider Fig. 10.12, in which a beta particle spectrum is depicted. As the operating voltage increases, the highest energy β particles eventually are able to produce pulses above the LLD. As the operating voltage is increased further, more β particles with lower energies produce pulses above the LLD, a trend that continues with increasing voltage. At high enough voltages, background counts are included in the measurements, as well as the possibility of including spurious "counts" from the high electric field, thereby causing a rapid increase in counts unrelated to the radiation source.

Electrons ejected by γ-ray interactions, β particles and positrons all have similar stopping powers $-dE/dx$ in the detector gas. Usually, proportional counter chambers are not large enough to capture all of the energy from β particle emissions before they collide with the chamber wall. Consequently, the counting plateau usually appears at a similar location in the counting curve regardless of the energy of the electron. Distinction among energies becomes difficult unless the detector chamber is large enough to absorb all (or most) of the energy. However, such chambers are very much larger than normal proportional counters. Note that large gas-filled chambers do exist, many used for high energy physics experiments that require the capture of all or much of the energy from weakly ionizing particles.

For some proportional counters, particularly pancake designs, the chamber dimension parallel with the particle trajectories can be so small that higher energy α particles lose less energy in the chamber than lower energy α particles, thereby producing less ionization than the lower energy α particles; hence, the appearance of the counting plateaus is reversed in order from that normally expected. The case becomes clear by considering the Bragg ionization curves depicted in Fig. 10.13. In this case the highest energy α particles deposit the least amount of energy before striking the chamber wall. As a result, it is the lowest

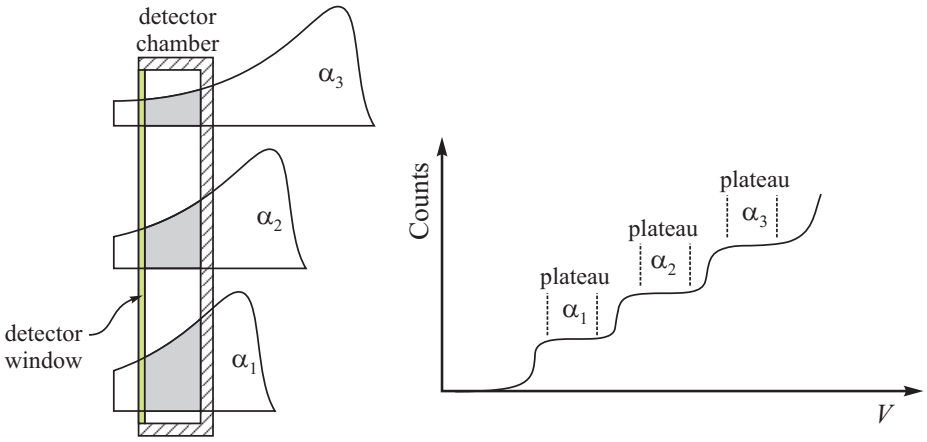

Figure 10.13. Depiction of Bragg ionization curves for multiple α particle energies as they intersect a narrow detector chamber and the resulting counting curve. The shaded regions in the Bragg ionization curves depict the integrated energy deposited in the chamber.

energy α particle that produces a counting plateau at the lowest operating voltage. Example radioactive sources that can exhibit this property with pancake proportional counters include ^{228}Th and ^{226}Ra. Note that particles entering the detector at oblique angles deposit more energy in the detector; however, the flat portion of the counting plateau appears when nearly all particles of a particular energy produce pulses above the LLD. Under appropriate detector design and operating conditions, it is possible that the different alpha particles have overlapping counting plateaus, making distinction among them difficult.

10.5.4 Fluctuations of the Gas Multiplication Process

Because the proportional counter maintains a proportional relation between absorbed energy and the input pulse $V_{in}(t)$, it is possible to operate proportional counters as energy spectrometers. Consider the case of a monoenergetic radiation source, in which the emitted radiations deposit their total energy into the detector upon each interaction. The average number of secondary electrons m produced through avalanching by a single initial electron is given by a PDF $p_{aval}(m)$ with a mean $\langle m \rangle$ and a variance $\sigma^2(m)$. Various models for $p_{aval}(m)$ are presented later in this section.

For a *single event* that produces n initial electron-ion pairs, there is an average multiplication factor $M(n)$ for the *total* avalanche shower, that is given by

$$M(n) \simeq \sum_{i=1}^{n} m_i, \tag{10.62}$$

where the $\{m_i\}$ are random variables sampled from $p_{aval}(m)$ representing independent electron avalanches. The average multiplication per initial electron is

$$\overline{m} = \frac{1}{n} \sum_{i=1}^{n} m_i = \frac{1}{n} M(n), \tag{10.63}$$

whose variance is

$$\sigma^2(\overline{m}) = \frac{1}{n^2} \sum_{i=1}^{n} \sigma^2(m_i) = \frac{\sigma^2(m)}{n}. \tag{10.64}$$

The expected or mean value of $M(n)$, a sum of n independent random variables (the $\{m_i\}$), is

$$\langle M \rangle = \Big\langle \sum_{i=1}^{n} m_i \Big\rangle = \sum_{i=1}^{n} \langle m_i \rangle = n\langle m \rangle, \tag{10.65}$$

and the variance is [Dunn and Shultis 2012]

$$\sigma^2(M) = \sum_{i=1}^{n} \sigma^2 m_i + 2 \sum_{i=1}^{n} \sum_{\substack{j=1 \\ j<i}}^{n} \text{covar}(m_i, m_j). \tag{10.66}$$

If the $\{m_i\}$ are independent and identically distributed,[7] then the covariances vanish leaving

$$\sigma^2(M) = \sum_{i=1}^{n} \sigma^2 m_i = \sum_{i=1}^{n} \sigma^2(m) = n\sigma^2(m). \tag{10.67}$$

For a given source, detector, geometry, etc., the probability that a radiation event produced n electron-ion pairs in the chamber gas is denoted by $p_{in}(n)$ with a mean $\langle n \rangle$ and variance $\sigma^2(n)$. This PDF is very complex because it involves modeling the electron-ion pairs produced along the trajectory of the incident radiation particle. As a result no explicit expression for $p_{in}(n)$ is usually available, but, conceptually, it exists.

A pulse height spectrum is a histogram depicting the frequency of observing the total charge Q liberated in a detector. For each monoenergetic radiation particle interacting within the detector, there are n_j electron-ion pairs initially liberated, and the shower produced has an average multiplication factor $\overline{m}_j$. As information is accumulated, i.e., more interaction events are observed, an average number of initial electron-ion pairs $\overline{n}$ becomes evident as does an average multiplication factor $\overline{M}$. The average charge collected over multiple monoenergetic events is, therefore, $\overline{Q} = q\overline{nM}$ where

$$\overline{nM} \simeq \langle nM \rangle = \sum_{i=1}^{\infty} n_i M(n_i) p_{in}(n_i). \tag{10.68}$$

The variance $\sigma^2(\overline{Q})$ defines the theoretical limit on energy resolution for a proportional counter. Two sources of variance are identified above, namely, the variance $\sigma^2(\overline{n})$ in the initial number of electron-ion pairs produced and the variance $\sigma^2(\overline{m})$ in the multiplication factor for each avalanche triggered by an initial electron. Because $\overline{n}$ and $\overline{m}$ are independent variables, simple error propagation can be used to give

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \left(\frac{\sigma(\overline{n})}{\overline{n}} \right)^2 + \left(\frac{\sigma(\overline{m})}{\overline{m}} \right)^2. \tag{10.69}$$

Substitution of Eq. (10.64) into Eq. (10.69) yields

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \left(\frac{\sigma(\overline{n})}{\overline{n}} \right)^2 + \frac{1}{n} \left(\frac{\sigma(m)}{\overline{m}} \right)^2. \tag{10.70}$$

For a purely stochastic Poisson process, the expected variance for n is $\sigma^2(\overline{n}) = n$, where $\overline{n} = E/w$, E is the energy deposited in the detector and w is the average ionization energy. Therefore, the expected standard

[7] This assumption is not valid if the positive ions create significant space-charge effects.

error for a Poisson distribution is $\sigma(\overline{n}) = \sqrt{E/w}$. However, Fano [1947] points out that the ionization process does not strictly follow a Poisson probability density function.

The process by which charged particles lose energy by impacting gas atoms to produce electron-ion pairs is complex. One can measure the distance in the gas that an alpha particle travels (Δx) and the associated energy loss ($-\Delta E_\alpha$). After numerous trials, fluctuations are observed in ΔE_α about some average value $\overline{\Delta E_\alpha}$. Now consider the inverse case, in which the change in energy ΔE_α is constant and the associated fluctuation in Δx is recorded. Such a problem is similar to the alpha particle straggling issue described in Chapter 4.

Suppose it is determined that the average energy lost over distance x_0 is E_0. If instead, the alpha particle loses energy E over distance x_0, then it is expected that the average energy loss E_0 is achieved within an additional travel distance Δx, such that

$$\Delta x = \frac{x_0(E_0 - E)}{E_0}. \tag{10.71}$$

Note that Δx may be positive or negative. For any amount of energy lost, there is an average number of electron-ion pairs w produced for that energy loss, thereby producing an average number of ions n_0 for a defined energy loss E_0. If, instead, the alpha particle produces n ionizations along Δx while losing the energy E, then it is expected that the difference in ionization is realized within,

$$\Delta n = \frac{(E_0 - E)}{w}. \tag{10.72}$$

Adding n to both sides of this result and using $E_0/w = n_0$ one obtains

$$n + \Delta n - n_0 = n - \frac{E}{w}. \tag{10.73}$$

Consider a charged particle that has a total of I ionization impacts with the host gas. For the ith impact, n_i is the number of ionizations produced and u_i is the energy lost. The result of each impact is independent of other impacts; hence, averaged over many histories it can be assumed that $\overline{n}_i = \overline{n}$ for all n_i, and $\overline{u}_i = \overline{u}$ for all u_i. It is therefore shown, for distance x_0, $I = E_0/\overline{u} = n_0/\overline{n}$, and the variance is [Fano 1947]

$$\sigma^2_{n_0} = \langle (n - E/w)^2 \rangle = I \langle (n_i - u_i/w)^2 \rangle = F n_0, \tag{10.74}$$

where F is

$$F = \frac{\langle (n_i - u_i/w)^2 \rangle}{\overline{n}}, \tag{10.75}$$

and is traditionally called the *Fano factor*. The Fano factor accounts for the deviation from statistical fluctuations expected with a Poisson distribution. Hence, the Fano factor can be defined as

$$F = \frac{\text{observed variance}}{\text{expected variance from Poisson statistics}}. \tag{10.76}$$

Equation (10.70) then can be rewritten as,

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \frac{F}{\overline{n}} + \frac{1}{\overline{n}} \left(\frac{\sigma(m)}{\overline{m}} \right)^2. \tag{10.77}$$

Table 10.9. Fano factors for several detector gases.

Experimental measurements and theoretical calculations of Fano factors for various gases and gas mixtures have been reported in the literature with varying agreement [for example, Alkhazov et al. 1967, Alkhazov and Vorobe'ev 1969; Grosswendt 1984; Dias et al. 1997; Pansky et al.1997; Krajcar-Bronić 1998]. Dias et al. [1997] and Pansky et al. [1997] report that the Fano factor is dependent upon the initial energy of the primary ionizing particle, particularly important near photon absorption edges. The Fano factors for several gases are given in Table 10.9.

The Avalanche Distribution Function $p_{aval}(m)$

The theory of electron multiplication seeks to find the probability distribution function $p_{aval}(m)$ that gives the probability that an avalanche initiated by a single electron produces m electrons. This distribution problem has been studied by Snyder [1947], Frisch [1947, 1959], and Wijsman [1949]. All make several simplifying assumptions. Secondary electrons are produced only by impact ionization (one per impact) and production by photoionization is neglected. Recombination, electron attachment, and space charge effects are likewise neglected. Finally, the probability of an impact ionization is solely dependent upon the electron distance from surface of the anode.

In this section the approach used by Wijsman [1949] to find p_{aval} for a planar device is followed, In such a device, avalanching can occur anywhere within the chamber, i.e., avalanching could occur anywhere between the cathode ($x = 0$) and the anode ($x = d$). In Wijsman's approach it is also assumed that an impact collision creates only one additional electron.

Consider a coaxial ion chamber with the central wire as the anode. As electrons approach the inner anode wire, the avalanche region begins at the critical radius r_c from the coaxial center. When electrons enter the region defined by radius r_c, they attain sufficient kinetic energy to cause impact ionization. A local radial coordinate x is now introduced such that $x = 0$ at r_c and $x = 1$ at anode radius a, i.e.,

$$x = \frac{r_c - r}{r_c - a}\ , \quad a \le r \le r_c. \tag{10.78}$$

The probability an electron causes an ionization within dx about x is $\alpha_T(x)dx$, where α_T is the first Townsend coefficient. Wijsman sought $p(n, x)$ the probability that a single electron that started at $x = 0$ had grown to an avalanche of n electrons at a distance x. The probability no ionization occurs between $x = 0$ and x is

$$p(1, x) = \exp[-\tau(x)], \qquad \text{where} \qquad \tau(x) = \int_0^x \alpha_T(x')\, dx'. \tag{10.79}$$

To find $p(n, x)$, proceed as follows. The probability the avalanche contains $n - 1$ electrons at x' is $p(n - 1, x')$. The probability that one and only one of these electrons causes an ionization between x' and $x' + dx'$ is the probability that one of the $(n - 1)$ electrons causes an ionization multiplied by the probability that the other $(n - 2)$ electrons produce no ionization, i.e., $(n - 1)\alpha_T(x')dx'[1 - \alpha_T(x')dx']^{n-2}$. As $dx' \to 0$ this probability becomes,

$$(n - 1)\alpha_T(x')dx'. \tag{10.80}$$

Now the avalanche contains n electrons and the probability that none causes further ionizations between x' and x is

$$\exp[-n\{\tau(x) - \tau(x')\}]. \tag{10.81}$$

To find $p(n, x)$ multiply $p(n - 1, x')$ by the factors of Eqs. (10.80) and (10.81) and integrate over $(0, x)$ to obtain, for $n > 1$,

$$p(n, x) = \int_0^x p(n - 1, x')(n - 1)\alpha_T(x') \exp[-n\{\tau(x) - \tau(x')\}]dx'. \tag{10.82}$$

To solve this equation for $p(n,x)$, subject to Eq. (10.79), use a change of variables $y(x) = \exp[\tau(x)]$ from which it is found $y(0) = 1$ and $dy/y = d\tau$. Let $q(n,y) \equiv y^n p(n,y)$. Equation (10.82) transforms to

$$q(n,y) = (n-1)\int_1^y q(n-1,y')\,dy'. \tag{10.83}$$

Differentiation of this equation gives

$$\frac{dq(n,y)}{dy} = (n-1)q(n-1,y) \qquad \text{with} \qquad q(1,y) = 1. \tag{10.84}$$

Solve these equations successively by induction for $n = 2,3,4,\ldots$ to find

$$q(n,y) = (y-1)^{n-1}. \tag{10.85}$$

Finally, transforming y back to x, the solution of Eq. (10.82) is

$$p(n,x) = \exp[-n\tau(x)]\{\exp[\tau(x)] - 1\}^{n-1}. \tag{10.86}$$

In particular, when the avalanche reaches the anode, $x = 1$ and $n \to m$ so

$$p(m,1) = \exp[-m\tau(1)]\{\exp[\tau(1)] - 1\}^{m-1}, \tag{10.87}$$

or in terms of the original coordinate system

$$p(m,a) = \exp[-m\tau(a)]\{\exp[\tau(a)] - 1\}^{m-1}, \tag{10.88}$$

where the "optical thickness" of the avalanche region is

$$\tau(a) = \int_a^{r_c} \alpha_T(r')\,dr'. \tag{10.89}$$

This distribution is known as the Furry distribution.[8] It is easily shown

$$\overline{m} \equiv \langle m \rangle = \sum_{m=1}^{\infty} m p(m,a) = \exp[\tau(a)]. \tag{10.90}$$

Thus, $p_{aval}(m|\overline{m})$ is given by

$$\boxed{p_{aval}(m|\overline{m}) = \frac{1}{\overline{m}}\left(1 - \frac{1}{\overline{m}}\right)^{m-1}} \quad . \tag{10.91}$$

[8] This distribution was derived earlier by Furry [1937] who was studying electron showers produced by very high energy electrons incident on lead. Furry found the number n of secondary electrons produced in a lead sheet of thickness t was given by

$$p(n|\lambda t) = e^{-\lambda t}(1 - e^{-\lambda t})^{n-1}, \quad n \geq 1,$$

where λ is an interaction coefficient with units of reciprocal length. The mean of this PDF is $\langle n \rangle = e^{\lambda t}$ so the PDF can be written as

$$p(n|t) = \frac{1}{\langle n \rangle}\left(1 - \frac{1}{\langle n \rangle}\right)^{n-1}.$$

It is interesting that two different problems yield the same result. Wijsman was unaware of this earlier work, but because of Furry's primacy, the distribution of Eq. (10.91) is named after him.

The second moment of this PDF is $\langle m^2 \rangle = 2\overline{m}^2 - \overline{m}$, so the relative variance is

$$\frac{\sigma^2(m)}{\overline{m}^2} = 1 - \frac{1}{\overline{m}}. \tag{10.92}$$

For large values of $\overline{m}$, which is usually the case, Eq. (10.92) reduces to [Lansiart and Morucci 1962],

$$\frac{\sigma^2(\overline{m})}{\overline{m}^2} = 1. \tag{10.93}$$

Equation (10.91) can be expanded as

$$p_{aval}(m|\overline{m}) = \frac{1}{\overline{m}} \left[1 - (m-1)\frac{1}{\overline{m}} + \frac{1}{2}(m^2 - 3m + 2)\left(\frac{1}{\overline{m}}\right)^2 - \mathcal{O}\left(\frac{1}{\overline{m}}\right)^3 \right]. \tag{10.94}$$

In the limit of large $\overline{m}$

$$p_{aval}(m|\overline{m}) \simeq \frac{1}{\overline{m}} \left[1 - \frac{m}{\overline{m}} + \frac{1}{2}\left(\frac{m}{\overline{m}}\right)^2 \right] \simeq \frac{1}{\overline{m}} \exp\left(-\frac{m}{\overline{m}}\right). \tag{10.95}$$

For values of $\overline{m} \gtrsim 50$, Eq. (10.95) approximates Eq. (10.91) quite well.[9] It should be noted that this exponential PDF gives large fluctuations in m about the mean. Genz [1973] also points out that, for low values of the reduced electric field ($\mathcal{E}/P$), the exponential approximation of the Furry model of Eq. (10.95) adequately describes the probability distribution of avalanche electrons.

Effects of High Electric Fields

However, as noted by Byrne [1962], the Furry model fails to predict the observed results reported for the distribution function of m under high electric field conditions [Curran et al. 1949]. The Furry model was initially developed for high-speed particle impacts and it was assumed that the electrons have equal probability of the causing impact ionization, within a differential distance of travel, regardless of their origin. Thus, the effects of high electric fields, which accelerate the electrons, were ignored. In a coaxial gas detector, as the electron shower progresses, the distance between ionizing collisions decreases because of the increasing electric field as electrons approach the anode. Further, as the applied electric field is increased, eventually the average distance between collisions in the highest field region is about the same as the minimum travel distance for impact ionization, thereby fluctuations about $\overline{m}$ are suppressed [Schlumbohm 1958a]. As a result, it is not surprising the Furry model does not hold for high values of $\mathcal{E}/P$.

Distribution functions $p_{aval}(m)$ from avalanche data for different values of $\mathcal{E}/P$ are given in the literature for selected gases [Curran 1949; Schlumbohm 1958a, 1958b; Cookson and Lewis 1966a, 1966b; Genz 1973]. From the literature, it becomes apparent that at high values of $\mathcal{E}/P$ the data distribution functions deviate from the exponential approximation of the Furry PDF but, instead, develop a maxima in the distribution as can be seen in Fig. 10.14. Several alternative models have been proposed to account for the high-field measured distributions of $p_{aval}(m)$. These models are discussed by Genz [1973], and are shown to match the measured distributions with varying degrees of success. One of the more popular models is based on the *Pólya* statistical model [Pólya 1930]. Arley [1943] introduced the use of the Pólya model for the analysis of an electron shower in lead, a similar problem considered by Furry.

[9] From Eq. (10.95) the relative variance is found to be,

$$\sigma^2(m) = \int_0^\infty (m - \overline{m})^2 \frac{1}{\overline{m}} \exp\left(-\frac{m}{\overline{m}}\right) dm = \overline{m}^2,$$

so that $\sigma^2(m)/\overline{m}^2 = 1$, in agreement with Eq. (10.93).

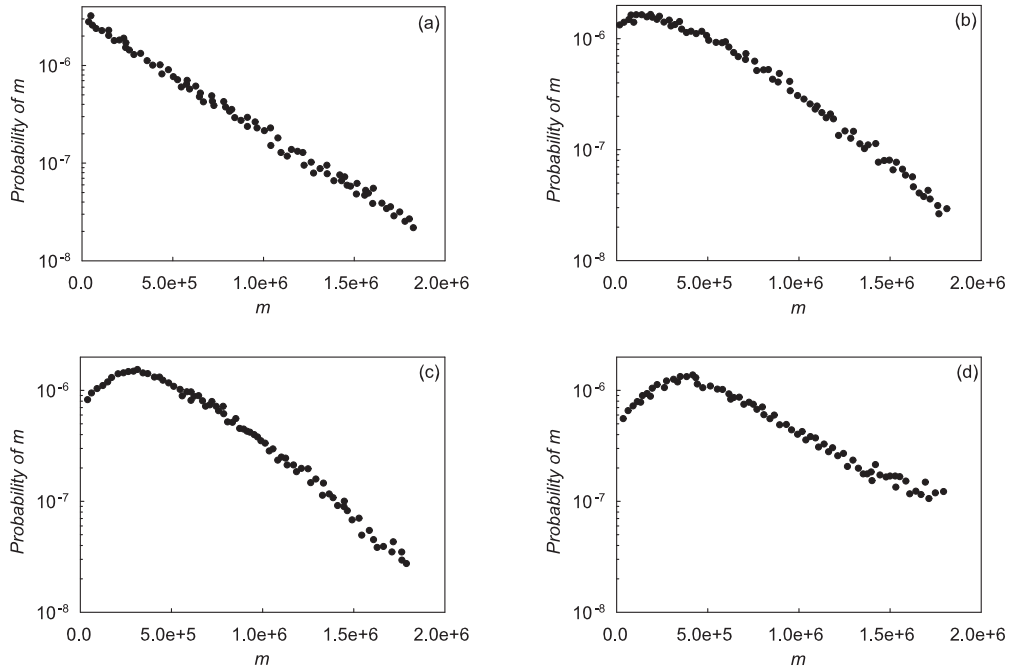

Figure 10.14. Measured multiplication factor distributions for methane gas at reduced electric fields of (a) 48, (b) 120, (c) 156, and (d) 218 V cm^{-1} torr^{-1}. Only under the lowest electric field reported (a) does the distribution follow Furry's prediction. The other distributions shown in (b)–(d) resemble a Pólya distribution. Data from [Cookson and Lewis 1966b].

Byrne [1962] relaxed many of the assumptions used by Wijsman and developed a more general expression for $p_{aval}(m)$. In the present notation, Byrne obtained

$$p_{aval}(m|\overline{m}) = \left(\frac{\overline{m}}{1+b\overline{m}}\right)^m \frac{(1)(1+b)...(1+(m-1)b)}{m!}(1+b\overline{m})^{-1/b}, \quad m \geq 1. \tag{10.96}$$

This PDF is the Pólya distribution, also known more commonly as the negative binomial distribution, in which $b \geq 0$ is a parameter.

The first and second moments of Eq. (10.96) are [Byrne 1962],

$$\langle m \rangle = \overline{m} \qquad \text{and} \qquad \langle m^2 \rangle = (1+b)\overline{m}^2 + \overline{m}. \tag{10.97}$$

Hence, $\sigma^2(m) = \langle m^2 \rangle - \langle m \rangle^2 = b\langle m \rangle^2 + \langle m \rangle$ and the relative variance is thus

$$\boxed{\frac{\sigma^2(\overline{m})}{(\overline{m})^2} = b + \frac{1}{\overline{m}}} \quad . \tag{10.98}$$

Some measurements of the relative variance indicate that average values as low as 0.45 can be expected [Sipila 1976]. For large values of $\overline{m}$, the limiting case for Eq. (10.98) reduces to,

$$\frac{\sigma^2(\overline{m})}{(\overline{m})^2} = b, \tag{10.99}$$

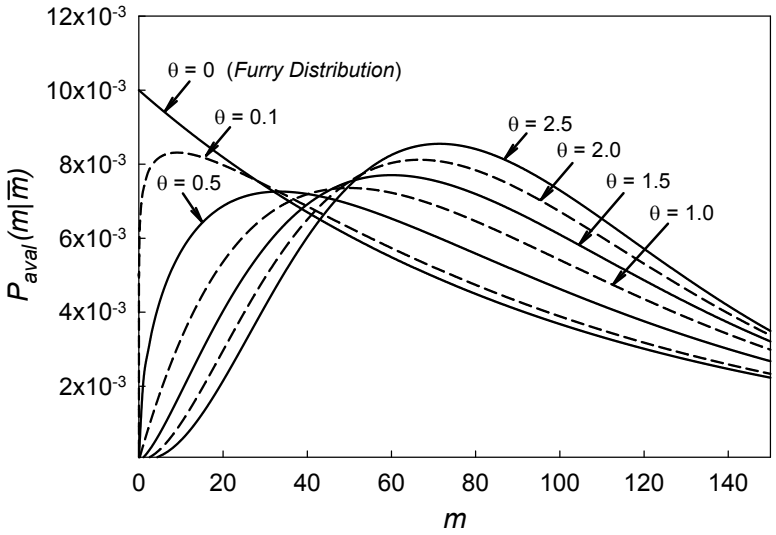

Figure 10.15. The Pólya distributions of (Eq. (10.102)) for $\overline{m} = 100$ and $\theta = 0, 0.1, 0.5, 1.0, 1.5, 2.0,$ and 2.5.

a result reported by Lansiart and Morucci [1962].

Cookson and Lewis [1966a] assumed that the first Townsend coefficient α_T can be represented as

$$\alpha_T = \alpha_{T(max)} \left(1 + \frac{\theta}{m}\right), \tag{10.100}$$

where $\alpha_{T(max)}$ is the limiting value of α_T for large m ($m \gtrsim 100$) and $\theta \geq 0$ is a parameter dependent upon the gas type and operating conditions. Byrne [1962] and Cookson and Lewis [1966b] demonstrated that the assumption of Eq. (10.100) leads to a Pólya distribution,

$$p_{aval}(m|\overline{m}) = \frac{\widetilde{b}}{\overline{m}} \frac{1}{(\widetilde{b}-1)!} \left(\frac{\widetilde{b}m}{\overline{m}}\right)^{\widetilde{b}-1} \exp\left(-\frac{\widetilde{b}m}{\overline{m}}\right), \tag{10.101}$$

where $\widetilde{b} = b^{-1} = (\theta+1)$ and $\widetilde{b} \geq 1$. Byrne showed that as $\widetilde{b}$ increases above unity (or θ increases above zero), Eq. (10.101) has a maximum at increasing values of m, as shown in Fig. 10.15. The physical significance of θ (or $\widetilde{b}$) is debatable. Byrne [1962, 1969] suggests that it represents the fraction of electrons above the necessary gas ionization energy in the presence of large numbers of electrons. However, Cookson and Lewis [1966a] and Alkhazov [1970] have contested Byrne's explanation of θ (and $\widetilde{b}$). Limiting conditions indicate that for $\widetilde{b} \to 1$ (or $\theta \to 0$), Eq. (10.102) reduces to the Furry statistical model, whereas when $\widetilde{b} \to \infty$, Eq. (10.102) reduces to the Poisson statistical model.

With a value of $\widetilde{b} \simeq 3/2$, Eq. (10.101) agreed with the measured values of Curran et al. [1949]. This agreement supports the validity of using the Pólya model for the electron avalanche. Substitution of $\widetilde{b} = (1+\theta)$ into Eq. (10.101) yields,

$$\boxed{p_{aval}(m|\overline{m}) = \frac{(1+\theta)}{\Gamma(1+\theta)} \frac{1}{\overline{m}} \left(\frac{(1+\theta)m}{\overline{m}}\right)^{\theta} \exp\left(-\frac{(1+\theta)m}{\overline{m}}\right)}. \tag{10.102}$$

The total limiting variance for the avalanche electron population is found by substituting Eq. (10.92) or Eq. (10.98) into Eq. (10.77), thereby yielding

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \frac{F}{\overline{n}} + \frac{1}{\overline{n}}\left(1 - \frac{1}{\overline{m}}\right), \tag{10.103}$$

for low $\mathcal{E}/P$ values, and

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \frac{F}{\overline{n}} + \frac{1}{\overline{n}}\left(\frac{1}{\overline{b}} + \frac{1}{\overline{m}}\right), \tag{10.104}$$

for high $\mathcal{E}/P$ values.

Example 10.4: Determine the limiting resolution for 122-keV γ rays in a proportional counter backfilled with Ar for which $\overline{m} = 100$. Disregard any recombination effects.

Solution:

From Table 10.9, $F = 0.17$ for Ar, and from Table 9.1, $w = 26$ eV/iep pair for Ar. Assume a value of $b \approx 0.45$. From Eq. (10.104) and use of $\overline{n} = E_\gamma/w$

$$\frac{\sigma^2(\overline{Q})}{\overline{Q}^2} = \frac{w}{E_\gamma}\left[F + \left(\frac{1}{\overline{b}} + \frac{1}{\overline{M}}\right)\right] = \frac{26 \text{ eV/eip pair}}{122000 \text{ eV}}\left[0.17 + \left(0.45 + \frac{1}{100}\right)\right] = 1.34 \times 10^{-4}.$$

The fractional energy resolution is defined as,

$$\frac{\text{FWHM}}{Q} = 2\sqrt{2\ln 2}\left(\frac{\sigma(\overline{Q})}{\overline{Q}}\right) = 0.0273. \tag{10.105}$$

This result predicts an energy resolution of 2.73%.

In practice, the energy resolution of a proportional counter of the magnitude predicted by Example 10.4 is unusually small because many other factors affect the energy resolution. Sources of resolution degradation include noisy electronics, varying gas pressure, gas impurities, avalanche saturation, anode wire eccentricity and end effects, and anode wire uniformity [Charles and Cooke 1968].

Sources of electronic noise include variations in operating voltages from the high voltage power supply, detector leakage current and amplifier electronic noise, all of which can be reduced to negligible levels for well-designed equipment. Gas pressure variations can be caused by temperature changes, or, for gas-flow systems, by variations in the gas flow, although such variations are usually small if the measurement period is relatively short. Gas impurities can alter ion speeds and increase electron attachment. However, if the gas detector system is thoroughly purged with a purified counting gas before use, the effect of gas impurities on energy resolution can be eliminated. The gas flushing should be conducted long enough to remove moisture contamination from the system interior surfaces.

Avalanche saturation causes the appearance of non-linear pulse heights, a result of operating the counter in Region IIIa, the transition region, as was discussed in Sec. 10.5.2. To reduce the shift in pulse heights, Spielberg [1967] reports that larger diameter wires produce less signal variance, and that tungsten wires show smaller shifts in pulse heights than do steel wires. Limiting counting rates below 2000 cps also helps minimize the variance [Charles and Cooke 1968]. Anode wire eccentricity can create axial non-uniformities in the electric field, thereby adding to the variance about $\overline{m}$, although this effect is generally small in well-built

proportional counters [Rossi and Staub, 1949]. The uniformity of the wire has been shown also to affect the shift in pulse heights [Spielberg 1967], but thermal cleaning (heating to temperatures capable of evaporating a microscopic layer from the wire) improved performance. However, the benefit of thermally cleaning degraded over a period of a week, presumably from deposition of gas products upon the wires. Indeed, for proportional counters in a high radiation environment, the breakdown of counting gases, especially those with organic quenching gases, tends to coat the anode wires and leads to an increase in electrical resistance and wire diameter. As a result, the variance in the avalanching electric field increases the variance about $\overline{m}$. Despite these complications, energy resolutions below 8% FWHM have been reported for low-energy gamma rays [Charles and Cooke 1968, Sakurai and Ramsey 1992], and below 2% FWHM for neutron induced reaction products [Oed 1988].

10.6 Selected Proportional Counter Variations

Since their introduction by Geiger and Rutherford in 1908, gas-filled detectors have been used widely for many different radiation measurements, ranging from small pocket dosimeters to large chambers for high-energy physics measurements. Proportional counters are of particular interest, mainly due to their high signal gain while preserving energy deposition information. There are two basic types of proportional counters: gas flow detectors and sealed detectors. Proportional counters can detect charged particles, energetic photons, and neutrons. They are made in many sizes and shapes, too many to describe in this chapter, although many variations are described elsewhere [Rossi and Staub 1949; Staub 1953; Price 1964; Sauli 2014]. However, some common proportional counter geometries, along with a few uniquely interesting detectors, are described in the following sections.

10.6.1 Gas-Flow Proportional Counters

Gas flow detectors are operated with the detection gas being constantly replenished during operation. This constant gas replenishment allows gas molecules degraded from ionizing interactions to be removed and replaced with fresh gas molecules. Moreover, the gas supply can be shut off when not in operation. Gas flow detectors can operate indefinitely, provided that a gas source is available. Consequently, gas flow detectors are usually operated as laboratory instruments due to the inconvenient requirement of an external gas supply. This requirement makes portable instrumentation awkward.

2π and 4π Counters

The general construction of a 2π proportional counter is depicted in Fig. 10.16. The chamber is usually cylindrical, as shown in Fig. 10.17; but sometimes the chamber may be hemispherical. In either case, a radioactive sample placed in the chamber, usually through a rotating sample changer, is exposed to a detector solid angle of 2π steradians; hence the name "2π counter". An anode wire loop extends into the chamber through an insulating high-voltage electrical feedthrough. Typically, the anode wire is on the order of 25 to 75 microns in diameter, often composed of a gold-tungsten alloy. For safety reasons, positive high voltage is applied to the anode wire while casing of the chamber is kept at ground potential.

The usual gas used in a gas-flow counter is P-10, and flows into the chamber through an input port and exits through a gas metering device, such as a "bubbler" or gas flow meter. A common flow rate is "one bubble per second", which is about 50 to 60 sccm (standard cubic cm per minute). Because a detector remains unvented between uses, it is common practice to purge the detector with the chosen detection gas for several minutes before operation, usually at a higher flow rate than used during operation. For instance, the purge may use gas flows >300 sccm to remove any air from the chamber, but then is reduced to about 55 sccm during operation. The reduction in gas flow reduces the possibility of perturbing charge collection in the chamber, with the added advantage of conserving the detector gas.

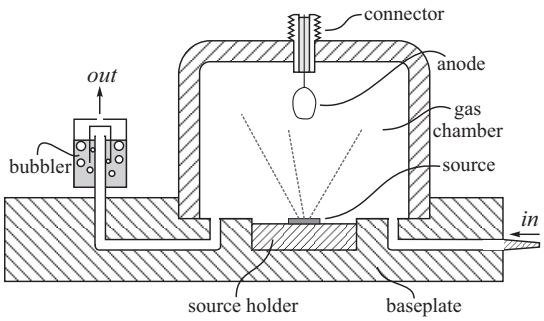

Figure 10.16. Diagram of a 2π gas-flow proportional counter.

Figure 10.17. A 2π gas-flow proportional counter, showing the detector base-plate, bubbler, 2π detector, and gas inlet.

A major feature of the "windowless" gas flow detector depicted in Fig. 10.16 and Fig. 10.17 is the absence of an attenuating medium between the radiation source and the detector, because the source is inside the detector. In the 2π detector approximately 50% of emissions enter the detector gas, although self-absorption and backscattering effects must still be taken into account. Alpha particles, with ranges of a few centimeters, deposit a large fraction of their energy in the chamber. Beta particles, usually having ranges up to tens of centimeters, usually deposit only a small portion of their energy in the chamber. Gamma rays usually interact in the walls of a proportional counter rather than with the gas. Interactions in the wall can eject energetic electrons into the gas chamber. The stopping power $-dE/dx$ is much higher for alpha particles than for beta particles (or electrons/positrons). As a result, for sources that emit both alpha and beta particles, a counting curve similar to that shown in Fig. 10.12 is expected, in which the alpha particle plateau(s) appears at a much lower voltage than the beta particle plateau. Consequently, beta particles and gamma rays are easily discriminated against by setting the high voltage to the center of the alpha particle counting plateau and adjusting the LLD above the pulse heights produced by beta particles and gamma rays. The windowless gas-flow detector also has the advantage of being able to detect low energy beta particles that would otherwise be attenuated by the intervening air and the detector window. This advantage is important for radionuclides that emit low energy beta particle such as ^{14}C and ^{3}H, provided that such sources are properly prepared so as to reduce self-absorption effects.[10]

The 4π windowless gas-flow detector is designed so the radioactive source is placed upon a thin platform between two 2π detectors [Martin and Green 1958]. If the combined thickness of the platform and radioactive sample is relatively thin compared to the ranges of the particles of interest, then almost all of emitted particles enter one of the detector halves. This configuration reduces uncertainty from backscattering, although self-absorption may still be an issue. These devices have been used to measure absolute beta particle activities. For radiation particles ejected simultaneously in relatively opposite directions, the two halves of a 4π counter can be operated in coincidence to record only those events (or operated in anti-coincidence to reject those events).

Thin Window Counters

Gas-flow detectors with thin windows are used when the radioactive source is outside of the detector, thereby restricting the detector solid angle to $<2\pi$. A common laboratory thin-window gas-flow detector configuration

[10] Low energy beta particles are more commonly measured with liquid scintillation detectors, covered in Chapter 13.

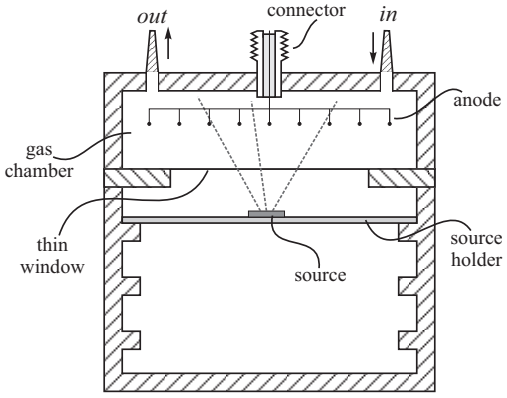

Figure 10.18. Diagram of a thin-window, gas-flow, proportional counter. A multi-wire anode is depicted in the figure; however, many thin-film proportional counters have a single wire loop for the anode.

Figure 10.19. A thin-window, gas-flow, proportional counter, showing a metallized boPET window and sample holder slots.

is shown schematically in Fig. 10.18 and a photograph is given in Fig. 10.19. Commercial units commonly have windows fabricated from thin boPET material that has been aluminized to block interference from electromagnetic and visible light. The windows typically have mass thicknesses of about 0.4 to 2.0 mg/cm^2. To avoid damaging the window, the gas exit port must remain unobstructed.[11] Gas purge and operational flow rates are similar to those used for windowless gas-flow detectors.

Disadvantages of using a thin-window gas-flow proportional detector include decreased detector solid angle, parallax effects (see Sec. 7.5), and particle backscattering off the window. However, thin-window chambers are usually compact and relatively easy to load. Unlike windowless gas-flow detectors, the radioactive source distance for many thin-window detectors is variable, either incrementally with shelving slots, as shown in Fig. 10.18 and Fig. 10.19, or with the source mounted on a retractable threaded rod. Some commercial proportional counters have a head that can be mounted to a customized measurement system.

Thin-window gas-flow detectors, used as portable units at frisking stations, can have windows ranging from 25 to 100 cm^2 window area. They also have input ports for constant gas replenishment as shown in Fig. 10.20. Some commercial models have the gas input through the detector cable rather than through a separate gas supply line, thus simplifying cable/detector connections. The gas exits the detector through a pin-sized hole located at the top of the detector body. Thin-window gas-flow detectors are also configured as floor monitors, in which the detector height with respect to the floor is adjustable. The systems include a gas supply bottle, portable cart, readout ratemeter, and cable connections.

Specially designed thin-window, gas-flow, proportional counters are used for detection of low energy photons, such as characteristic x-rays [Goldstein et al. 1981], and are often used in measurement systems for wavelength dispersive x ray spectroscopy. The windows of these detectors can be made from boPET; however, higher transmission for low energies is obtained with lower density windows, such as polypropylene (1 to 6-microns thick) and Formvar® (polyvinyl formal), usually < 1 micron thick. For example, a 6 micron thick boPET window absorbs 74% Al-K$_\alpha$ (1.487 keV), 85% Mg-K$_\alpha$ (1.254 keV), 92% Na-K$_\alpha$ (1.041 keV) and 99% F-K$_\alpha$ (0.677 keV) x rays (see Fig. 10.22). Overall, polypropylene of the same thickness (6 microns) absorbs approximately 60% fewer low energy photons than does boPET, consequently, it is routinely used for detection of characteristic x rays emitted by low Z elements. These low energy detectors typically have two windows, an entrance window usually fashioned from a low density organic material, and an exit window

[11] You can guess why one author of this book knows this.

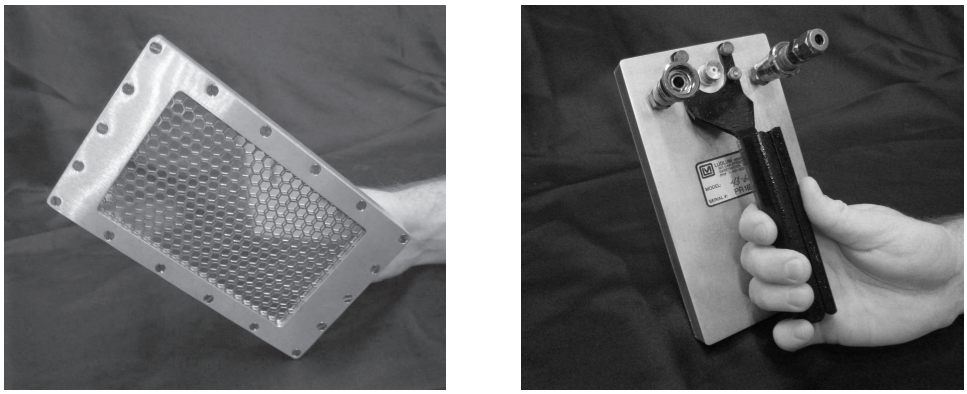

Figure 10.20. (left) Handheld thin-window gas-flow proportional counter (Ludlum 43-68) in which the thin aluminized boPET window and window guard are visible, and (right) handheld thin-window gas-flow proportional counter in which the gas and electronic connections are visible.

composed of 25 micron thick Be that helps to reduce the production of secondary radiation (ejected electrons) from photon interactions with the back wall (see Fig. 10.21).

10.6.2 Sealed Proportional Counters

Sealed proportional counters are available in a variety of geometries, although the most popular configurations are based on coaxial cylindrical designs. These proportional counters offer an economical method of radiation detection and come in sizes ranging from 1-cm diameter to several centimeters in diameter and with lengths of up to 1 to 2 meters. Unlike gas-flow detectors, the detector gas is not replenished, and consequently, the quenching gas can be depleted over time. Common commercial units are backfilled with H_2, Ne, Ar, Xe, Kr, P-10, ^{3}He, or $^{10}BF_3$.

Voltages applied to proportional counters are typically higher than those used for ion chambers; hence, it is necessary, as with ion chambers, to design the chamber to reduce electronic noise arising from leakage currents. As discussed in Sec. 9.5.1, a guard ring or guard tube is positioned around the anode wire, as depicted in Fig. 10.23. The voltage drop across the insulator between the guard tube and anode is effectively reduced, thereby lowering the leakage current as shown in Fig. 9.25. Leakage currents on the order of 10^{-16} amps can be achieved with the addition of a guard tube in the chamber [Borkowski 1947].

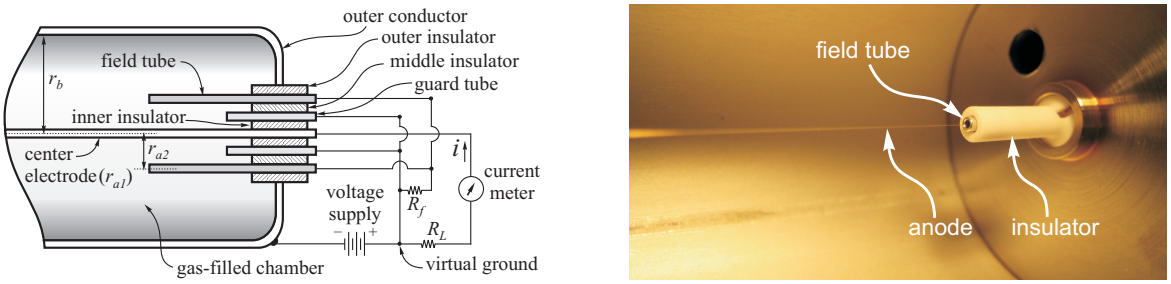

Figure 10.23. (left) Diagram of a sealed proportional counter tube with guard ring and field tube, and (right) inside chamber of a cylindrical steel proportional counter with a field tube.

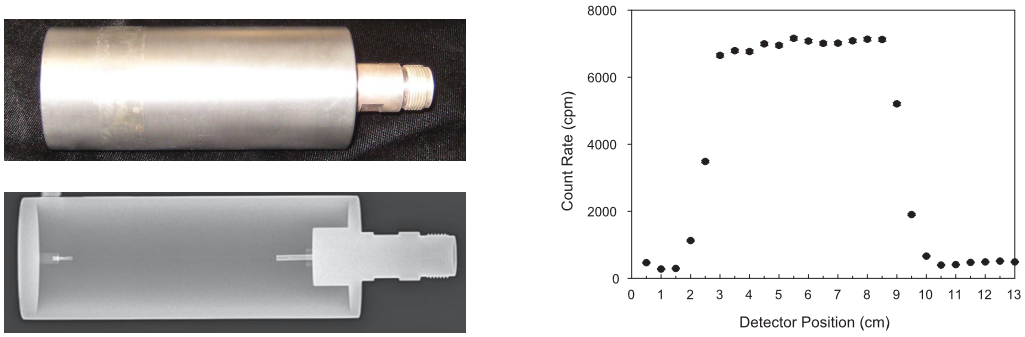

Figure 10.24. (upper left) Sealed ^{3}He-filled proportional counter, and (lower left) x-ray image of the sealed ^{3}He-filled proportional counter. The Teflon® insulator standoffs are barely visible in the x-ray image. (right) Detector response to a collimated thermal neutron beam as a function of position. The active region of the device is confined to the length between the ends of the standoff connectors, approximately 42% of the detector length.

The variation in the electric field around the anode near the insulating standoffs can have deleterious "end-effects" [Cockroft and Curran 1951]. Consequently, the sensitive region within a proportional counter is not well defined, as shown in Fig. 10.24, In this example, the sensitive region that limits the full development of the multiplication factor $\overline{M}$ amounts to only 42% of the detector length. However, the electric field end effects can be rendered negligible by fitting *field tubes* over and around the grounded guard tube (see Fig. 10.23). For a field tube of radius r_{a2}, the potential is adjusted such that the surface potential is the same as the radial potential in the gas at radial distance $r = r_{a2}$ near the detector center. The potential at the surface of the field tube and the resulting electric field are too small to produce an avalanche. If the field tube length is approximately the same as the detector radius r_b, then the electric field lines emanating from the anode wire between the ends of the field tubes are also radial with almost no distortion [Cockroft and Curran 1951].

Other sealed detector geometries include "pancake" detectors, side window detectors, end window detectors, quadrilateral detectors, spherical detectors, straw tube detectors, multi-wire detectors, microstrip detectors, and position sensitive detectors. A few of these detectors are described below.

10.6.3 Proportional Counters for Low Energy Gamma-Rays

As mentioned earlier, one important use of proportional counters is for detection of low energy x rays, especially for electron microprobe applications and wavelength dispersive spectroscopy. Such detectors can

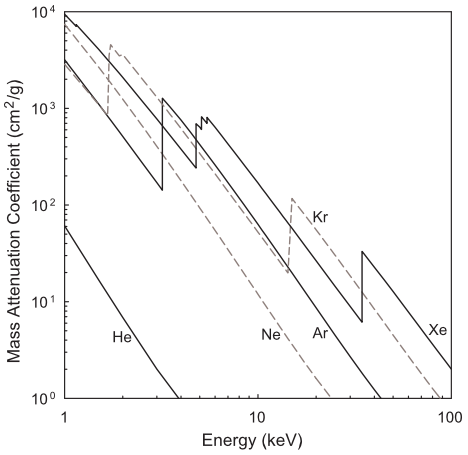

Figure 10.25. Gamma-ray total mass attenuation coefficients for common detector gases. Data from [NIST].

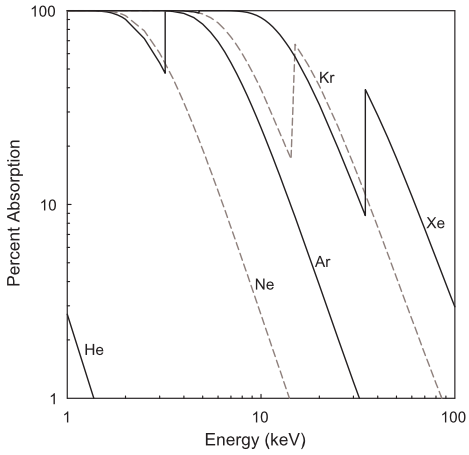

Figure 10.26. Gamma-ray percent absorption through a 2.54-cm diameter proportional counter at 1 atm pressure. Data from [NIST].

be fashioned as gas-flow detectors [Hendee et al. 1956; Dolby 1960; Riggs 1963] or sealed tubes [Lang 1951, 1956; Arndt et al. 1954]. To increase detection efficiency, the detector requires a thin entrance window that does not appreciably absorb the photons of interest (see Fig. 10.22). Additionally, the fill gas must be able to absorb the total energy of the photons, an ability that depends on atomic number of the gas, the gas pressure, and the detector width. Shown in Fig. 10.25 are the photon mass attenuation coefficients $\mu_m = \rho\mu$ for noble gases often used in proportional counters. An estimate of the expected intrinsic detection efficiency ϵ_I for a collimated photon beam intersecting the detector is

$$\epsilon_I = 1 - e^{-\mu_m \rho t} \tag{10.106}$$

where ρ is the gas density in g cm^{-3} and t is the proportional counter tube diameter. Results for several noble gases loaded into a 2.54-cm diameter tube are shown in Fig. 10.26. Careful selection of the fill gas can reject high energy photons while giving acceptable detection efficiency of characteristic x rays. For instance, Ar gas effectively detects characteristic x rays up to approximately 10 keV, while higher energy x rays ($>$ 30 keV) generally pass through the device without detection. As mentioned in a prior section, a thin back window, usually constructed of Be or perhaps Al, can be used to reduce the probability that these higher energy x rays interact with the detector walls. Kr or Xe gas can be used to extend the detector sensitivity to higher energies.

Of special note are the gas K absorption edges that cause a reduction in efficiency at the absorption energy limit. For instance, the K edges for Ar, Kr, and Xe are 3.208 keV, 14.323 keV, and 34.579 keV, respectively. Directly below these energies for each respective gas, there is a sharp decrease in efficiency as can be seen from Figs. 10.25 and 10.26. Additionally, because of the characteristic x-ray transitions among different shells, energy can be lost from the detector. For instance, electrons excited from the K shell of Xe have K_α or K_β transitions of approximately 29.8 keV and 22.64 keV, respectively. If these Xe characteristic x rays escape the detector, the total energy deposited is reduced by the lost x-ray energy, which results in the formation of an *escape peak* in the pulse height spectrum.

10.6.4 Position Sensitive Proportional Counters

A method to turn a cylindrical gas filled detector into a position sensitive detector is described by Kuhlmann et al. [1966], McDicken [1967], and Borkowski and Kopp [1968]. The basic configuration takes advantage of

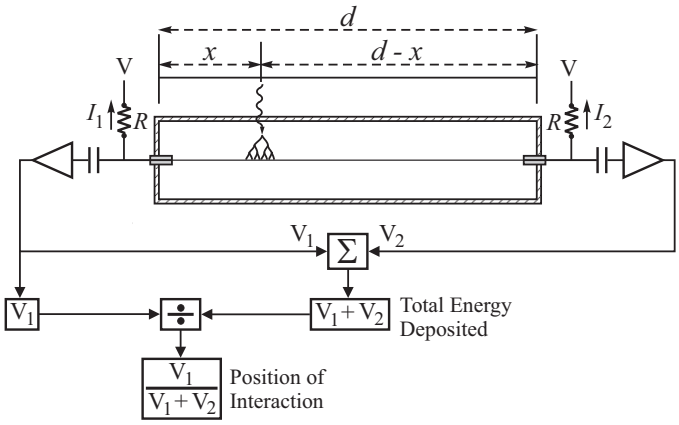

Figure 10.27. Schematic diagram of a position sensitive gas-filled proportional counter for the voltage division (charge division) method.

the distributed resistance of the central anode wire. An avalanche initiated by an ionizing particle causes current to flow through the anode and can be measured by preamplifiers at each end of the detector (as depicted in Fig. 10.27). The currents I_1 and I_2 flowing through the load resistors at each end of the detector are proportional to the input voltages of each preamplifier. The output voltages from each preamplifier, V_1 and V_2 are summed in a circuit to produce a signal that is proportional to the total ionization in the counter. The quotient of V_1 divided by V_1+V_2 produces a signal proportional to the location of the avalanche centroid with respect to the anode.[12] Although the configuration and concept are quite simple, the actual implementation can be somewhat complicated, as pointed out by Fischer [1977]. Regardless, for small localized avalanches, a spatial resolution FWHM below 1.6 mm is possible [Kuhlmann et al. 1966]. The position information has been shown to be remarkably linear with the method.

By measuring differences in the risetime of the signals from a detector, spatial resolution below 1 mm has been reported [Borkowski and Kopp 1968, 1970]. Charge collected from an anode of length d at some arbitrary position x causes a current to flow through the anode resistance over length x in one direction and over length $d-x$ in the other direction. The risetime of the input voltage into each preamplifier is a function of x and is independent of the total charge liberated in the detector. The input voltage is amplified and shaped with a double RC differentiator to obtain a bipolar pulse, and the risetime of the voltage is measured by the time of the crossover point of the resulting bipolar pulse. The difference between the risetimes of the pulses from each end of the detector is a function of the interaction location x [Borkowski and Kopp 1970].

10.6.5 Multiwire Proportional Counters

Multiwire proportional counters (MWPCs), as the name implies, are detectors with several anode wires, and sometimes several cathode wires, in the same chamber. Developed in 1968 by Charpak, position sensitive MWPCs use a criss-cross array of wires. Covering large surfaces with layers of classical cylindrical proportional tubes was regarded as impractical,[13] and the MWPC concept stems from this perceived limitation. The original MWPC design consisted of a parallel array of anode wires strung between two cathode planes,

[12] The technique has also been used with Geiger-Müller counters by performing the spatial measurement at a preset saturation threshold V_S where $V_S = V_1 + V_2$ at a set pulse height before the Geiger discharge is fully developed; therefore, the position x becomes proportional to V_1/V_S where V_S is approximately constant.

[13] This problem was greatly mitigated by the advent of the *straw tube* detector.

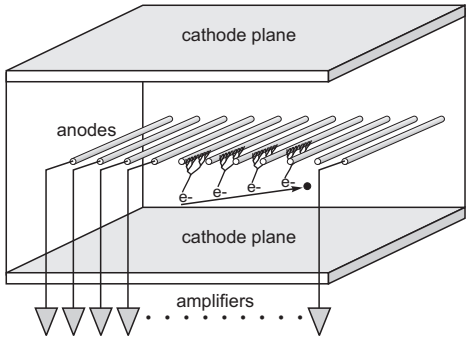

Figure 10.28. Cross section diagram of a MWPC.

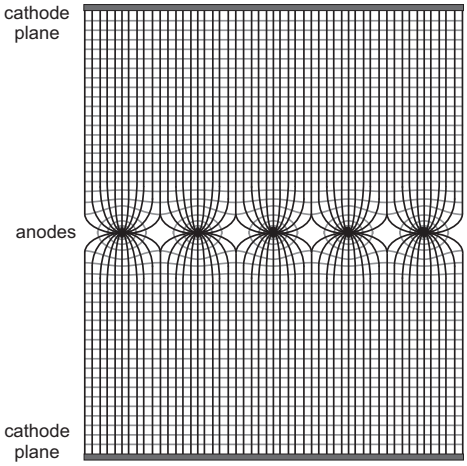

Figure 10.29. Electric field lines in a multiwire proportional counter (MWPC).

as shown in Fig. 10.28, with the parallel anode wires arranged only a few millimeters apart [Charpak 1970; Charpak and Sauli, 1979]. During operation, the detector electric field is perpendicular to the cathode planes, except in the close vicinity of the anodes as seen in Fig. 10.29. In the near field region of the anodes, the electric field lines must terminate perpendicularly to the anode wire surface, thereby producing a high electric field similar to a traditional cylindrical proportional counter. As a result, each wire operates as an individual proportional counter without a grounded barrier between the wires. Georges Charpak was awarded the 1992 Nobel Prize in Physics for his invention of the multiwire proportional chamber.

Particles entering the detectors produce a track of electron-ion pairs. It is possible with a MWPC to determine the (x, y, z) coordinates of track of the initial electron-ion pairs. Electrons drift towards the array of anodes, and when they enter the high field region, they initiate a Townsend avalanche. These electrons drift into the high field regions of the closest anode wires. The cloud of positive ions from the avalanche drifts towards the cathode planes, thereby inducing a fast rising current on the anodes from which they are departing. As discussed in Sec. 10.5.1, the short risetime of the pulse is a fraction to a few microseconds for most of the induced charge. The pulse is sensed upon those wires closest to the avalanche, thereby localizing in one dimension, x for instance, the particle track. The y dimension can be determined by connecting each wire in the same position sensing scheme as shown in Fig. 10.27. Although these anode wires are usually about 1 to 2 mm apart, the actual spatial resolution achieved is generally less than the wire spacing. Finally the third z coordinate of the original track location can be deduced from the time required for the electrons to drift to the anode wire array. A MWPC of this form is commonly referred to as a *drift chamber*, and is capable of determining the original track location with sub-millimeter spatial resolution.

Two-dimensional, position-sensitive MWPCs are an advancement on the original design. Typically there are two planar arrays of parallel cathode wires with the arrays positioned perpendicularly to each other [Sauli 1994]. One might consider one set of wires parallel to the x direction and the other set parallel to the y direction. In between the two cathode wire array planes is a parallel planar array of anode wires, which are typically arranged at a 45°-angle to the cathode wires, as shown in Fig. 10.30. As with the simple proportional counter, ionizing radiation produces primary electron-ion pairs in the detector gas. Electrons travel towards the nearest anode wires in the array, which then produce a Townsend avalanche of electron-ion pairs. The cloud of positive ions separates and travels towards the nearest cathode wires in the planes on

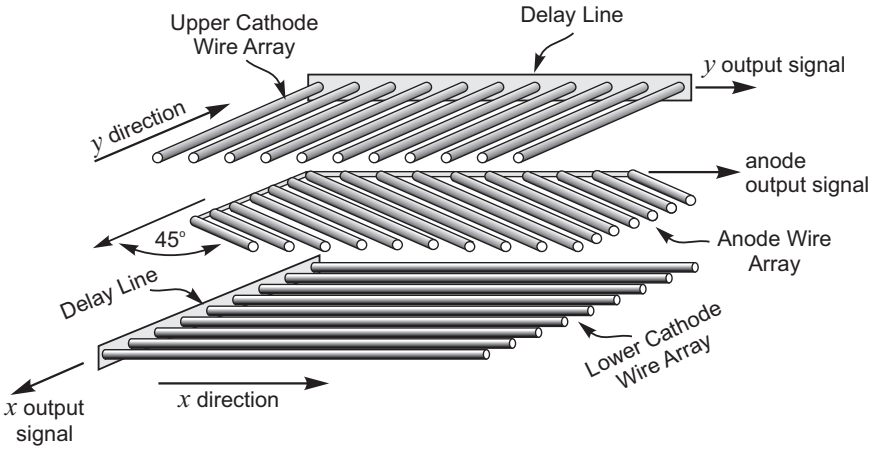

Figure 10.30. A multiwire gas filled proportional counter is composed of parallel layers of wire arrays. Shown is a system with three parallel wire arrays, in which the upper and lower arrays are cathode wires arranged orthogonally. The middle anode array is arranged at a 45°-angle to the cathode arrays.

both sides of the anodes. Hence, the position of the event is determined by which cathode wires deliver a signal on the x-y plane. Overall, the multiwire proportional counter can provide both energy information and position information of the ionizing event.

The multiwire concept has been used in a variety of detector designs, including open cell detector designs, gas-flow alpha particle detectors, and straw tubes. The interlacing of anodes and cathodes in a larger tube facilitate faster response times from these detectors. For planar devices, such as those shown in Figs. 10.18 and 10.20, the electric field is flattened throughout much of the active region, thereby providing a uniform response over most the detector area.

10.6.6 Microstrip Gas Chambers

A clever method to produce a microscopic electrode is to pattern the tiny anode upon an insulating substrate. The process is commonly used for microwave and millimeter wave transmission lines, in which a metallic strip is placed upon a dielectric substrate. The design has been used to produce compact proportional counters [Oed 1988].

The microstrip gas chamber (MSGC) is produced by photolithography means, in a similar fashion as used for semiconductor microelectronics. An insulating substrate, such as glass, precoated with a conductive metal, such as Cr, Cu or Au, is patterned with a photo sensitive chemical commonly referred to as a photoresist. A photomask with an image of the desired pattern is brought into close proximity of the substrate and the photoresist is exposed to ultraviolet light, usually with wavelengths of 360 to 420 nm. The transferred pattern is then developed on the substrate and the undesired regions of the conductive metal are etched away, leaving behind micropatterned microstrips. Afterwards, the photoresist is dissolved away, usually with an organic solvent.

This fabrication method can create microscopic metallic strips on the order of, or smaller than, common anode wires used in proportional counters and Geiger-Müller counters. The microstrips can be fabricated with great precision and have widths of about 10 ± 0.2 microns. Wider cathode strips with widths between 90 to 200 microns are also placed on the same substrate adjacent to the anodes, displaced by approximately 5 anode widths [Oed 1988; Workshop 1993]. As shown in Fig. 10.31, these MSPC plates are inserted into a gas chamber in which the entrance window also serves as the *drift cathode*.

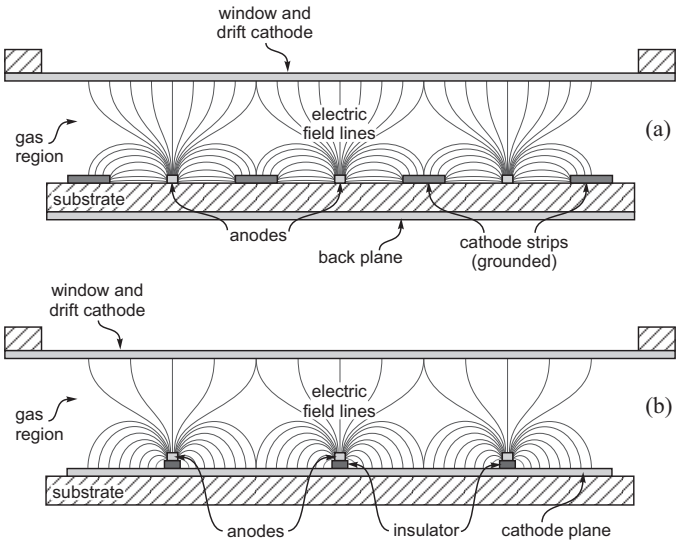

Figure 10.31. Cross section diagrams of (a) a gas-filled microstrip proportional counter and (b) a gas-filled micro-gap proportional counter. Typical dimensions for the anode width are 10 microns. The the MSPC, the cathode strip widths are between 90 and 200 microns with a repetitive pitch between 200 and 350 microns. The gas-filled region is on the order of 1 cm thick.

Radiation interactions in the chamber produce electron-ion pairs. The electrons drift towards the anodes, and when they come into the critical electric field region of the anode, a Townsend avalanche proceeds. The electrons are rapidly collected and the cloud of positive ions drift more slowly towards the adjacent cathode strips, thereby creating an induced signal that is input to the amplification electronics. Because of the very small anode dimensions, the applied potential required to produce an avalanching field is relatively low by comparison to traditional coaxial proportional counters. Further, the response times of the detectors is relatively short in the tens of nanoseconds range and are about 2 orders of magnitude faster than traditional coaxial proportional counters.

These detectors have demonstrated excellent energy resolution for thermal neutron reaction products when backfilled with a mixture of ^{3}He and an organic gas, and have a FWHM energy resolution of 1.43% [Oed 1988]. Further, energy resolution (FWHM) for 13.9-keV characteristic Np x rays from an ^{241}Am source was reported to be 18%, and 23% FWHM for 6.4-keV x rays from ^{57}Co.

Although positive ions drift towards the conductive cathode strips, some positive ions adhere to the insulating substrate. Those ions that come into contact with the insulating substrate tend to accumulate, creating a space charge field that, subsequently over time, reduces or negates the avalanching field. To eliminate space charge buildup, a conductive layer is applied to the back plane of the insulating substrate and biased at generally the same potential as the anodes. The back plane potential produces a repulsion field that emerges through the surface of the substrate not coated with conductive metal, thereby effectively protecting the insulating surface from buildup of space charge from the positive ions.

Another problem encountered in MSPCs is field sparking between the anodes and cathodes. Although the potential applied to the anodes is relatively low, the electric fields can be quite high and lead to electric arcing between the closely spaced electrodes. Such arcing can erode or damage the microstrips. One method to ameliorate the arcing is to apply an insulating polyimide spark guard, approximately 1 micron wide, over the edges of the cathode strips [Nagae et al. 1992].

An alternative design to reduce space charge buildup is the micro-gap gas chamber (MGC) [Angelini et al. 1993]. A pattern of insulating strips are applied on top of a substrate that remains completely coated with conductive material, as shown in lower part of Fig. 10.31. Because the substrate serves primarily as a mechanical foundation of the detector, the substrate no longer need be an insulator, and in fact may be a semiconductor coated with a conductive metal. The micropatterned insulating strips may be applied by common physical vapor deposition methods, such as evaporation or sputtering, or by chemical vapor deposition (CVD) methods, such as plasma enhanced CVD (PECVD). The thickness of the insulating strips is about two microns [Angelini et al. 1993]. Metal patterns serving as the anodes, slightly recessed by a few microns, are then micropatterned upon the insulating strips. The entire substrate surface of the resulting device is grounded, thereby preventing the accumulation of positive space charge.

The spectroscopic performance of a MGC is comparable to that of a MSPC, with reported FWHM energy resolution of 14.8% for 5.4-keV characteristic x rays from Cr. A major advantage of the MGC is its rapid response time. Because the positive ions travel such a short distance from the anode to cathode, the response times are on the order of a few nanoseconds comparable to those of semiconductor detectors [Angelini et al. 1993]. By comparison, common coaxial proportional counters have response times measured in microseconds, while the MSPC devices have response times approximately 10 times longer than those of MGC devices.

10.6.7 Straw Tubes

A variation of the sealed proportional counter is the *straw tube*, so named because the manufactured product resembles a drinking straw.[14] A common method used to fabricate straw tubes utilizes a cylindrical form, or mandrel, around which thin Mylar® strips are wound [Baringer et al. 1987; Marzec et al. 2002]. In some permutations, a 50-micron thick aluminized Mylar® strip is wound about a 7-mm diameter mandrel. Afterwards, a 35-micron thick clear Mylar strip is wound and glued over the first strip such that the outer strip covers the seam of the inner strip. The overlap for rotations is reportedly $\lesssim$2% of the area. After removal from the mandrel, insulating plugs are inserted into each end of the straw tube, through which a thin anode wire is threaded. By use of indexing tubules inserted into holes in each plug, the axial location of the wire is maintained within $\pm$50 microns of center [Baringer et al. 1987].

According to Toki [1990], advantages of a straw tube chamber over multiwire proportional counters include:

1. They are inexpensive, relatively simple to construct, and robust.
2. The damage caused by anode wire breakage has a minimal effect, because it can be disconnected without affecting the response of neighboring anodes.
3. Minimal signal cross talk because the straw provides an electrostatic shield between anodes.
4. Electrostatic alignment distortions are minimal (if the anodes are carefully centered).

New methods of manufacture have been introduced, although the straw-tube name continues. For instance, Takuba et al. [2005] describes seamless straw-tube detectors fabricated by painting carbon-filled polyimide upon a mandrel followed by sintering. Afterwards the seamless tube is removed from the mandrel. Another reported method uses an ultra-sonic weld and a shaped extrusion method to produce thin copper tubes [Lacy 2012]. Regardless, the end product is a miniaturized tube with a diameter of 4 to 8 mm that serves as the cathode shell for a coaxial, gas-filled, proportional counter. Straw tubes can be manufactured in lengths ranging from a few centimeters to several meters. Straw tubes are often bundled together to form

[14] The Precision Paper Tube Company, still in business, is referenced as the manufacturer of aluminized Mylar® straw tubes in many journal articles during the late 1980s and early 1990s.

a larger tube or compartment to improve overall detection efficiency [Oh et al. 1991; Avery et al. 1993; Basile et al. 2004].

Thin-wall devices are reported to have been manufactured with two-sided wall thicknesses of less than 25 microns [Toki 1990]. These thin, straw-tube proportional counters are formed into drift chambers to track particles in high energy physics experiments [Baringer et al. 1987; Ash et al. 1987; Toki 1990]. Vertex tracking chambers often have hundreds of straw tube detectors arranged in concentric circles. The thin walls of the straw tubes minimize energy loss as particles pass through the detectors. Further, because so many detectors are required to build such an instrument, the simplicity of the detectors is economically attractive. Common gas mixtures reported for use in straw tube detectors include mixtures of Ar, CO_2, C_2H_6, and CH_4 [Avery et al. 1993]. Linear time-to-distance relationships have been observed for gas mixtures of CH_4:CO_2:Ar (4:3:93), CO_2:Ar (1:4), and ethane:Ar (1:1), each having drift speeds of about 40 to 80 microns/second. Experiments with C_2H_6/CO_2 (1:19) have yielded higher drift speeds but at the expense of non-linear time-to-distance responses.

Other straw tube designs are under investigation. Recently, multi-anode straw tubes have been introduced to improve performance of track detectors [Oh et al. 2011]. Straw tubes with B_4C-coated inner walls have also been explored for neutron detection [Lacy et al. 2011] and are covered in more detail in Chapter 17.

10.6.8 Gas Electron Multiplier

The gas electron multiplier (GEM) was introduced by Sauli in 1997, and is a unique method to produce high gain in a gas-filled detector [Sauli and Sharma 1999]. In general, a thin insulating film between 50 to 100 microns thick, typically a Kapton® film, is stretched on a frame and coated on both sides with a conductive metal (typically Cu). Afterwards, miniature holes approximately 100 microns in diameter are etched through the metal and insulating film as shown in Fig. 10.32. The GEM is placed in a gas-filled chamber between cathode and anode plates, usually closer to the anode. When a voltage is applied across the GEM, a high electric field is formed in each of the holes, high enough to cause ion pair avalanching (see Fig. 10.33). Typically, the GEM is held at a potential that is positive with respect to the cathode plate and negative to the anode plate.

When an ionizing particle enters the gas detector between the cathode and GEM, primary electron-ion pairs are created as in a typical ion chamber or proportional counter. The electrons drift towards the GEM and the positive ions drift towards the cathode. When electrons reach the GEM, they are funneled into the tiny holes where avalanching gas multiplication occurs. Hence, a much larger cloud of electrons emerges from the GEM with gains up to 200. These electrons continue to drift towards the anode where they induce an output signal. By using several GEMs in stages, much higher gains can be achieved, often exceeding 1000. Position sensitive GEMs can be manufactured by using segmented anodes. Various additional coatings on top of the actual GEM conductor coatings can make the GEM more sensitive to gamma rays and neutrons. For instance, a GEM coated with Gd, ^{10}B, or ^{6}LiF is sensitive to neutrons, while a GEM coated with CsI or NaI will have enhanced sensitivity to gamma rays.

10.6.9 Neutron-Sensitive Proportional Counters

Gas-filled proportional counters designed for neutron detection are briefly described in the present section. A detailed discussion of gas-filled neutron detectors is reserved for Chapter 17.

Detectors based on Neutron Reactive Gases

The most commonly used materials in proportional counters that can detect neutrons are the gases ^{3}He and $^{10}BF_3$, and the solid ^{10}B. Although neutron sensitive, neither $^{10}BF_3$ nor ^{3}He are ideal proportional gases, but they perform adequately well. Because the device operates in proportional mode, a low resolution spectrum associated with the reaction product energies of the $^{10}B(n,\alpha)^{7}Li$ reactions or the $^{3}He(n,p)^{3}H$ reactions can

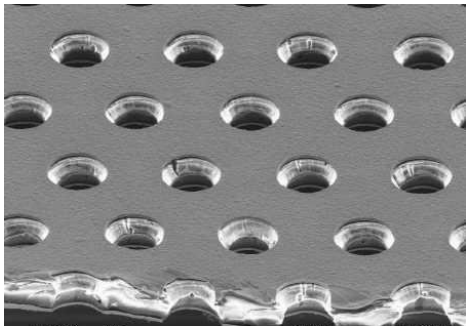

Figure 10.32. A scanning electron microscope photograph of a GEM section, showing the Kapton film, the Cu conductive surfaces, and the holes. The holes in the present photograph are approximately 75 microns in diameter. From Sauli and Sharma [1999]. Courtesy F. Sauli.

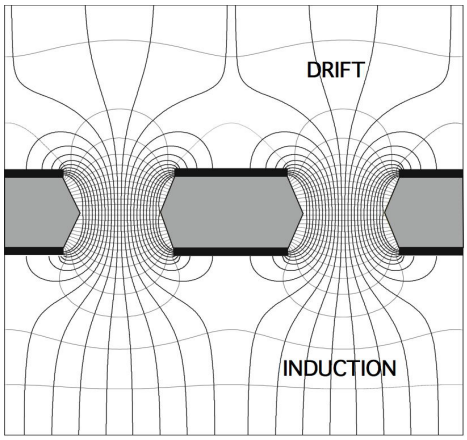

Figure 10.33. The electric fields around and in holes of a GEM detector. From Sauli [2016]. Courtesy F. Sauli.

be identified, depending on the gas used in the counter. The neutron detection efficiency can be increased by increasing the gas pressure of the counter so that there is more neutron absorber. Typical pressures for ^{3}He detectors range from 1 atm to 10 atm. Electron and ion speeds decrease inversely proportional to gas pressure and, consequently, increasing the gas pressure in the tube causes the dead time of the counter to increase. Gas-filled tubes come in a variety of sizes, ranging from only a few centimeterslong and one centimeter in diameter to several feet long and several inches in diameter.

Detectors based on Neutron Reactive Inserts

A traditional proportional gas may be used in the chamber, such as P-10, if instead of filling the chamber with a neutron reactive gas the walls are coated with ^{10}B. Unfortunately, the spectral features from such a device are harder to interpret due to interference from background gamma rays, and the total neutron detection efficiency is limited by the optimum ^{10}B absorber thickness, typically only 2 to 3 microns. The detectors are made more efficient by increasing the tube diameter, or by inserting additional ^{10}B-coated plates in the chamber. Neutron reactive inserts can also be introduced into the proportional counter, for example ^{6}Li blades. These detectors can be designed to preserve the reaction product spectra while delivering efficiencies competitive with detectors backfilled with ^{3}He or BF_3 [Nelson et al. 2012].

10.6.10 Selected Planar Proportional Counters

Finally there are several very specialized proportional counters that include detectors such as micro-mesh gaseous detectors (MicroMegas detectors) and resistive plate chambers (RPCs). The MicroMegas detector consists of a basic planar gas-filled chamber, on the order of 3 mm wide, that resembles the construction of a Frisch grid ion chamber [Giomataris et al. 1996]. The grid, or mesh, is located near the anode, usually within 100 microns. The voltage applied between the cathode and mesh drifts electrons towards and through the mesh ($\sim 10^3$ V cm^{-1}). The voltage applied to the region between the mesh and the anode produces an electric field above the critical field $\mathcal{E}_t$ required for avalanching ($> 10^5$ V cm^{-1}), and therefore, produces a Townsend avalanche. The resulting positive ions liberated in the avalanche are subsequently collected by the mesh electrode. Clever anode designs allow for MicroMegas detectors to be used as a position sensitive proportional counters [Derré and Giomataris 2001]. MicroMegas detectors are used as high-energy particle tracking detectors [Titov 2007].

The RPC is another planar style proportional counter dependent upon narrow gas-filled gaps. The basic construction has two parallel resistive plates, between which is a narrow gas-filled gap, which is usually a few hundred microns wide [Santonico and Cardarelli 1981; Cardarelli et al. 1988]. The resistivity of the materials is reportedly to be about 10^{10} to 10^{12} Ω-cm [Cardarelli et al. 1988]. A conductive electrode is applied to the outer surfaces of the insulators. A voltage applied across the detector will drop some voltage across the resistive materials; however, due to the high resistance of the gas-filled gap, most of the applied voltage appears across the gap, thereby producing an electric field above the critical electric field required for avalanching. Although there is signal reduction due to the capacitance of the resistive plates [Bacci et al. 1995], the increased signal from the avalanche is ample for detection. RPCs have reported timing resolution of around 100 ps [Santonico 2003]. Because the narrow gap absorbs little energy from the radiation particles of interest, these detectors generally consist of numerous RPCs in a stack. Patterned electrode designs and stacked configurations allow for the realization of relatively small position sensitive counters [Couceiri et al. 2007], with reported spatial resolution of 500 microns after the application of a reconstruction algorithm.

PROBLEMS

1. The electronic output from a cylindrical gas-filled chamber is primarily dominated by electron current when operated as an ion chamber. When operated as a proportional counter, the electronic output from the same detector becomes dominated by positive ion current. Explain why this change occurs.

2. A coaxial detector is backfilled with P-10 gas to 2 atm. The detector has anode wire with a radius of 25 microns and cathode radius of 1.5 cm. Determine r_c for an applied voltage of 1500 volts.

3. Use Stirling's approximation to prove that Eq. (10.102) becomes the Poisson distribution as $\theta \rightarrow \infty$.

4. Verify that the solution of Eq. (10.84) is given by Eq. (10.85).

5. Show that the second moment of Eq. (10.91) is $\langle m^2 \rangle = 2\overline{m}^2 - \overline{m}$.

6. Verify (a) that the Furry PDF of Eq. (10.88) is properly normalized, i.e., $\sum_{m=1}^{\infty} p(m|a) = 1$, (b) the first moment $\langle m \rangle = \exp[\tau(a)]$, (c) the second moment is $\langle m^2 \rangle = 2\langle m \rangle^2 - \langle m \rangle$, and (d) the relative variance is given by Eq. (10.92).

7. You have a coaxial detector with $r_a = 25$ microns and $r_b = 12.5mm$. The tube is pressurized to 1.5 atm with a mixture of 90% Xe/ 10% CH_4. What voltage must be applied to the anode to just barely produce a gas multiplication of $M = 20$?

8. A coaxial detector has $r_a = 25$ microns and $r_b = 15$ mm, and is backfilled with P-10 gas at 2 atm. The operating voltage is 1000 volts. A 5.5 MeV alpha particle interacts in the detector, producing an ionization trail parallel to the anode at a random distance r from the center. Approximate the time after the event ($t_{V_{max}/2}$) that 50% of the induced pulse is produced. How far did the ions travel to produce this pulse? You now change the gas pressure to 0.5 atm. What are the new values of ($t_{V_{max}/2}$) and the travel distance?

Chapter 11

Gas-Filled Detectors: Geiger-Müller Counters

The sudden current through the gas due to the entrance of an α-particle in the testing vessel was thus increased...

Sir Ernest Rutherford and Hans Geiger

Although Hans Geiger originally created the gas-filled detector in 1908 (with Ernest Rutherford) [Rutherford and Geiger, 1908],[1] the "Geiger" counter in wide use today is based on an improved version that his first PhD student, Walther Müller, constructed in 1928 [Geiger and Müller 1928a, 1928b, 1929a, 1929b]. Hence, the proper name for the device is the *Geiger-Müller* counter. The original "Geiger" counter was sensitive to alpha particles, but not so much to other forms of ionizing radiation. Müller's improvements included the utilization of vacuum tube technology to create a device that was compact and portable and that was sensitive to alpha, beta, and gamma radiations. In 1947, Sidney Liebson further improved the device by including in the tube gas a small amount of a halogen as a quenching gas, an improvement that allowed the detector to operate at lower applied voltages and to last significantly longer [Liebson 1947a, 1947b].

11.1 Geiger Discharge

Geiger-Müller counters are operated in region IV of the pulse height curve for gas detectors as shown in Fig. 11.1 and depend upon gas multiplication for signal amplification, much like proportional counters do. However, a single important difference is that, at any specific applied voltage, *all* output pulses from a Geiger-Müller counter have the same amplitude *regardless of the energy or type of incident ionizing radiation.* Hence, Geiger-Müller counters cannot discern any difference among alpha, beta, or gamma radiations, nor can they distinguish among different energies of these radiations. To understand the reason for this behavior, it is important to understand the progression of the Geiger discharge.[2]

Geiger counters typically have a coaxial configuration, in which a thin anode wire is placed on the axis of a cylindrical tube that serves as the cathode. A high voltage is applied to the central anode wire, while the cathode is held at ground potential, as depicted in Fig. 11.3. When an ionizing particle enters a Geiger-Müller counter, the counting gas becomes locally ionized in which a small cloud of electron-ion pairs is formed as depicted in Fig. 11.2(1) and described in the previous chapter. Because a high voltage is applied to the anode and the tube is operated in region IV of the gas curve, the electrons drift rapidly to the anode while the ions slowly drift towards the cathode, as shown in Fig. 11.2(2). When the electrons enter the high electric field near the anode above the critical field strength $\mathcal{E}_t$ needed to produce

[1] Hans Geiger was nominated for the Nobel Prize in physics three times, in 1935 by Walther Nernst, in 1937 by Walther Bothe, and in 1955 by Boris Rajewsky, but never received it.

[2] A Geiger discharge consists of multiple Townsend avalanches.

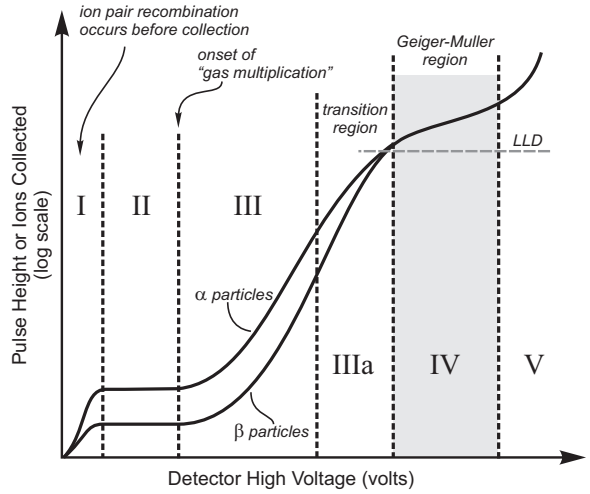

Figure 11.1. Geiger-Müller counters are operated in region IV of the pulse height curve for gas-filled detectors. The *LLD* is set to discriminate pulses produced in the proportional and lower regions.

avalanche ionization, they gain enough kinetic energy to produce more electron-ion pairs through impact ionization, and a large and dense cloud of electron-ion pairs is formed around the anode. Some of these energetic electrons lose energy, through bremsstrahlung, recombination, or de-excitation, processes that lead to the production of UV photons which, in turn, cause more ionization in either the cylinder gas or from interactions with the cathode wall. These newly freed electrons form new avalanches and yet more positive space charge builds up around the anode. This large accumulation of positive ions around the anode reduces the electric field near the anode as depicted in Figs. 11.2(3) and (4). There comes a point when the large accumulation of space charge around the anode is so high that the electric field is reduced below the critical field strength $\mathcal{E}_t$ needed to sustain avalanching. At this point the impact ionization ceases, as shown in Fig. 11.2(5). The positive ions then slowly drift towards the cathode where they are collected and produce the signal pulse for the detector. As they reach the cathode, the electric field near the anode recovers to full strength, and the detector is set to detect the next radiation interaction event, as depicted by Fig. 11.2(6).

Several features about the progression of the Geiger discharge should be noted. (a) The electric field in the detector increases with increasing applied voltage. (b) The discharge ceases when the electric field is reduced below $\mathcal{E}_t$ at the anode and, therefore, the required space charge to terminate the avalanching must also increase with applied operating voltage. (c) To prevent more electrons from being ejected when the ions strike the cathode, thereby preventing another avalanche, a form of quenching must be used. (d) The entire Geiger discharge process is slower than that of a proportional counter, mainly due to the longer time required to produce the dense cloud of positive ions around the anode. (e) Finally, the size of the output pulse is determined by how much space charge must accumulate to reduce the electric field below $\mathcal{E}_t$ and not by the initial energy absorbed or number of initial electron-ion pairs produced within the detector! Consequently, the pulse height for various energies of α-particles, β-particles, and γ-rays are all the same, within statistical variation, and the signal pulse height is predetermined solely by the applied operating voltage.

11.2 Basic Design

The basic design of a Geiger-Müller (G-M) counter is shown in Fig. 11.3 and consists of a coaxial chamber that serves as the detector cathode and the anode is threaded into the chamber through an insulator. The anode is small in diameter, yet robust enough to be rigidly suspended in the tube. Typically, wire diameters on the order of 100–200 microns can achieve the desired electric field. Thinner wires can be used if suspended by both ends. An insulating glass bead is attached to the anode wire, which helps stabilize the electric field at the end of the anode.

Older versions of G-M counters were constructed from glass envelopes, and a metal sleeve was inserted into the chamber to act as the cathode. The choice of cathode material affects the gamma-ray response of the chamber. High Z materials, such as Pb or Bi, have a fairly salient "over response" to gamma-ray energies below 500 keV (as discussed later in Section 11.5.3). Present day G-M counters are usually constructed from a stainless steel cathode tube without any such inserts, and rely on the stainless steel tube for gamma-ray interactions.

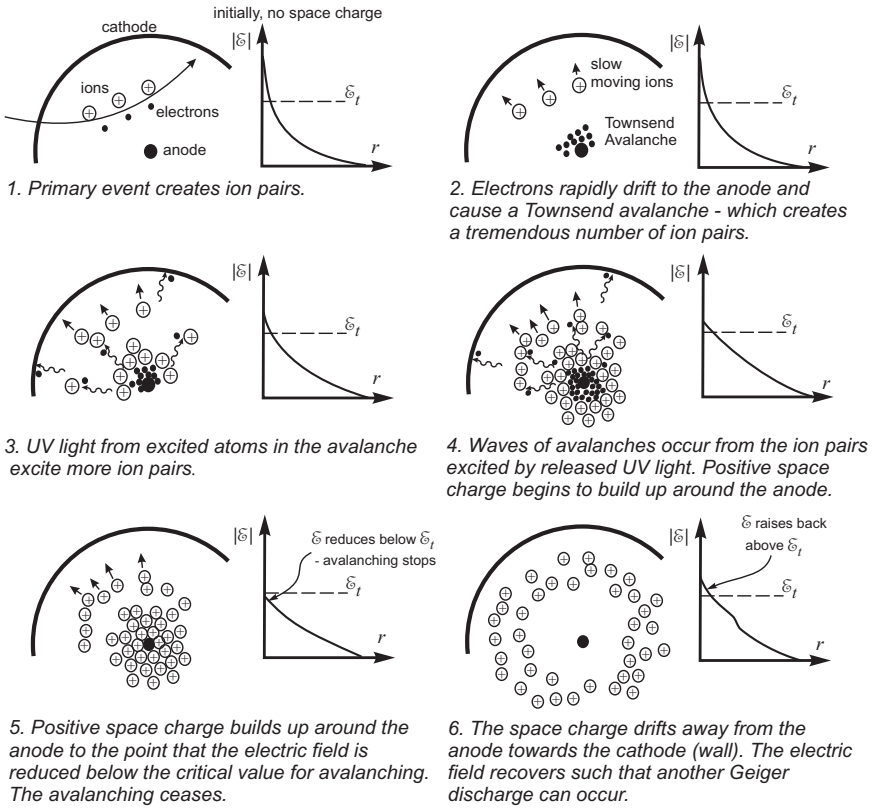

Figure 11.2. Geiger-Müller tube cross section depicting the progression of the Geiger discharge. The avalanching continues until the space charge accumulated around the anode wire decreases the electric field below the avalanche threshold, which then causes the progression to cease.

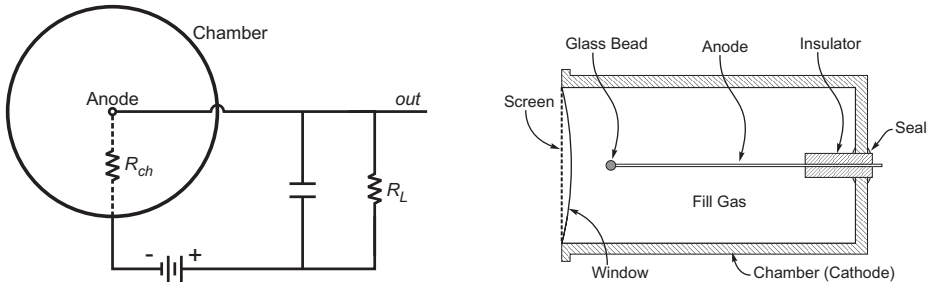

Figure 11.3. (left) simplified circuit for a G-M counter, and (right) the basic components of a G-M tube.

Because α and β particles cannot penetrate thick-walled G-M tubes, a thin entrance window is usually used to seal the end of the tube, thereby making a cantilevered anode wire essential. The window is usually made of either aluminized boPET or mica. The gas inside the G-M tube is under a mild vacuum (commonly between 0.1–0.2 atm) in order to reduce the detector dead time [recall Eq. (9.31)]. To prevent damage or contamination, many manufacturers of G-M tubes provide a protective screen over the entrance window.

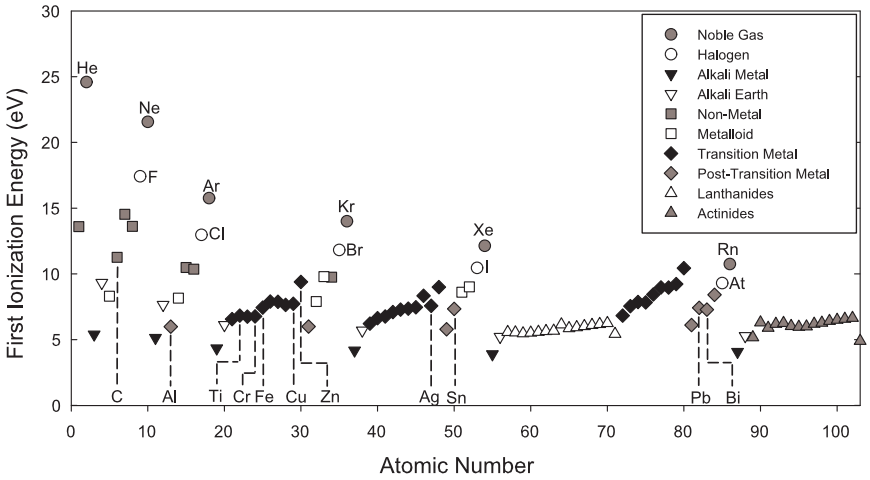

Figure 11.4. First ionization energies of the elements. Common gases and cathode materials that have been used in G-M counters are identified by their chemical symbol.

Care should be taken with G-M tubes and the ambient external pressure. At some altitudes, the external pressure can be lower than the internal tube pressure, thereby pressurizing the tube and causing a rupture in the window. Manufacturers usually document such restrictions on specification sheets.

11.3 Fill Gases

Although a variety of gases have been successfully used in G-M counters [Korff 1946; Sinclair 1956; Price 1963; Emery 1966], most often the host gas is one of the noble gases. From Fig. 10.10, neon allows the highest electron drift speeds, followed by those of He and Ar. Neon also has one of the highest ion drift speeds of the noble gases, second only to that of He [Munson and Tyndall 1941, Sharpe 1964, Barsuto et al. 2000].[3] Hence, Ne is usually the gas of choice, mainly because it helps reduce dead time by allowing the dense ion cloud to form more rapidly and to sweep out more rapidly the positive ions. However, Ne also has a higher first ionization coefficient (and higher average ionization energy) than Ar, although lower than that of He, as can be seen from Fig. 11.4. Thus, a higher specific ionization per unit length of electron travel is achieved in Ne than in He, while retaining a faster response than that of Ar. However, often a small amount of Ar is added to the gas to increase the specific ionization while still retaining a fast signal response.

There may be special applications where high atomic number noble gases are used in G-M counters, although this practice is uncommon. Under such conditions, it is possible for low energy gamma rays to interact directly with the gas. As can be seen from Fig. 10.26, high efficiencies can be achieved for gamma-ray energies below 30 keV. However, the electron velocities for Kr and Xe are significantly lower than those of Ne and Ar (see Fig. 10.10), as well as the ion mobilities [Munson and Tyndall 1941], thereby causing these G-M counters to have longer dead times.

Because of the large ionization clouds produced in G-M tubes, it is necessary to include a quenching gas along with the host detection gas inside sealed tubes. Organic polyatomic gases work well in G-M tubes, but these gases can be consumed after several months of continuous use as the molecules dissociate irreparably. Instead, it is a usual practice to use diatomic halogen gases to quench the Geiger discharge because these gases undergo a form of self-repair after dissociation.

[3]Recall from Fig. 10.10 that Ne has the highest electron drift speed of the noble gases.

11.3.1 Quenching

If a G-M tube is operated with a pure counting gas such as argon or neon, positive ions drifting to the cathode attract electrons to the surface, and upon contact, an electron from the wall neutralizes the positive ion. Ideally, the atom is neutralized and the collection process simply ends. However, the actual process is considerably more complicated.

When a gas ion comes into contact with the cathode wall, the absorption of an electron leaves the now neutralized atom in an excited state. This physical state occurs because of the differences in ionization energies between the gas atoms and the cathode atoms. Typically, a noble gas atom de-excites by releasing a photon with an energy comparable to the atom ionization energy. For example, the minimum ionization energy for Ar is 15.6 eV, corresponding to a photon wavelength of 78.47 nm and classified as belonging to the extreme ultraviolet (EUV) region of the electromagnetic spectrum. Almost all transition metals have minimum ionization energies ranging between 5–10 eV, as can be seen from Fig. 11.4. Consequently, if the EUV photon strikes the wall, a photoelectron may be ejected, thereby triggering another Townsend avalanche. Due to competing processes, the actual photo-efficiency for these UV photons is actually very small, on the order of 10^{-4} per photon [Korff 1946]. However, the number of electron-ion pairs produced for a single event and in the subsequent discharge usually produces many more than 10^4 electron-ion pairs per event so that there is an appreciable probability that a photoelectron is emitted from the cathode wall because of the absorption in the wall of a UV photon.

With sufficient excitation, it is also possible for atoms of the host gas to release, or excite, K-shell electrons. Further, it is possible that the host gas becomes multiply-ionized. By recombination and de-excitation, energetic x-ray photons can be emitted. For example, Ar photon emission energies can be over 3 keV ($K_\beta = 3.192$ keV; $K_{\alpha 1} = 2.957$ keV). Also, excited neutral gas atoms can emit one or more characteristic x rays. These characteristic photons have sufficient energy to cause direct ionization of the atoms of the host gas and, consequently, increase and prolong the avalanching process.

It is also possible for a gas ion, with sufficient kinetic energy, to directly cause the emission of an electron when it comes into contact with the cathode wall. The ejected electron then sets off another Geiger discharge.

In all these cases, there is a release of an electron that can cause another Geiger discharge, which is easily mistaken for another radiation interaction event, unless a mechanism is employed to prevent (quench) the release of another electron, or at least to render such secondary electrons incapable of starting another Geiger discharge. Geiger-Müller detectors are considered to be either "non-self-quenching" or "self-quenching" [Korff 1946]. Quenching in a non-self-quenched detector relies upon a combination of space charge accumulation and external resistance to terminate and quench the Geiger discharge. By contrast, self-quenching G-M detectors have a quenching gas added to the detection gas to prevent electron ejection by positive ions.

Non-Self-Quenching Detectors

Consider the circuit shown in Fig. 11.3, in which the potential across the detector is produced by a resistive divider, formed by the load resistor R_L and the chamber resistance R_{ch}. Because the chamber is filled with a neutral gas, $R_{ch} \gg R_L$. After a radiation particle enters the chamber and initiates a Geiger discharge, current from electron collection begins to flow through the anode wire, and also through the load resistor, thereby causing the voltage drop across R_L to increase at the expense of the voltage held across the chamber [Werner 1934a, 1934b]. As the Geiger discharge increases, so does the electron current and the space charge sheath surrounding the anode, until eventually the voltage held in the chamber falls below the threshold potential required to sustain a Geiger discharge. When the falling potential reaches a value such that the electric field at the anode surface falls below $\mathcal{E}_t$, the Geiger discharge terminates. Although this termination method was initially called "quenching resistance," Montgomery and Montgomery [1940] argue that a high load resistance actually prolongs the Geiger discharge, because the current leakage through R_L allows the

anode wire to maintain its original potential for a longer period of time;[4] hence, it is mainly the space charge accumulation that stops the Geiger discharge and not the voltage reduction produced by the load resistance.

Typically, it is multiple cascades of electrons liberated from the cathode wall by UV photons that builds up the Geiger discharge. Montgomery and Montgomery [1940] report the observed formation of multiple discharges until the space charge sheath eventually terminates the progression. Regardless, if $R_L > 10^8\ \Omega$, then the RC time constant of the chamber and circuit is usually longer than the collection time of the ions, thereby allowing collection of the positive ions before the chamber resets. In other words, the detector recovery time is longer than the positive ion collection time. Hence, any electrons ejected from the cathode during the recovery time cannot cause another Geiger discharge. This method of quenching is seldom, if ever, used in modern Geiger-Müller counters, mainly because these detectors suffer from long resolving times ($\geq$ 10 ms), thereby limiting their use to low radiation fields.

Self-Quenching Detectors

The almost universal method used today for quenching G-M counters is to add a small amount of quenching gas to the main detection gas. Polyatomic organic gases were initially used with much success, as described earlier in Chapter 10 for proportional counters. One function of polyatomic organic gases in the mixture is to absorb the UV photons emitted by excited atoms of the primary gas. Without the quenching gas, these photons would produce additional ionization in the detector gas or cause photoemission of electrons from the cathode wall. Upon absorption of a UV photon, a polyatomic molecule, with relatively weak molecular bonds, generally dissociates before the absorbed energy can be emitted in the form of photoelectrons or photons. This dissociation causes a dramatic reduction in the number of UV photons that reach the cathode. Further, if the polyatomic gas has a lower ionization potential than the primary detector gas, electron exchange can take place such that the detection host gas ion is neutralized and the polyatomic molecule becomes ionized. When an ionized polyatomic gas molecule strikes the cathode, it becomes neutralized, and the excited state of the molecule causes dissociation rather than photon emission, thereby preventing electron emission from the cathode wall. The three major quenching processes are depicted in Fig. 11.5.

Neon is perhaps the most popular counting gas used in Geiger-Müller counters, followed by argon. Successful organic quenching gases include CH_4 (methane), C_2H_5OH (ethyl alcohol), and $C_3H_6O_2$ (ethyl formate), often added as 10% of the total gas concentration [Sinclair 1956]. Because G-M counters are typically closed tubes, the organic quenching gas inside can be exhausted over time, eventually leading to sporadic counts as the quenching gas is exhausted. Higher voltages require more space charge to stop the Geiger discharge and, consequently, reduce the lifespan of tubes using organic quench gases. Also, using these counters in relatively high radiation environments reduces the lifetime of the quench gas. It has been reported that the expected life of an organically quenched counter is $\simeq 10^{10}$ counts [Spatz 1943], in which approximately 10^9 molecules are destroyed per discharge [Price 1963].

The discovery that halogens also act as quenching gases for Geiger-Müller detectors led to their popular use [Liebson 1947a; Liebson 1947b; Present 1947; Liebson and Friedmann 1948]. Halogens, unlike organic gases, appear to undergo a healing recombination reaction back into diatomic molecules, thereby extending the lifetime of the quenching gas in the detector. Only low concentrations of halogens are needed to effect the quenching process, usually less than 1% of the total gas concentration [Sinclair 1956]. Reported gas mixtures include Ne or Ar as the primary counting gas with 0.1% of either Cl_2 or Br_2 gas added.

There are performance differences between organic and halogen quenched Geiger-Müller counters. For example, the required operating voltage of a halogen quenched detector is significantly lower than that of an organic quenched detector. Typical operating voltages for halogen quenched G-M tubes range from 250–700 volts, whereas the same tube quenched with an organic gas may require well over 1000 volts for operation.

[4] Korff [1946] suggested that a better name would be "recovery resistance".

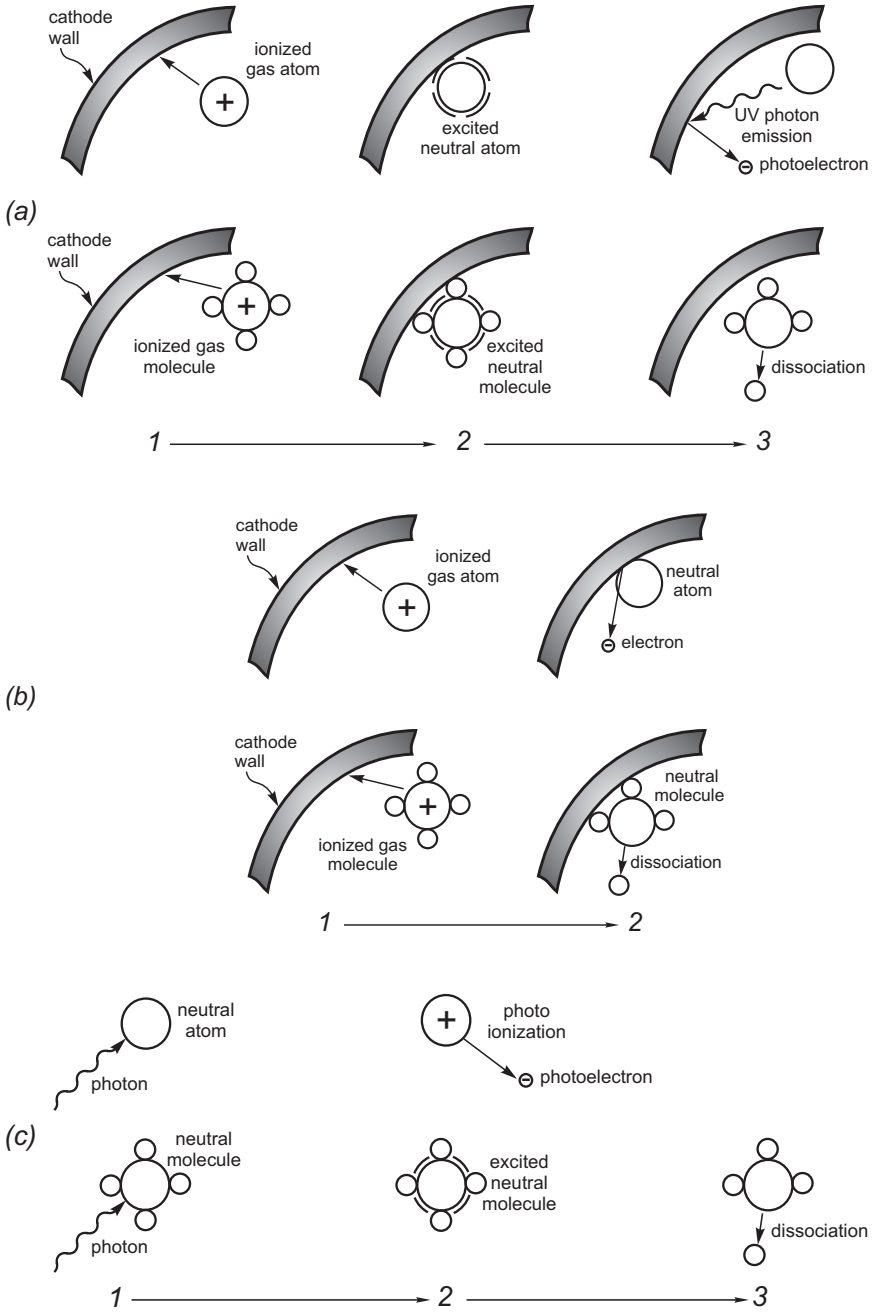

Figure 11.5. Quenching mechanisms of polyatomic gas molecules. In (a), an ionized gas atom comes into contact with the wall and neutralizes into an excited state. De-excitation produces an energetic photon that can eject photoelectrons from the cathode. However, excited gas molecules (organic or halogen), de-excite through dissociation and do not release additional electrons. Other processes of gas quenching through molecular dissociation are depicted in (b) and (c).

Also the plateau length of a halogen quenched G-M tube is usually shorter than one quenched with an organic gas, often having a plateau range no more than 150 volts. Further, the plateau slope is usually larger, typically on the order of a 10% increase over the plateau range.

Halogens are reactive oxidizers for many materials and this property can lead to corrosion over time of internal detector components. Although the concentration of halogen gas is small, caution is still necessary in selecting materials for the cathode and anode. Stainless steel as the anode and cathode has proven to work well with halogen quenched G-M counters and is frequently used in modern G-M counters. A popular choice of stainless steel for halogen quenched G-M counters is 446 SS (about 27% Cr, 73% Fe), a stainless steel with perhaps the best corrosion resistance of the Cr alloys.

Example 11.1: Consider a Geiger Müller tube pressurized to 0.2 atm filled with Ne and 10% CH_4. The tube has a diameter of 4 cm and a length of 15 cm. Estimate the number of counts that can be recorded before the quench gas is exhausted. Assume recombination of dissociated molecules is negligible.

Solution:

From the ideal gas law, the number of mols of gas in the tube is $n = PV/(RT)$ where the gas constant $R = 0.0821$ L atm K^{-1} mol^{-1} is

$$n = \frac{PV}{RT} = \frac{(0.2 \text{ atm})(\pi(2 \text{ cm})^2(15 \text{ cm}))}{(0.0821 \text{ L atm K}^{-1} \text{ mol}^{-1})(300 \text{ K})} = 1.53 \times 10^{-3} \text{ mol.}$$

The number of quench gas molecules N_{CH_4} initially in the tube is

$$\begin{aligned} N_{CH_4} &= 0.1(nN_a) = 0.1(1.53 \times 10^{-3} \text{ mol})(6.022 \times 10^{23} \text{ molecules mol}^{-1}) \\ &= 9.21 \times 10^{19} \text{ } CH_4 \text{ gas molecules.} \end{aligned}$$

where N_a is Avogadro's number.

If 10^9 quench molecules dissociate for each count, then the counter can have a maximum of 9.21×10^{10} counts before the quench gas is completely exhausted. In reality, the side effects of losing the quench gas molecules appear much earlier, manifested as an increase in counting plateau slope and the increasing appearance of sporadic counts.

11.4 Pulse Shape

Because the Geiger discharge produces a large signal voltage, Geiger-Müller counters can be operated without amplification circuitry, a clear advantage over other types of gas-filled detectors. The shape of the signal voltage pulse produced by a G-M counter is defined by the rise time and decay time of the detector.[5] The rise time constant is determined mainly by the load resistor and detector capacitance (see Fig. 11.3). There is a time delay between the initial ionizing event and the start of an avalanche, a delay that depends mainly on the electron drift speed and tube radius. The lighter high-mobility noble gases, such as He and Ne, have much shorter time delays than those in the heavier noble gases such as Kr and Xe. Hence, the observed signal pulse begins slightly after the radiation interaction, a delay of a few microseconds for low electron mobility gases.[6]

[5] The input voltage V_{in} is defined as the signal transferred from the detector to the initial amplification stage of a preamplifier, whereas the output voltage V_{out} is the output signal of the preamplifier. Because G-M counters are often operated without a preamplifier, the term "signal voltage" is adopted here for pulses produced by a G-M detector.

[6] For most applications, this fact is of little consequence. However, if one wishes to use a G-M counter for timing purposes, the delay time between the ionizing event and the pulse trigger must be taken into account.

The actual pulse from a G-M counter, during the progression of the Geiger discharge, develops from multiple avalanches. These avalanches eventually cause the space charge sheath to completely cover the anode wire. The electrons are rapidly collected, but contribute little to the signal pulse. It is instead the motion of positive ions towards the cathode that produces almost all of the signal. Recall from Chapter 10 that most of the induced signal from a coaxial detector is formed within the first few microseconds of ion drift. Hence, a load resistor is chosen to yield a time constant of a few microseconds.

A coupling capacitor between the load resistance and recording electronics effectively blocks DC current from the detector, while allowing signals to pass through. The signal continues to increase as the positive ions drift to the cathode; however, the slow motion of ions causes a slow rise in signal. The coupling capacitance is chosen to ensure that the decay time constant is sufficiently large to reduce signal attenuation, while still allowing reasonable count rates.

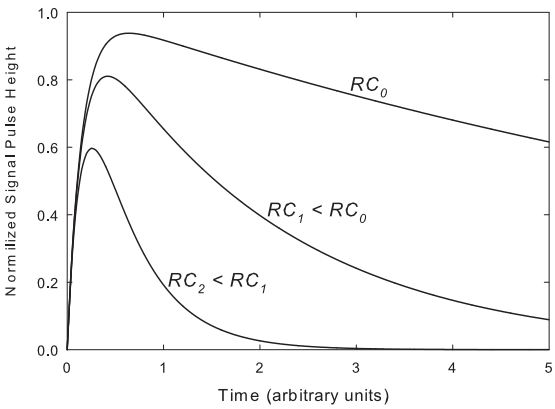

Figure 11.6. Depiction of Geiger-Müller tube signal pulse shapes for different differentiating *RC* time constants.

Consider the pulse shapes of Fig. 11.6. Large coupling capacitances increase the total pulse height, but also produce long decay times and, consequently, produce large dead times. Low coupling capacitances shorten the decay time and dead time, at the expense of a reduced pulse height. Although the signal is lowered by reducing dead time, it is of minor consequence, mainly because the ion density developed in a G-M counter is large to begin with so that a reduction in pulse height can be tolerated. Finally, because the space charge sheath needed to terminate the Geiger discharge is nearly the same (at a given operating voltage), then the signal pulses are also nearly the same, within statistical fluctuations.

11.4.1 Dead, Resolving, and Recovery Times

Immediately following the Geiger discharge, the space charge sheath formed around the anode wire lowers the electric field such that avalanching ceases. Not until the electric field at the anode recovers above the critical avalanching threshold field $\mathcal{E}_t$ can another Geiger discharge occur. As the positive ions drift away from the anode, the electric field at the anode begins to increase, as depicted in Fig. 11.2. The dead time is the time interval between the initial pulse trigger and the electric field recovery to $\mathcal{E}_t$ and depends strongly upon the number of ions in the space charge sheath. In other words, the dead time is dependent upon the applied operating voltage. Dead times for Geiger-Müller counters can be on the order of 10 times longer than those of proportional counters of similar size, typically 80–300 microseconds, and represents the *minimum* time required between the arrival of successive incident radiation particles that allows their detection. The longer dead times associated with Geiger-Müller counters are a consequence of relatively long pulse formation process depicted in Fig. 11.2.

Although it is theoretically possible to register a count after the electric field has recovered to $\mathcal{E}_t$, Geiger-Müller counters are almost always operated with the *LLD* set to exclude electronic noise; hence, counts cannot be registered until the resulting pulse height surmounts the preset *LLD* threshold. The *resolving time* is the interval between the initial pulse trigger and when the pulse height reaches the *LLD* threshold. Clearly, the resolving time is a function of both the applied voltage and the preset *LLD* threshold; therefore, the resolving time is not an intrinsic feature of the detector, but instead changes with the operator's *LLD* setting. It is the resolving time that is usually reported as the detector dead time, although in the strictest

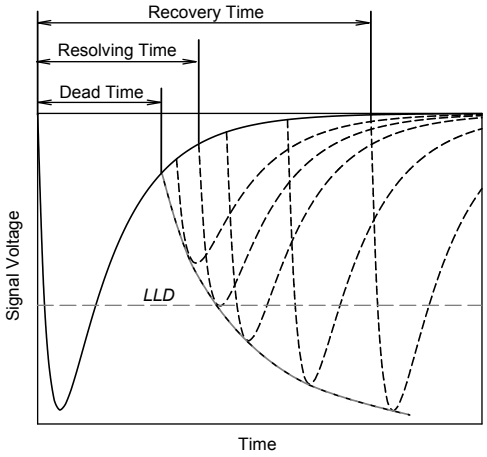

Figure 11.7. Illustration of dead, resolving, and recovery times with respect to signal pulses for a Geiger-Müller tube.

sense it is not the dead time, although it certainly has the same effect. Overall, count rates from a G-M counter are affected principally by the resolving time of the instrument.

The *recovery time* is defined as the interval between the initial pulse trigger and the time that another pulse signal can achieve the maximum amplitude possible. Intuitively, one might surmise that the recovery time is synonymous with the positive ion collection time; however, as explained previously for non-self-quenching detectors, the signal tail is also a function of the RC time constant of the detector. Hence, for a large load resistance R_L, the recovery time is a function of both the ion drift time and the detector time constant. Signal pulses formed during the time interval between the resolving time and the recovery time have lower amplitudes than those produced by a full Geiger discharge. Shown in Fig. 11.7 is an illustration of the relation between dead, resolving, and recovery times from a G-M counter.

11.5 Radiation Measurements

Although there are multiple variations and uses of Geiger-Müller counters, it is customary to determine first a proper operational voltage for the devices. This calibration process usually requires radioactive sources to determine the appropriate LLD setting and the boundaries of the counting plateau. G-M counters cannot distinguish among different types of incident radiation particles; however, the large signal pulses they produce make it relatively easy to detect radiation, be it alpha, beta, or gamma radiation.

11.5.1 Counting Plateau

As with proportional counters, proper operation of a G-M counter requires the appropriate voltage setting. At too low a voltage, the detector functions in the ion-chamber or proportional regions, and generally less efficiently than detectors designed for such operations. As previously discussed, the amplitude of signal pulses from a G-M counter operating in region IV of the gas pulse height curve is strongly dependent upon the space charge sheath required to terminate the Geiger discharge. Consequently, as voltage is increased in the Geiger-Müller region, the amount of space charge required to terminate the discharge also increases. If the operating voltage is further increased, eventually the detector is driven into a state of continuous discharge (region V).

An operator can determine a proper operating voltage as follows. First the detector is placed in a well-shielded or relatively radiation-free environment, and the high voltage is applied to the detector in increasing increments. In doing so, the operator establishes the discrimination level LLD necessary to eliminate electronic noise. Then the high voltage is reduced back to zero and a calibration source is placed in the vicinity of the detector. Signal input pulses produced by radiation particles from a detector operating in the ion-chamber or proportional regions are smaller than pulses produced in the G-M region and depend on the type of incident radiation. Also, pulses produced from mixed α and β sources have a large variation in signal amplitudes when the detector is operated in either the ion-chamber or proportional regions. As voltage is increased beyond the proportional region, the variation in pulse amplitudes reduces and the pulse amplitudes, although increasing with increasing voltage, converge to equal amplitudes in the G-M region.

If the signal pulse amplitudes produced by β and α particles are equal, within statistical fluctuations, then detector operation is at the beginning of the G-M region. The LLD is set at the signal voltage produced at the onset of the G-M region, as depicted in Fig. 11.1. Because Geiger discharges produce voltage pulses

of equal amplitudes, at any set voltage, for any type of incident ionization radiation, the LLD is mostly ineffective at eliminating background radiations; however, the equality of the pulse amplitudes can be used to ensure that the detector is operating in the G-M region. With a source present, the operator can then track the count rate as a function of applied voltage, thereby producing a counting curve.

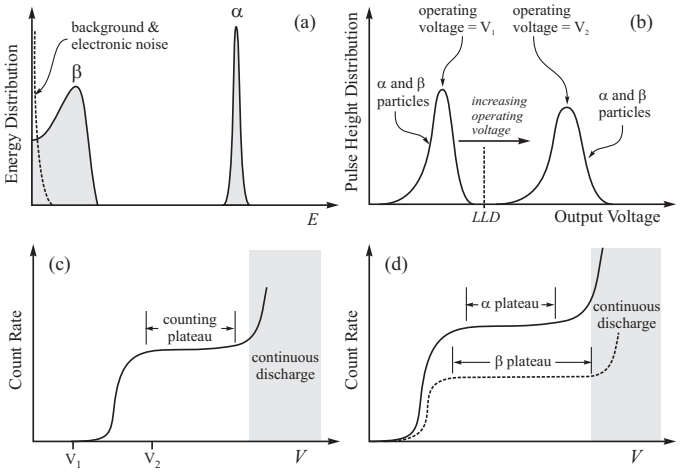

Figure 11.8. (a) Although the energy spectra of α and β particles are different, the (b) combined signal pulses from Geiger discharges, regardless of radiation energy or particle type, are nearly indistinguishable. At low operating voltages V, the resulting signal voltages fall below the LLD. As the operating voltage is increased, the signal voltages increase until most or all surpass the LLD threshold. (c) For a set LLD threshold, pulses below the LLD are not counted, whereas, for higher applied voltages that produce Geiger discharges above the LLD threshold, the counts are recorded. (d) Because the signal pulses are indistinguishable between α and β (and γ) particles, their counting plateaus (for separate and combined sources) appear at nearly the same applied high voltages.

Consider Fig. 11.8(a), where it is shown that alpha and beta particles have significantly different energy spectra. When these particles interact in a G-M counter, the pulses they produce are indistinguishable as shown in Fig. 11.8(b), thereby producing a continuous pulse height spectrum. With the LLD set to some arbitrary level, Geiger discharges that produce voltage pulses below the LLD threshold are not recorded. The combined spectrum of pulses from the α and β particles increases as the operating voltage increases. Further, the increase in signal amplitude allows some pulses to surmount the LLD threshold and causes a rapid increase in count rate as shown in Fig. 11.8(c). At higher voltages, all Geiger discharges exceed the LLD threshold and produce a counting plateau as shown in Fig. 11.8(c). At higher voltages, continuous discharging occurs and appears as a large increase in count rate. If the operator were to compare the counting plateaus for separate alpha and beta particle sources, both with the same LLD setting, then the counting plateaus would appear at approximately the same voltage, as depicted in Fig. 11.8(d) and shown in the measurements of Fig. 11.10. Typically, after the counting plateau is measured, the operator sets the operating voltage in the center of the plateau. Note that the plateau formed by the β-particle source is considerably flatter and wider than the plateau formed by the α-particle source, a feature not seen in a proportional counter.

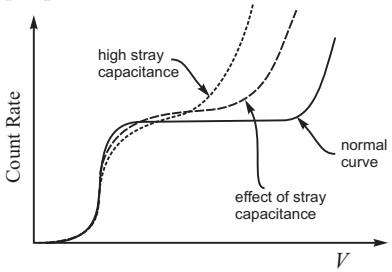

Figure 11.9. Stray anode capacitance from signal wires can cause problematic distortions in the counting curve.

The slope of the counting plateau is determined in the same manner described by Eq. (10.60) and Eq. (10.61). The slope of the curve is caused for two main reasons [Centronic 2014]. (1) The increased voltage causes the active volume of the detector to expand, thereby increasing the count rate. (2) Even with a quench gas present, there remains a small probability that residual positive ions or excited gas molecules may produce a spurious count, an effect that increases with voltage. The slope of the counting plateau can also be affected by stray capacitance associated with the detector anode (see Fig. 11.3). This anode stray capacitance, generally arising from signal wires connecting to the detector, has deleterious effects upon the detector performance [Centronic 2014], manifested as a shortened counting plateau and increased plateau slope (see Fig. 11.9). Other effects include an increase in dead time, shortened tube life, and spurious counts.

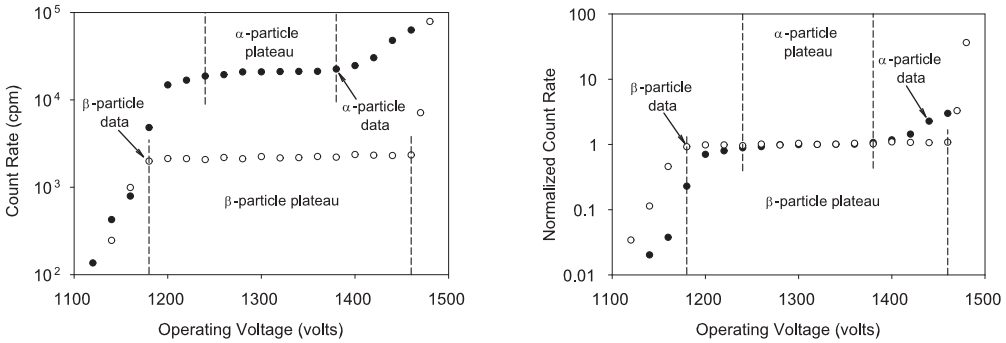

Figure 11.10. (left) A comparison of α- and β-particle counting plateaus from a single Geiger-Müller counter for different α- and β-particle sources with different activities, and (right) the count rate data normalized at 1320 volts. The LLD was kept constant for all measurements.

11.5.2 Alpha and Beta Particle Counting

Geiger-Müller counters have a thin central wire on the axis of a cylindrical tube, as depicted in Fig. 11.3. Most Geiger-Müller counters are completely sealed, and consequently, alpha and beta particles can be blocked by the detector wall from entering the sensitive volume of the detector. However, there are G-M tubes designed for α and β particle detection that have thin windows to allow charged particles to enter the sensitive gas-filled volume.

Although alpha particles typically have sufficient energy to pass through a window composed of boPET or mica, the transport of particles through air from the source to the detector window may result in so much energy loss they cannot pass through the window or, perhaps, not even reach the window. Consequently, the window portion of the detector should be positioned within a centimeter or so of the suspected source material so that alpha particles can enter the device.

It is also common for survey units to be enclosed and sealed in a plastic envelope or bag, mainly to prevent inadvertent contamination of the delicate entrance window. If the plastic bag becomes contaminated, it can be properly discarded and replaced with a new one. Unfortunately, such an envelope can prevent the entrance, and detection, of alpha particles and low-energy beta particles. Consequently, detection of alpha particles with a survey unit does run the risk of possible contamination of the detector window. Some manufacturers have a metal guard screen secured in front of the window to reduce the possible contamination or damage to the thin window. Plastic protection caps are also available that can be slipped over the entrance window, thereby protecting the thin window from damage or contamination while still permitting gamma-ray detection.

Energetic beta particles can pass through thin plastic and have manageable ranges in air. As a result, even enclosed in a plastic bag, a G-M counter can usually be used for counting beta particles. However, there are a few important radionuclides that emit low energy beta particles that present a detection challenge. These include ^{3}H, ^{14}C, and ^{45}Ca, which have, respectively, maximum emission energies of 18.6 keV, 154 keV, and 250 keV, low enough to be absorbed by any intervening materials such as air or the detector window, unless special precautions are exercised. For typical G-M counters with window mass thicknesses equivalent to 30 mg cm^{-2}, the transmission percentage is $\sim$ 0%, 0.04% and 3.0% for ^{3}H, ^{14}C, and ^{45}Ca, respectively.[7] There are commercial detectors with thin windows formed of mica or aluminized boPet, with

[7] Because it is difficult to measure low energy beta particles with a survey meter, liquid scintillation counting has become the preferred measurement choice for low energy beta particles.

mass thicknesses of 1–2 mg cm^{-2}, that can be used to detect beta particles from ^{14}C and ^{45}Ca, although tritium still remains a problem largely because of the short range of its beta particles in air. Higher energy beta particles can enter detectors with thicker windows; hence, common G-M counters can be used to detect beta particles with $E_{max} \gtrsim 250$ keV.

11.5.3 Gamma-Ray Detection

Gamma-ray detection with G-M counters is fairly straightforward. To reduce dead time, the gas in G-M tubes usually has pressures of less than 1 atm, and it is unlikely that a gamma ray interacts with the rarefied detection gas. Instead, x rays and gamma rays mostly interact with the walls of a G-M counter to produce an energetic electron, either through photoelectric, Compton scattering, or pair-production interactions, as shown in Fig. 11.11. If an energetic electron escapes into the detector gas, then it produces electron-ion pairs in the gas, which subsequently cause a Geiger discharge.

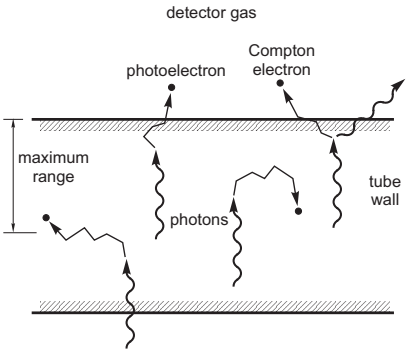

Figure 11.11. Gamma-ray interactions in the G-M tube wall produce energetic electrons that can enter the detector gas and create electron-ion pairs. Electrons liberated too far from the gas interface, or scattered away from the gas-wall interface, cannot enter the detector.

The response of Geiger-Müller tubes to gamma-rays is dependent upon the cathode material. From Fig. 11.12, it is evident that high Z elements have an "over-response" to low-energy gamma rays. The intrinsic efficiency of a G-M counter is defined as the number of primary electrons emitted into the counter gas divided by the number of photons incident on the detector. Hence, intrinsic efficiency includes gamma-ray absorption and electron escape probabilities. For low energy gamma rays, for which photoelectric absorption is dominant, $\sigma_{ph} \propto Z^4/E^3$ and large Z materials have higher absorption probabilities for gamma rays than do small Z materials. Consequently, the response of G-M counter to gamma rays is much higher for large Z materials than small Z materials in the low energy region and, thus, causes the observed over response (see Fig. 11.12).

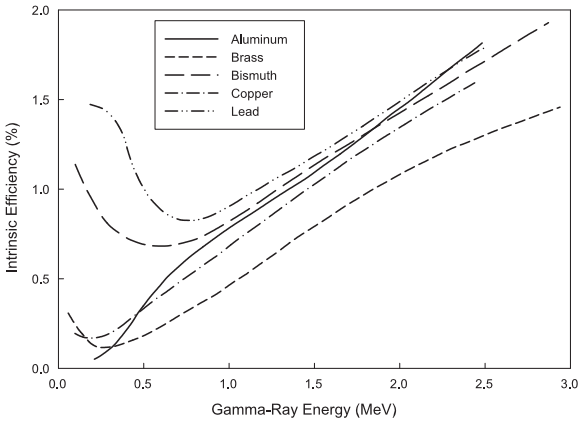

Figure 11.12. Gamma-ray detection efficiency in a Geiger-Müller counter as a function of energy and cathode material. Data from [Bradt et al. 1946, Sinclair 1956].

In the energy region largely dominated by Compton scattering, the gamma-ray interaction probability is approximately proportional to Z, whereas the electron escape probability is approximately proportional to Z^{-1}; hence the two probabilities more or less cancel. As a result, the G-M counter response to gamma-rays in the intermediate region between 500 keV and 2 MeV is relatively unaffected by the Z of the cathode material. From Fig. 11.12, it is seen that Al ($Z = 13$) and Bi ($Z = 83$) have nearly the same response for 1 MeV gamma rays. Although older G-M tube designs were lined with Bi or Pb, modern detectors generally have a Cr/Fe stainless steel alloy[8] cathode, and for enhanced gamma-ray response a Pt ($Z = 80$) cathode liner [Centronic 2014]. The Cr/Fe alloy can be processed to have a relatively high work function, thereby reducing the probability of secondary electron emission. Further, the Cr/Fe stain-

[8] 446 stainless steel and is composed of 73% Fe and between 23% and 27% Cr.

less steel alloy is non-corrosive in the presence of the halogen quenching gas, while still having a reasonable response to gamma rays at approximately 1% detection efficiency.

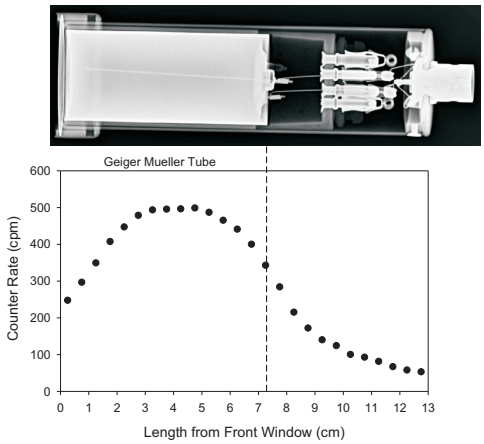

Figure 11.13. (top) X-ray photo of a Ludlum LND 723 G-M tube in its Al container. The detector gas occupies about 60% of the aluminum casing with the remainder filled with wire leads, connectors and resistive divider components. (bottom) The count rate response as a collimated ^{60}Co gamma-ray source moves along the container axis.

The response of G-M counters can be tailored by carefully selecting cathode materials inserted into the chamber. However, this practice is impractical for commercial sealed tubes, most of which are manufactured with stainless steel cathodes. Instead, instruments frequently come with an external shutter that the operator can open or close so as to change the G-M counter response to low- and high-energy gamma rays. Some commercial manufacturers offer detachable field flattening filters designed for special purposes, to reduce the over response to gamma rays at low energies.

The gamma-ray counting efficiency is also a function of the interaction location. An x-ray photograph of a Geiger-Müller tube is shown in Fig. 11.13. The tube, manufactured from stainless steel, rests inside an aluminum casing, connected to electronics through a "C"-type connector. The actual G-M tube takes up approximately 60% of the Al casing. Also shown in Fig. 11.13 is a count rate profile from a collimated ^{60}Co source. The count rate is highest near the center of the actual G-M tube, but drops off near the entrance window and also near the anode feed through. Counts observed from positions beyond the G-M tube are from Compton scattered gamma rays that interact with the Al casing and other materials surrounding the G-M tube.

11.6 Special G-M Counter Designs

Although G-M counters produce substantially similar output pulses regardless of the interacting radiation, special design features can be implemented to improve responses to specific forms of ionizing radiation. For instance, G-M tubes designed for alpha particle counting are outfitted with a thin mica window that allows easy penetration of alpha particles into the chamber. Other designs are optimized for beta particle penetration with either a thicker entrance window that blocks alpha particles or with thinned regions along the metal tube length. Some designs may include a shutter that can be optionally rotated into place to block beta particles while passing gamma rays (see Fig. 11.18). Such devices can be used to distinguish between beta-particle and gamma-ray induced counts.

Detectors may also be filled with different types of counting gas, including He, Ne, Ar, Kr, and Xe for the detection gas while CH_3 or various halogens (usually Cl_2 or Br_2) are used for the quenching gas. Electron mobility is higher in Ne gas, while gamma-ray interaction efficiency is higher in the heavier gases (Kr and Xe). Introduction of an organic gas can also improve electron speeds and, at the same time, serve as the quenching gas. Halogens, as already discussed, serve as a quenching gas while extending the tube life.

Detectors backfilled with Xe gas can be used for detecting low-energy gamma rays, and are often fabricated with thin beryllium or mica entrance windows. These devices are, therefore, designed to operate with the window-end pointing at the radiation source. To improve efficiency, these detectors have higher gas pressures (between 600 to 800 torr) than do conventional G-M tubes. Further, the length is longer than other G-M tubes to improve the gamma-ray absorption probability.

As already mentioned, the response to energetic gamma rays can be increased by lining the cathode with high Z material. Detectors designed for high energy gamma-ray detection generally do not have an entrance

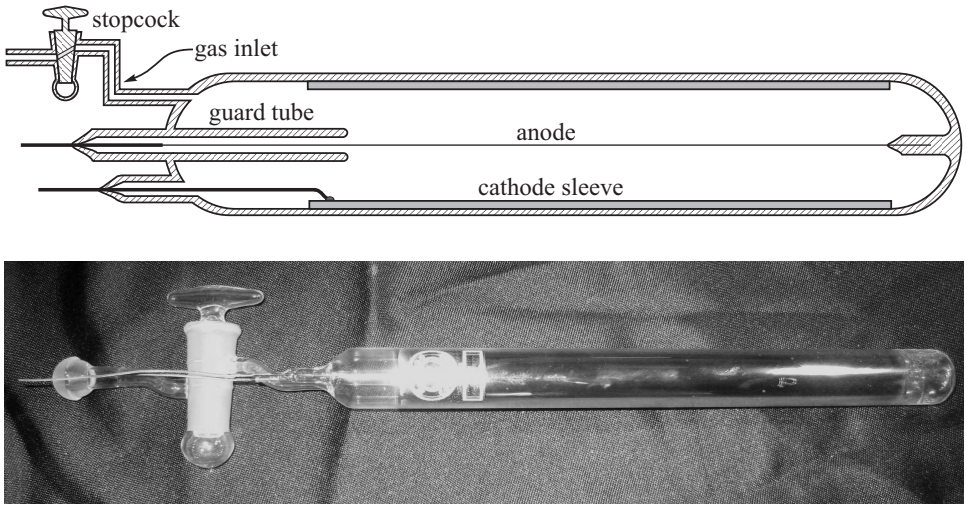

Figure 11.14. (top) Diagram of a refillable cylindrical glass GM counter and (bottom) photograph of a refillable cylindrical glass GM counter manufactured by N. Wood Counter Laboratory.

window and are usually designed for side irradiation to improve interaction efficiency. G-M counters can be made sensitive to slow neutrons by including a Cd liner, but this modification is traditionally not done because of intrinsic problems distinguishing between types of radiation.

11.7 Commercial G-M Counters

Commercial G-M counters of notable variety have been offered for decades. Many of the earliest G-M counters were manufactured as glass tubes, similar to vacuum tubes. These tubes could be acquired as refillable chambers, especially important if organic gases were used as the quenching gases. One such model is shown in Fig. 11.14. These refillable G-M tubes allow a variety of host gases and quenching gases to be used. Current manufacturers of G-M tubes supply numerous detector companies that install them in portable or laboratory instruments. Although many geometries are available, there are perhaps four main types, namely, end-window tubes, pancake detectors, thin wall beta/gamma sensitive tubes, and miniature tubes. The variety of Geiger-Müller tubes, and the equipment in which they are installed, is much too vast to cover in a single book chapter. More information on G-M tubes and equipment can be readily found at internet sites for many of the larger G-M counter manufacturers.[9] A few types of G-M counters are presented here as examples.

LND Inc. is one of the largest manufacturers of gas-filled Geiger-Müller counters and has provided G-M counters to commercial detector instrumentation companies for over 50 years, and a large variety of configurations with different detection gases are available. Their G-M counters are often filled with Ne gas under a mild vacuum, with a small amount of halogen added, usually Cl_2 or Br_2. The use of Ne as the gas, under slight vacuum, reduces the dead time of the detector by increasing the electron and ion mobilities and drift speeds (see Fig. 10.10). To reduce corrosion from the halogen quenching gas, the cathode and anode are constructed from 446 stainless steel. LND provides G-M counters to many detector manufacturers who package them in a variety of configurations, including laboratory detectors, handheld instruments, and portal

[9] For example Centronic, LND, Ludlum, Canberra, Thermo Fisher, and Saint Gobain have data sheets, schematics, and operating procedures available in varying detail.

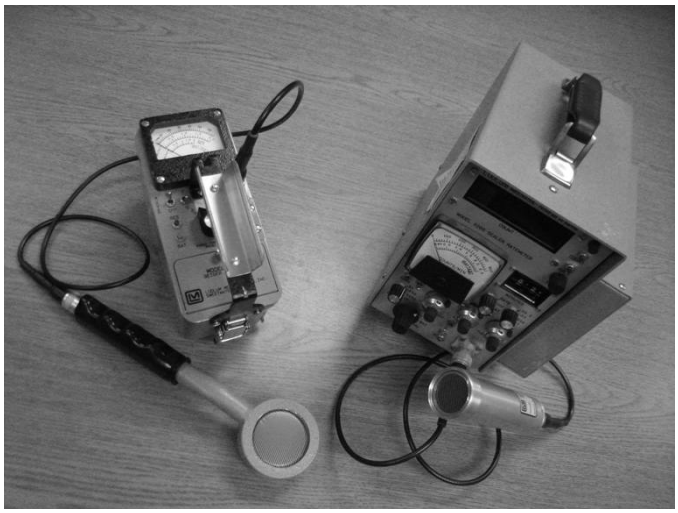

Figure 11.15. Shown are two commercial portable G-M counters manufactured by Ludlum Measurements, Inc. On the left is a 44-9 G-M pancake frisker attached to a model 14C G-M meter, and on the right is a 44-7 G-M tube attached to a model 2200 scaler rate meter.

monitors. An established radiation detector instrument manufacturer is Ludlum Measurements Inc., which offers several small and large instruments outfitted with G-M detectors. For instance, a popular instrument is the 44-9 pancake frisker hand held G-M counter used for general survey work. This instrument incorporates a LND 7311 pancake detector and can be attached to a variety of counters and rate meters as shown in Fig. 11.15.

Portable battery-operated G-M counters are relatively inexpensive and convenient for general survey work. The counters usually have a rate meter with either an analog scale or a digital counter. In either case, the device measures the rate that radiation interacts in the detector, but does not yield any information about the dose rate at a given location because G-M counters are insensitive to energy deposition.

G-M counters notoriously overestimate exposure and dose for low-energy gamma rays if the cathode is fabricated from moderately high atomic number materials. Most G-M counters are presently fabricated from stainless steel, composed primarily of Fe ($Z = 25$) and Cr ($Z = 24$). Although the atomic numbers of Fe and Cr are not considered overly large, the gamma-ray response is still exaggerated for energies below 100 keV. However, selective choice of filters placed over the sensitive portion of the G-M tube can flatten the response by reducing the counting efficiency at low energies, a method referred to as *energy compensation*.

Compensated Geiger-Müller tubes have a tubular collar as part of the detector, commonly an alloy of Sn and Pb, placed around them to flatten the response to gamma-rays at lower energies. Some filters are available as detachable units easily added to the sensitive window of a detector, as depicted in Fig. 11.16, while other detector probes have a rotatable filter as part of the probe unit. Shown in Fig. 11.17 are gamma-ray sensitivity response curves to a Ludlum standard 44-9 pancake G-M counter with and without the optional detachable filters [Ludlum 2014b]. The exposure filter is composed of Sn (1 mm) and plastic (.62 mm) inserts, while the dosimeter filter is composed of Al (0.4 mm), Sn (0.9 mm), and plastic (0.12mm) inserts. G-M counters designed primarily for gamma-ray and beta-particle counting may have a thinned portion of the tube that allows for beta particles to pass into the detector gas, but generally not as thin as windows needed for alpha-particle counting. Probes with rotating shields allow beta-particle counting

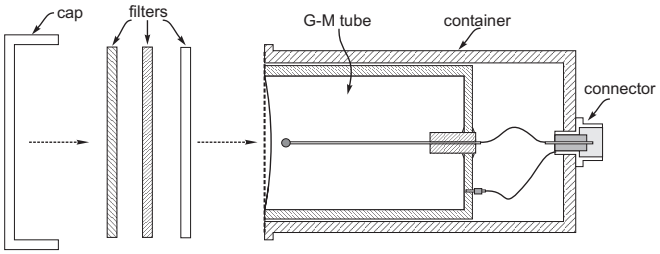

Figure 11.16. The gamma-ray response from a G-M counter can be altered by adding filters to the detector entrance window. With a proper selection of materials and orientation, the gamma-ray response of a G-M counter can be reasonably constant over a wide range of photon energies.

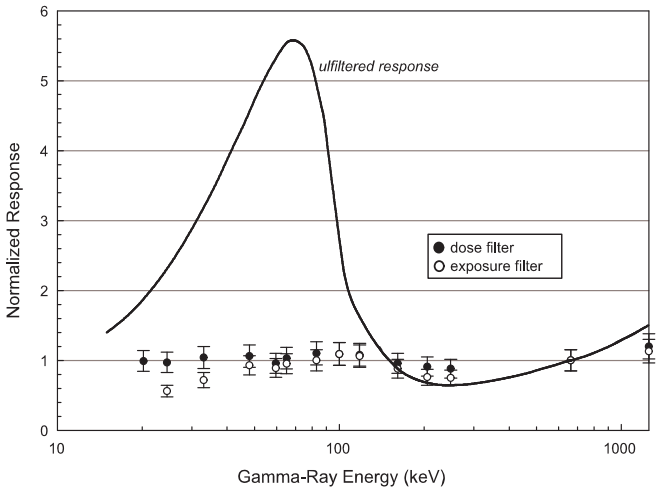

Figure 11.17. Gamma-ray responses from a commercial Ludlum 44-9 G-M pancake detector with and without filtration. The responses are normalized at 662 keV. The filters work to suppress the over-response to gamma rays at low energies. Data from [Ludlum Measurements, Inc. 2014a, 2014b].

when the shield is opened, and filtered gamma-ray counting when the shield is closed. Detectors of this sort are shown in Fig. 11.18, manufactured by Eberline[10] and Ludlum. The Ludlum 44-6 and 44-38 G-M probes come equipped with a Sn side shield that can be rotated in front of the thin G-M tube. The G-M tube listed as the detector in Ludlum 44-6 and 44-38 probes is a LND 725, which does not come equipped with a front window, but has a relatively thin stainless steel body designed to record counts from the side.[11] The LND 725 is backfilled with Ne with a halogen quenching gas, usually Cl_2 or Br_2. The capacitance of the tube is 3 pF, with a recommended load resistance of 1 MΩ, thereby yielding a rise time constant of 3 microseconds. When the Sn shield is rotated back, the G-M tube is exposed through open windows along the probe body (see Fig. 11.18), thereby allowing beta-particle counting for energies above 200 keV [Ludlum 2013a]. Shown in Fig. 11.19 is the gamma-ray response, with and without the shield, for a LND 725 G-M tube installed in a Ludlum 44-6 or Ludlum 44-38 handheld probe. The data were recorded with a few

[10] Now owned by Thermo Fisher.
[11] Some of the Ludlum 44-6 probes come equipped with a TGM N112 G-M tube with similar properties as the LND 725.

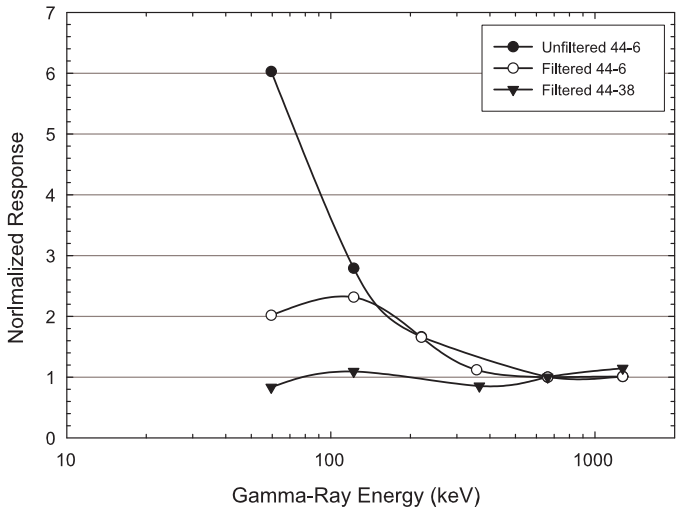

Figure 11.19. Gamma-ray response from an LND 735 G-M tube installed in commercial Ludlum 44-9 and 44-38 beta-gamma counters with and without filtration, normalized at 662 keV. The filters work to suppress the over-response to gamma rays at low energies. Data from [Ludlum Measurements 2013a, 2013b].

gamma-ray standard check sources, namely, ^{241}Am, ^{57}Co, ^{133}Ba, ^{137}Cs, and ^{60}Co. Because ^{133}Ba and ^{60}Co have multiple gamma-ray emissions, weighted averages for their emission energies were reported [Ludlum 2013a, 2013b].

Although G-M counters are used widely for portable handheld instrumentation, there are some larger instruments that have several G-M tubes operating as a single unit. For instance, portal and contamination monitors have multiple G-M counters installed in them. Hand and shoe monitors have multiple G-M counters installed in hand ports and underneath a foot screen for shoe monitoring. A single instrument may have over 20 pancake type G-M tubes, divided amongst the hand and shoe locations. Portal monitors have G-M tubes of varying geometries arranged about a frame that surveys the entire body.

PROBLEMS

1. Consider Fig. 11.10. Why is the β-particle counting plateau for a G-M counter wider and flatter than achieved with a proportional counter?

2. A G-M tube, which contains 0.12 atm of argon and 0.01 atm of alcohol, has a lifetime of 2×10^9 counts. If the end of the tube life occurs when all the alcohol molecules have been dissociated, estimate the number of alcohol molecules dissociated per discharge.

3. If the voltage applied to a G-M tube increases above that needed to achieve a full Geiger discharge, the pulse height continues to increase. Explain.

4. What would be the effect on the starting voltage of the Geiger plateau if (a) the pressure of the fill gas were doubled, or (b) the small concentration of the quench gas were doubled, or (c) the diameter of the anode wire were doubled?

5. An engineer decides to test a G-M counter with Ar as the host gas without the quenching gas. Estimate the number of electrons ejected from a cathode wall for a 5 MeV alpha particle fully absorbed in a G-M counter. Assume M = 1000 and the photoelectric efficiency of the wall is 10^{-4}.

6. Consider a typical G-M tube with dimensions of $D = 2.5$ cm and $L = 15$ cm. The tube is pressurized to 0.15 ATM with Ne gas along with 0.1% Cl_2 gas. If the quenching gas does not recombine, estimate the limiting number of counts possible with this G-M tube. If the actual number of counts observed is 10^{13}, what conclusions can you draw about the quenching gas?

7. While operating a G-M counter, the LLD is adjusted such that the resolving time is 220 μs. At what count rate do resolving time losses reach 5% for this detector? Plot the resolving time losses as a function of count rate from 0% up to 10% loss.

8. A G-M tube is used with a counting system that requires a full Geiger discharge in order to register a count. Is the dead time of such a system better described by an extendable or nonextendable model? Explain.

9. If a G-M counter internal wall is coated with ^{10}B, or is instead backfilled with ^{3}He or BF_3 gas, it can be made sensitive to neutrons; however, this is typically not done. Explain the disadvantage to using a G-M tube for neutron detection.

Chapter 12

Review of Solid State Physics

Nothing exists except atoms and empty space; everything else is opinion.
Democritus

12.1 Introduction

Before scintillation detectors are discussed in the next chapter and light collection devices are discussed in Chapter 14, it is necessary to have this introductory chapter on solid state physics. Further, the information in this chapter is also pertinent to the chapters on semiconductor radiation detectors (Chapters 15 and 16). Here many basic concepts are developed including the fundamental theory of solid state energy bands, effective mass, density of states, mobility, resistivity, impurity doping, and compensation methods. Note that those already familiar with basic solid state physics, including band theory and electronic properties of materials, may safely proceed on to Chapter 13 with, perhaps, little consequence.

12.2 Solid State Physics

Proficiency in the design and fabrication of scintillation and semiconductor detectors requires an understanding of basic solid state and semiconductor physics; and addressing this requirement is the purpose of the present chapter. Here the necessary background about crystalline solid state materials is presented. The physics reviewed here is needed for the chapters that follow.

12.2.1 Crystals and Periodic Lattices

A crystal is composed of atomic or molecular structures (the *basis*) arranged and repeated in a *lattice* arrangement [Kittel 1966]. The basis of the system is the grouping of atoms, which may be a single atom or may be a large molecular group of atoms. The lattice is the structure onto which the basis is projected and repeated. Together they form a crystal structure. Figure 12.1 depicts the basis and lattice of a crystal. When the basis is placed upon each of the lattice points, a crystal is formed. The lattice itself is a periodic structure that can be reduced to a single *unit cell* which, when repeated, reproduces the entire crystal. In other words, by simply repeating the unit cell over and over with each unit cell placed adjacent to the last, a crystal is formed. Figure 12.2 shows two possible unit cells for the lattice, both of which are valid. Unit cells do not have to be *primitive cells*, which are the smallest possible unit cell that, when repeated, forms the crystal. In fact, unit cells are not unique and can be formed in many geometric shapes, provided that the shapes, when stacked, again form the crystal.

The unit cell is related to the lattice in terms of *basis vectors*. Consider the two lattices shown in Fig. 12.3. Then $\mathbf{a}$ is a basis unit vector of length a, and $\mathbf{b}$ is a basis unit vector of length b. An equivalent

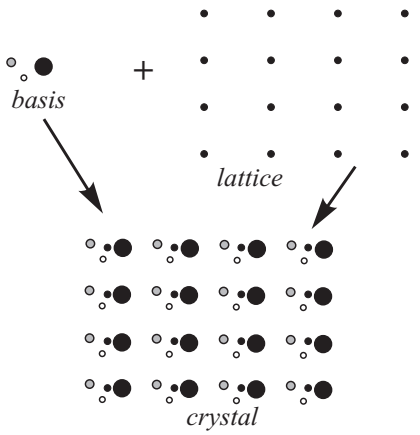

Figure 12.1. A crystal is formed by repeating a basis over the points of a lattice.

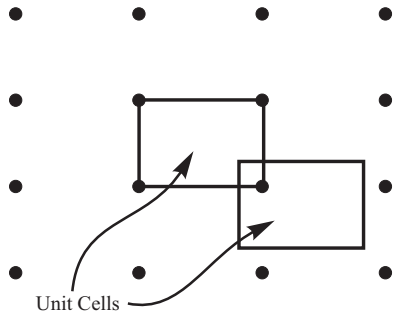

Figure 12.2. Two possible unit cells for the lattice shown.

point anywhere on the lattice can be found by translating the basis vectors by integers. In other words, equivalent points in a two-dimensional lattice can be represented by

$$\mathbf{r} = h\mathbf{a} + k\mathbf{b} \quad , \tag{12.1}$$

where h and k are positive or negative integers. As a result, the entire crystal can be reproduced by translating the unit cell by allowing the integers h and k to assume all possible values.

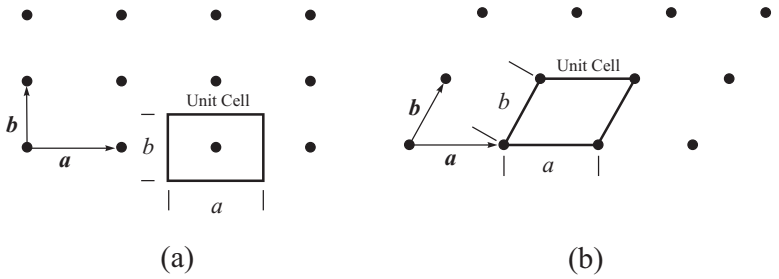

Figure 12.3. The unit cell can be defined by the unit basis vectors, **a** and **b** with magnitudes a and b, respectively. Shown are (a) rectangular and (b) oblique 2-dimensional lattices. Notice that the unit basis vectors are oriented in space according to the lattice alignment points, and is not necessarily a Cartesian system.

12.2.2 Bravais Lattice

It turns out that there are only five possible lattices for a 2-dimensional crystal. The five possibilities, referred to as the 2-dimensional Bravais lattices, named after the man who categorized them [Bravais 1850], are shown in Fig. 12.4. There are four crystal systems, namely the square, rectangular, oblique and hexagonal systems. The centered rectangular is part of the rectangular system, in which an additional lattice point is centered within the rectangle. Hence, the simple rectangle has one lattice point per unit cell (1/4 lattice point per corner), whereas the centered rectangle has two lattice points per unit cell. However, it should be

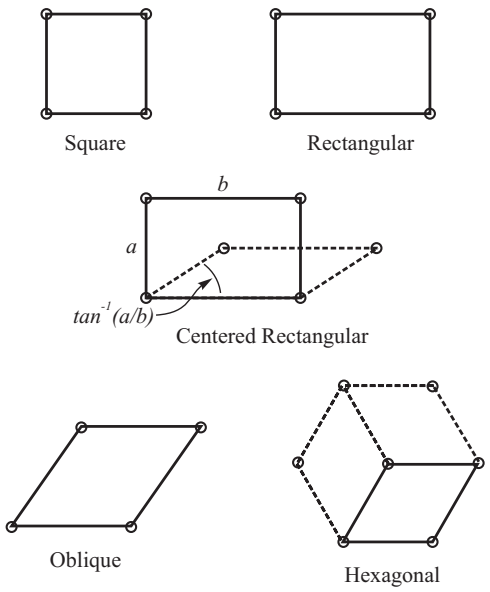

Figure 12.4. The 5 different 2-dimensional Bravais lattices.

pointed out that the centered rectangle can be represented as a special form of the oblique lattice, in which the angle formed between the basis vectors is represented by $\tan^{-1}(a/b)$ with a and b being the magnitude of the two different sides of the rectangle. Hence, the reduced oblique lattice has only one lattice point per unit cell and half the volume of the centered rectangular cell.

The concept can be expanded to 3 dimensions, in which a 3-dimensional crystal can be described by

$$\mathbf{r} = h\mathbf{a} + k\mathbf{b} + l\mathbf{c}, \tag{12.2}$$

where h, k and l are integers. As before, the entire crystal can be reproduced by translating a unit cell by consecutively translating the basis vectors alternately in the a, b and c directions, i.e., by allowing the integers h, k and l to assume all possible values. Although the number of possible unit cells is enormous, there are only 14 possible point lattices for a 3-dimensional system, which are shown in Fig. 12.5. Table 12.1 lists the conditions that define the 7 different crystal systems and the 14 different three-dimensional Bravais lattices. The angles between the basis vectors are denoted α, β and γ, in which

$$\mathbf{b}\bullet\mathbf{c} = |b||c|\ \cos\alpha \qquad \mathbf{a}\bullet\mathbf{c} = |a||c|\ \cos\beta \qquad \mathbf{a}\bullet\mathbf{b} = |a||b|\ \cos\gamma. \tag{12.3}$$

The cubic system has three unique lattice arrangements, the most fundamental unit being the simple cubic. By placing a lattice point in the center of the cubic unit cell structure, the body-centered cubic unit cell is formed. The third fundamental unit cell is formed by placing centered lattice points on the faces of the cube, thereby producing a face-centered cubic unit cell. The simple unit cell is denoted as P (for primitive), the body-centered as I (from the German *Innenzentrierte*), and the face-centered as F. Notice that some crystal systems have a single set of faces with a lattice point, denoted as C for base-centered. However, such an arrangement for the cubic system can be shown to produce a tetragonal P unit cell, and therefore does not constitute a unique cubic lattice arrangement. The tetragonal system has P and I unit cells, yet does not have unique F and C unit cells. It can be shown that a tetragonal F cell can be reoriented such that it is actually a tetragonal I unit cell. Further, the tetragonal C cell can be reoriented such that it is actually

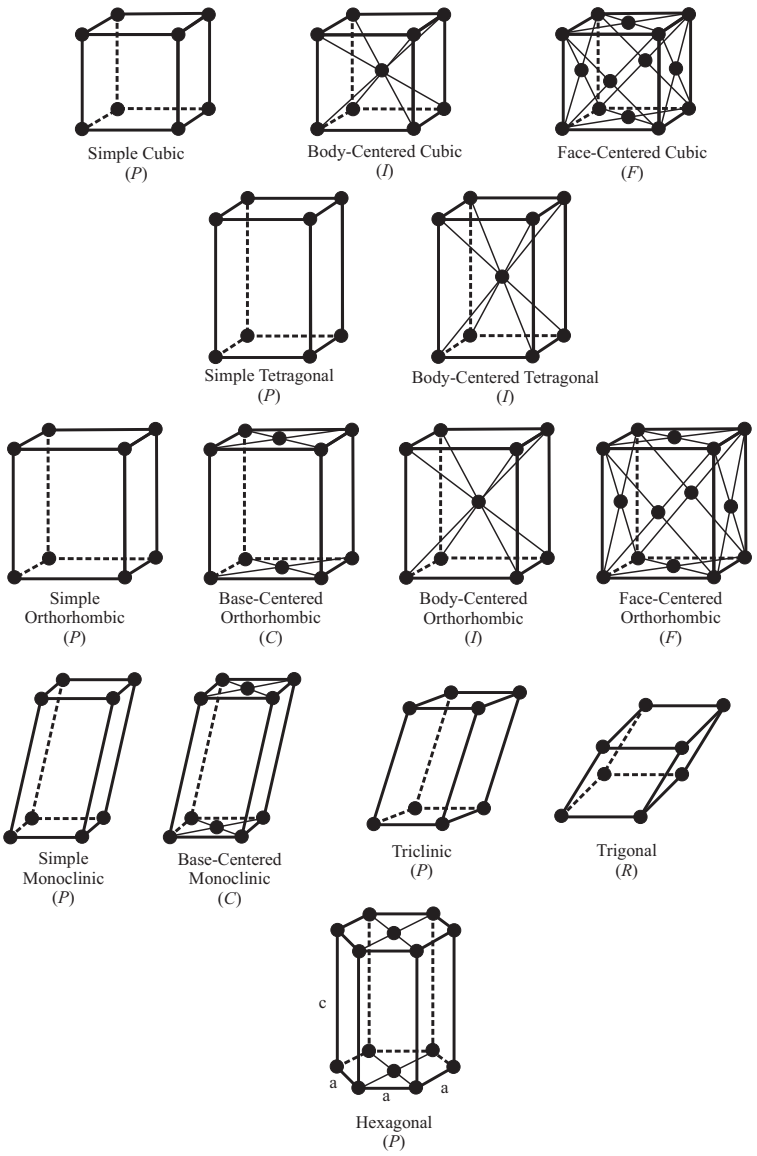

Figure 12.5. The 14 different 3-dimensional Bravais lattices.

a simple tetragonal P unit cell. The trigonal system has a single rhombohedral primitive unit cell, denoted as R. The hexagonal unit cell can actually be shown to be composed of three primitive rhombohedral cells, much like the 2-dimensional counterpart.

12.2.3 Miller Indices

Thus far it has been shown that a crystal is composed of a basis and a lattice. Further, there are only 14 possible Bravais lattices for 3-dimensional crystals. Shown in Fig. 12.6 is a coordinate system for a cubic

Table 12.1. Conditions for the 7 crystal systems and 14 Bravais lattices.

System	Dimensions and Angles	Lattices in System
Cubic	$a = b = c$ $\alpha = \beta = \gamma = 90^o$	P primitive I body centered F face centered
Tetragonal	$a = b \neq c$ $\alpha = \beta = \gamma = 90^o$	P primitive I body centered
Orthorhombic	$a \neq b \neq c$ $\alpha = \beta = \gamma = 90^o$	P primitive C base centered I body centered F face centered
Monoclinic	$a \neq b \neq c$ $\alpha = \gamma = 90^o \neq \beta$	P primitive C base centered
Triclinic	$a \neq b \neq c$ $\alpha \neq \beta \neq \gamma$	P primitive
Trigonal	$a = b = c$ $120^o > \alpha = \beta = \gamma \neq 90^o$	R rhombohedral primitive
Hexagonal	$a = b \neq c$ $\alpha = \beta = 90^o, \gamma = 120^o$	P primitive rhombohedral

three-dimensional lattice. Lattice planes can be defined by *Miller indices*[1]. To describe a single plane, the following procedure is used:

1. Set up a coordinate system along the edges of a unit cell.
2. Note where the plane of interest intercepts the axes and record those integer values. If a plane is parallel to the axis, then it is stated that it intercepts it at ∞. A minus sign is placed *over* the number for intercepts in the negative direction.
3. Invert the intercept values and convert to the smallest set of whole numbers.
4. Enclose the numbers in curved brackets (hkl).

For example, the plane shown in Fig. 12.6 has intercepts at $h = 3$, $k = 2$, and $l = 4$. Inversion gives $\frac{1}{3}$, $\frac{1}{2}$ and $\frac{1}{4}$. Multiplication by 12 reduces the set to the smallest whole numbers, hence the plane is identified as the (463) plane.

Finally, the set of equivalent planes by symmetry are designated by curly brackets, $\{hkl\}$. Note that in the cubic system that a set of planes applies to all permutations with the same indices. For instance, (100), (010), (001), $(\overline{1}00)$, $(0\overline{1}0)$ and $(00\overline{1})$ all belong to the $\{100\}$ set of planes. This is not necessarily the case for other crystal systems. For instance, in the tetragonal system, (100), (010), $(\overline{1}00)$ and $(0\overline{1}0)$ all belong to the $\{100\}$ set of planes, but the (001) and the $(00\overline{1})$ planes are dissimilar to the $\{100\}$ planes, and instead belong to the set of $\{001\}$ planes. Hence, extra care should be taken with non-cubic coordinate systems.

The *direction* vector describes a specific direction in the crystal lattice, and is found in the following manner:

[1] In 1829, the system of Miller indices was introduced by W. Whewell, the Chair of Mineralogy at Cambridge University. His successor was W.H. Miller who further developed the system, also receiving his name, and in 1839 published in his book "A Treatise on Crystallography" [Faria 1990].

1. Set the vector in the direction under investigation.
2. Compose a basis vector **r** by noting its projections along the coordinate axes.
3. Use a multiplier to convert to the smallest set of whole numbers.
4. Assign a direction vector, $\mathbf{r} = h\mathbf{a} + k\mathbf{b} + l\mathbf{c}$.
5. Enclose the numbers in square brackets, $[hkl]$.

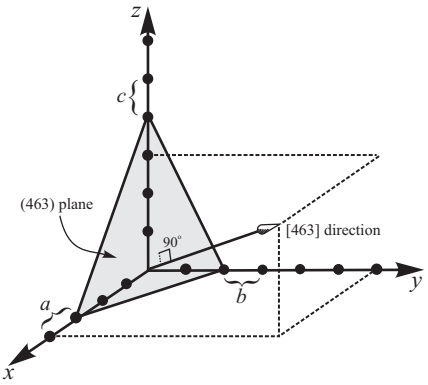

Figure 12.6. Miller indices are used to identify crystal planes and directions. In the cubic system, the crystal plane (hkl) has direction $[hkl]$ orthogonal to the plane.

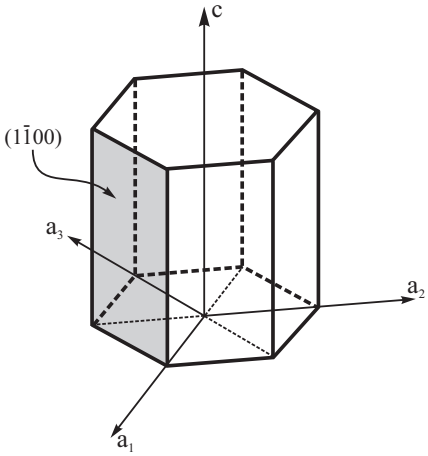

Figure 12.7. Coordinate system for hexagonal crystals, showing the $(1\bar{1}00)$ plane. The system is typically described with four index values.

Direction vectors perpendicular to lattice planes have identical Miller indices for the three cubic crystal lattices, a condition that is *not* necessarily true for any of the other 11 Bravais lattices. For example, Cartesian coordinates with axes x, y and z can be used for a cubic lattice. The direction shown in Fig. 12.6 has projections at $h = 4$, $k = 6$, and $l = 3$. The numbers are already reduced to the smallest of whole numbers, so that the direction is denoted as the [463] direction. As with planes, the minus sign is placed *over* the number for projections in the negative direction. The set of symmetrically equivalent directions are designated by triangular brackets, ⟨hkl⟩.

One of the more common lattices encountered in semiconductors, although definitely not the only one, is the cubic lattice. Si, Ge, GaAs, CdTe, CdZnTe, and InP are all cubic lattice materials, whereas HgI_2, GaSe, and PbI_2 are not. Common planes referenced when dealing with cubic crystals are shown in Fig. 12.8. There are occasions in which planes must be described that fall between lattice planes, as shown in Fig. 12.9. For instance, the (200) plane falls between two (100) planes, where the use of the numeral 2 indicates that it falls halfway between the planes. As mentioned above, cubic lattices have a unique feature that the $[hkl]$ directions are orthogonal to the (hkl) planes, as with the example in Fig. 12.6. This feature is a direct result of the high symmetry along the three axes. In the cubic system the spacing d between the atomic planes is

$$d = \frac{a}{\sqrt{h^2 + k^2 + l^2}}, \tag{12.4}$$

where a is the lattice constant. The cosine of the angle between two different crystal directions for the cubic system, h_1, k_1, l_1 and h_2, k_2, l_2, is

$$\cos\theta = \frac{h_1h_2 + k_1k_2 + l_1l_2}{\sqrt{h_1^2 + k_1^2 + l_1^2}\sqrt{h_2^2 + k_2^2 + l_2^2}}. \tag{12.5}$$

Finally, not all systems are defined by only three Miller indices. The hexagonal lattice requires four Miller indices, namely $hkil$, in which h, k and i are integers along the a_1, a_2 and a_3 axes, and l is along the c axis, as shown in Fig. 12.7. Also shown in Fig. 12.7 is a plane that intercepts the a_1 axis at 1, the a_2 axis at -1, and is parallel to the a_3 and c axes. Inversion and reduction to the smallest integer set of whole numbers, the plane is found to be the $(1\bar{1}00)$ plane. Because a hexagonal unit cell is really three primitive rhombohedral cells, it is really only necessary to have three Miller indices for the hexagonal lattice; however, the established convention remains with four.

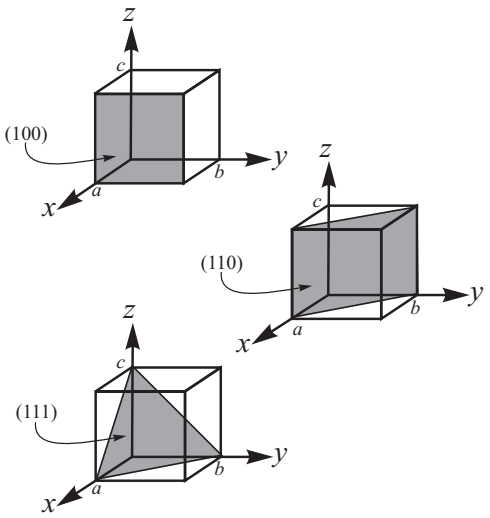

Figure 12.8. Common planes referred to and used for cubic crystals, showing the (100), (110) and (111) planes. The directions for the planes are perpendicular to the planes, namely [100], [110] and [111], respectively.

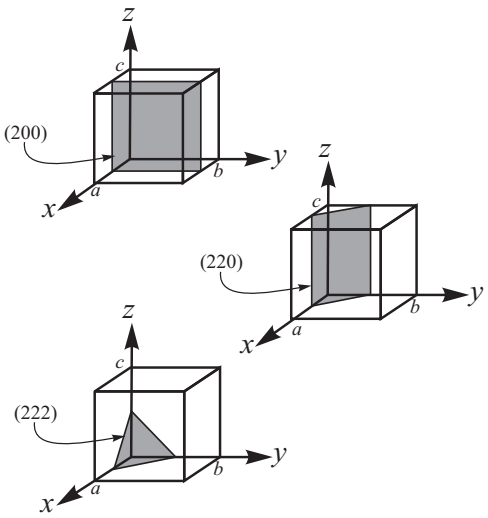

Figure 12.9. Planes that fall between lattice planes can be described without reducing the Miller indices to the lowest integer. Shown are three examples in which the (200) plane falls halfway between two (100) planes, the (220) plane falls halfway between two (110) planes and the (222) plane falls halfway between two (111) planes.

12.2.4 Reciprocal Lattice

Crystalline planes are described in what is usually referred to as *reciprocal lattice space*, a concept used throughout this text. From the real lattice space, which uses unit basis vectors **a**, **b**, and **c**, the fundamental reciprocal lattice vectors are [Kittel 1986]

$$\mathbf{a}^* = \frac{2\pi \mathbf{b} \times \mathbf{c}}{\mathbf{a} \bullet (\mathbf{b} \times \mathbf{c})}, \qquad \mathbf{b}^* = \frac{2\pi \mathbf{c} \times \mathbf{a}}{\mathbf{a} \bullet (\mathbf{b} \times \mathbf{c})}, \qquad \text{and} \qquad \mathbf{c}^* = \frac{2\pi \mathbf{a} \times \mathbf{b}}{\mathbf{a} \bullet (\mathbf{b} \times \mathbf{c})}. \tag{12.6}$$

It is easily seen that

$$\mathbf{a}^* \perp \mathbf{b} \text{ and } \mathbf{c}, \qquad \mathbf{b}^* \perp \mathbf{a} \text{ and } \mathbf{c}, \qquad \mathbf{c}^* \perp \mathbf{b} \text{ and } \mathbf{a}, \tag{12.7}$$

and that $\mathbf{a}^* \bullet \mathbf{a} = \mathbf{b}^* \bullet \mathbf{b} = \mathbf{c}^* \bullet \mathbf{c} = 2\pi$. Notice that the denominators in Eq. (12.6) are the volume of the space-lattice unit cell. Vectors in the real crystal lattice have dimensions of length; hence the reciprocal vectors have dimensions of inverse length. Further, the factor of 2π adjusts the reciprocal space to be numerically and dimensionally consistent with wave-vector space. Multiplication of each coordinate by $\hbar$ converts reciprocal space into momentum space (length^{-1}). From the conditions of Eq. (12.7), it is seen that

$$\mathbf{a}^* \bullet \mathbf{b} = \mathbf{a}^* \bullet \mathbf{c} = \mathbf{b}^* \bullet \mathbf{a} = \mathbf{b}^* \bullet \mathbf{c} = \mathbf{c}^* \bullet \mathbf{a} = \mathbf{c}^* \bullet \mathbf{b} = 0. \tag{12.8}$$

The reciprocal lattice vector is

$$\mathbf{G} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* \tag{12.9}$$

where the reciprocal lattice vector is perpendicular to the hkl plane in real space. A reciprocal lattice can be constructed in much the same way that a real space lattice is constructed, by simply translating each lattice

point in **G** by having the integers h, k, and l assume all possible values. The distances between the points in the reciprocal lattice are inversely proportional to the distances between lattice points in real space.

Suppose one wished to find the fundamental reciprocal lattice vectors for a cubic lattice. The cubic lattice, as represented with Eq. (12.2), has all unit vectors of equal length, namely lattice constant a. For a simple cubic lattice with lattice constant a and the use of basic Cartesian coordinates, the basis vectors are

$$\mathbf{a} = a\hat{\mathbf{i}} \quad \mathbf{b} = a\hat{\mathbf{j}} \quad \text{and} \quad \mathbf{c} = a\hat{\mathbf{k}} \quad . \tag{12.10}$$

From Eqs. (12.6) and Eqs. (12.10), the fundamental vectors of the reciprocal lattice are found to be

$$\mathbf{a}^* = \frac{2\pi}{a}\hat{\mathbf{i}} \quad \mathbf{b}^* = \frac{2\pi}{a}\hat{\mathbf{j}} \quad \mathbf{c}^* = \frac{2\pi}{a}\hat{\mathbf{k}} \tag{12.11}$$

where $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, and $\hat{\mathbf{k}}$ are unit vectors along the x, y, and z axes. The reciprocal space is widely used in solid state physics, and is generally referred to as *k-space*. The concept of reciprocal lattice space is used throughout the text.

12.2.5 Energy Band Gap

In free space, a single atom has discrete quantized energy states for the orbital electrons. Further, the Pauli exclusion principle states that no two electrons of an atom can have the same values for the four quantum numbers (n, l, m_l, m_s), where n is the principle number, which determines the electron's energy, l is the angular momentum quantum number, m_l is the magnetic quantum number, and m_s is the spin.

However, a solid material, such as a semiconductor crystal, is a matrix of atoms arranged in a lattice such that the various potentials of each of the atoms affect the surrounding atoms and their associated electrons. If two atoms, whose electrons initially have identical quantum numbers, are forced into close proximity then something must change so that Pauli's exclusion principle is not violated as the atoms' electrons begin to interact with each other. What happens is the appearance of new degenerate electron energy states. In other words, the original quantum energy levels split such that two states appear where there was only one before the atoms began interacting with each other.

Consider the case of a solid, in which typical atomic densities range from 10^{21} to 10^{23} atoms cm^{-3}. The total number of energy states must split to accommodate the increased electron density in solids. These degenerate energy states form bands of states in place of what were once individual states for a single atom. These bands may overlap, they may be relatively close to each other in energy with a small energy gap between them, or they may form with energy gaps between the bands (see Fig. 12.10). Electrons in the bands behave almost as though they are in an energy continuum, but it is actually a *quasi-continuum*, in which there is a density of available states that each of which can be occupied by an electron. The density of states is determined by the original total number of states of the individual atoms.

The electrical conductivity of a solid is determined by many parameters such as the charge carrier mobility, the density of free charge carriers available in a partially filled energy band, and the availability of unfilled energy states in the partially filled band. Figure 12.11 shows simplistic band diagrams for (a) insulators, (b) conductors, and (c) semiconductors. In Fig. 12.11(a) the *valence band*, which is active in chemical binding of electrons in compounds, is filled, and the next available higher energy band is devoid of electrons. In typical notation, the upper energy limit of the valence band is denoted E_V and the lower energy limit of the *conduction band* is denoted E_C. The energy difference between E_C and E_V is a forbidden energy region, referred to as the *energy band gap* and is denoted by E_g. No states exist between energies E_V and E_C, i.e., in the band gap. If the band-gap energy is sufficiently large, electrons cannot be thermally excited from the valence band into the conduction band. Such materials are said to be insulators. Conduction occurs only if there are empty states in the same energy band for charge carriers to occupy as they move through

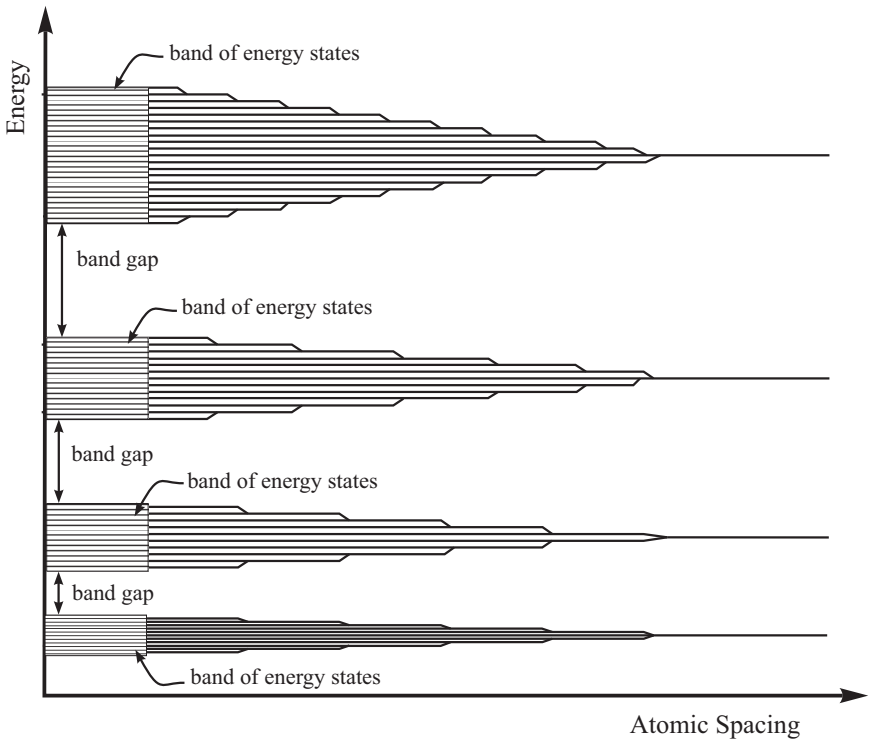

Figure 12.10. As atoms are brought closer together, their allowed energy states split into degenerate states. In a solid medium, the high atomic density causes these degenerate states to form quasi-continua referred to as energy bands.

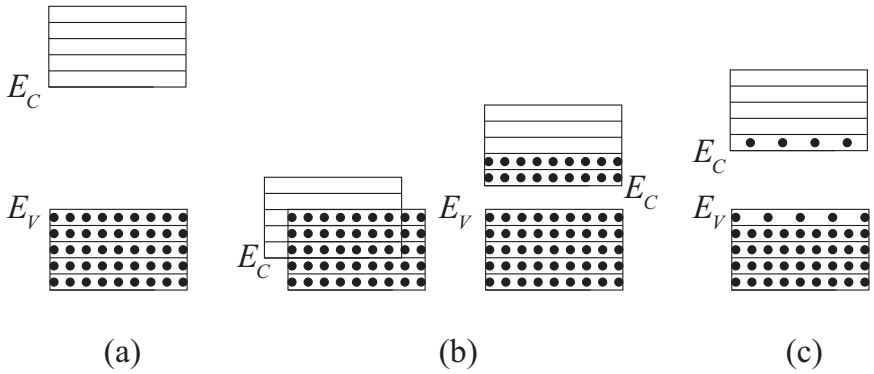

Figure 12.11. Depictions of simple band diagrams for (a) insulators, (b) conductors and (c) semiconductors. In (b) there are two depictions for conductors, one in which a filled valence band overlaps the conduction band, and the other in which the valence band is full with a partially filled conduction band.

the crystal. Because the valence band is completely full of charge carriers in Fig. 12.11, there are no empty states and hence no conduction. Further, the conduction band has empty states, but no charge carriers, hence again conduction does not take place.

In Fig. 12.11(b), there are two examples of conductors. In the first example, the valence band and the conduction band overlap such that electrons can easily move from the filled valence band into the partially filled conduction band without a change of energy. Hence, there are plenty of unfilled states with an overlapping reservoir of electrons (the valence band) that can move to the conduction band, thereby producing free conduction. In the other example, the valence band is filled, and the conduction band is partially filled with a high density of electrons, even at low temperature. Again the conditions exist for free conduction.

Table 12.2. Constants used for Eq. (12.12).

Semiconductor	E_{g0}	α	β
Si	1.170 eV	4.73×10^{-4}	636
Ge	0.7437 eV	4.774×10^{-4}	235
GaAs	1.519 eV	5.405×10^{-4}	204

In Fig. 12.11(c), there is a band gap, similar to that of the insulator example, except the band gap is relatively small. As a result, some electrons are thermally excited from the valence band into the conduction band where they can freely move through the crystal. However, the density of the electrons in the conduction band is determined largely by the band-gap energy and the temperature. At sufficiently low temperatures, the electrons all return to the valence band and the material behaves as an insulator. As the temperature is increased, more and more electrons cross the band gap into the conduction band, and the material conductivity increases. The band-gap energy is an inverse function of temperature, with empirical dependence,

$$E_g(T) \simeq E_{g0} - \frac{\alpha T^2}{T + \beta}, \tag{12.12}$$

where T is the absolute temperature, E_{g0} is the band gap at absolute zero, and α and β are experimentally determined constants. Table 12.2 shows constants reported for semiconductors Si, Ge, and GaAs [Sze, 1985].

Often the class of materials represented by Fig. 12.11(c) is separated into *semiconductors* and *semi-insulators*, the distinction roughly defined by the band-gap energy. Typically, band-gap energies up to about 1.4 eV constitute a class of materials usually designated as semiconductors, while band-gap energies from 1.4 eV to about 5 eV are considered semi-insulators. Band gaps exceeding 5 eV form the insulator class of materials. However, these ranges are not rigidly classified, and often semi-insulators and semiconductors are treated as the same as done in this chapter.

12.3 Quantum Mechanics

Quantum mechanics play a key role in understanding the behavior of electrons in semiconductor materials. An introduction to some quantum mechanics concepts and models is presented in Chapter 3. In this section two more important quantum mechanics models are presented.

12.3.1 Potential Barriers

Quantum mechanical tunneling is a phenomenon often observed and *used* for the design and development of semiconductor devices, including semiconductor radiation detectors. For instance, potential barriers form when a metal is attached to a semiconductor surface, which can cause the contact to have undesirably high resistance. Often, low-resistivity contacts, sometimes referred to as “ohmic contacts”, are generally made by introducing impurity dopants on the surface along with the metal to such concentrations that barriers forming between the metal and the semiconductor are thin, typically only a few angstroms thick. As a result, electrons can tunnel through the potential barrier, and the effective contact resistance is reduced. By contrast, in classical mechanics an electron that encounters the potential barrier would simply be reflected.

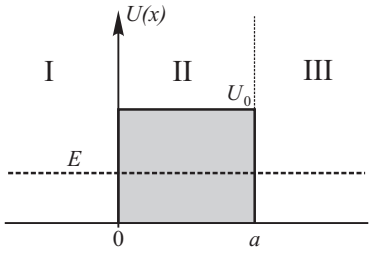

Figure 12.12. Square potential barrier in which the particle energy is less than the barrier height. In classical mechanics, such particles would be reflected by the barrier.

Depicted in Figure 12.12 is a potential barrier of height U_0 and width a. To find a solution for transmittance of electrons, with energy E less than U_0, through the potential barrier, three regions are defined: in region I ($x < 0$) $U(x) = 0$, in region II ($0 < x < a$) $U(x) = U_0$, and in region III ($x > a$) $U(x) = 0$.[2]

From Schrödinger's time independent wave equation, Eq. (3.33), namely,

$$\frac{d^2\psi}{dx^2} + \frac{2m_e}{\hbar^2}(E - U_0)\psi = 0, \tag{12.13}$$

the general solutions for the three regions can be written in the form

$$\psi_1(x) = Ae^{ikx} + Be^{-ikx},\ \psi_2(x) = Ce^{-\phi x} + De^{\phi x},\ \text{and}\ \psi_3(x) = Fe^{ikx}, \tag{12.14}$$

where

$$k^2 = \frac{2m_eE}{\hbar^2} \qquad \text{and} \qquad \phi^2 = \frac{2m_e}{\hbar^2}(U_0 - E). \tag{12.15}$$

The wave function in region I represents a wave traveling in the positive x direction and a reflected wave traveling in the $-x$ direction. In region II, reflections occur at the boundaries such that waves also travel in both directions. In region III, it can be assumed that waves travel only in the positive x direction after passing beyond the barrier. From the boundary condition at $x = 0$, namely, $\psi_1(0) = \psi_2(0)$, it is found that

$$A + B = C + D. \tag{12.16}$$

The boundary condition $\psi_2(a) = \psi_3(a)$ gives

$$Ce^{-\phi a} + De^{\phi a} = Fe^{ika}. \tag{12.17}$$

The boundary condition

$$\frac{d\psi_1}{dx}(0) = \frac{d\psi_2}{dx}(0)$$

yields

$$ik(A - B) = \phi(D - C), \tag{12.18}$$

and the boundary condition

$$\frac{d\psi_2}{dx}(a) = \frac{d\psi_3}{dx}(a)$$

gives

$$\phi(De^{\phi a} - Ce^{-\phi a}) = ikFe^{ika}. \tag{12.19}$$

Now seek a relation between A and F. Towards this end, divide Eq. (12.18) by ik and add the result to Eq. (12.16) to yield

$$2A = C\left(1 - \frac{\phi}{ik}\right) + D\left(1 + \frac{\phi}{ik}\right). \tag{12.20}$$

[2]Strictly speaking this problem should be treated with the time-dependent Schrödinger equation with the particle represented as a wave packet moving along the x axis. But it is also possible to solve this problem as a time-independent one, by imagining that, instead of a single particle, there is a continuous stream of particles moving towards the barrier, some of which are reflected and the rest transmitted through the barrier.

Now add and subtract Eq. (12.19) with Eq. (12.17) to obtain

$$2De^{\phi a} = Fe^{ika}\left(1 + \frac{ik}{\phi}\right) \qquad \text{and} \qquad 2Ce^{-\phi a} = Fe^{ika}\left(1 - \frac{ik}{\phi}\right). \tag{12.21}$$

Substitute Eqs. (12.21) into Eq. (12.20) to obtain the following relationship between A and F

$$4A = Fe^{ika}\left[\left(1 - \frac{\phi}{ik}\right)\left(1 - \frac{ik}{\phi}\right)e^{\phi a} + \left(1 + \frac{\phi}{ik}\right)\left(1 + \frac{ik}{\phi}\right)e^{-\phi a}\right]. \tag{12.22}$$

The above relationship is important because A defines the amplitude of the initial electron wave striking the barrier and F defines the portion of the wave that tunnels through the barrier. By finding the ratio of the fluxes defined by F and A, the transmission coefficient T can be determined. With a small amount of algebra, Eq. (12.22) becomes

$$4A = \frac{Fe^{ika}}{ik\phi}\left[(2ik\phi + k^2 - \phi^2)e^{\phi a} + (2ik\phi - k^2 + \phi^2)e^{-\phi a}\right], \tag{12.23}$$

which can be rewritten as

$$4A = \frac{Fe^{ika}}{ik\phi}\left[2ik\phi(e^{\phi a} + e^{-\phi a}) - (\phi^2 - k^2)(e^{\phi a} - e^{-\phi a})\right]. \tag{12.24}$$

Equation (12.24) can be written in terms of hyperbolic sines and cosines such that

$$2A = \frac{Fe^{ika}}{ik\phi}\left[2ik\phi\cosh(\phi a) - (\phi^2 - k^2)\sinh(\phi a)\right]. \tag{12.25}$$

The magnitude of A is easily found from Eq. (12.25) to be

$$|A|^2 = \frac{|F|^2}{4k^2\phi^2}\left[4k^2\phi^2\cosh^2(\phi a) - (\phi^2 - k^2)^2\sinh^2(\phi a)\right]. \tag{12.26}$$

Because $|\psi(x)\psi^*(x)|\,dx$ is the probability of finding a particle in dx about x, the probability of finding an electron in region I is $|Ae^{ikx}A^*e^{-ikx}|\,dx = |A|^2\,dx$, i.e., independent of position. Likewise the reflected wave in region I Be^{ikx} and the transmitted wave in region III Fe^{ikx} are also independent of position in their respective regions. Because the electrons in the incident beam must be conserved, $|A|^2 = |B|^2 + |F|^2$ or

$$1 = \frac{|B|^2}{|A|^2} + \frac{|F|^2}{|A|^2} \equiv R + T, \tag{12.27}$$

where R and T are the reflection and transmission probabilities or coefficients.

From Eq. (12.26)

$$T = \frac{|F|^2}{|A|^2} = \frac{4k^2\phi^2}{\left[4k^2\phi^2\cosh^2(\phi a) - (\phi^2 - k^2)^2\sinh^2(\phi a)\right]}. \tag{12.28}$$

With the identity that $\cosh^2(\phi a) - \sinh^2(\phi a) = 1$, this result reduces to

$$\frac{1}{T} = 1 + \frac{(k^2 + \phi^2)^2 \sinh^2(\phi a)}{4k^2\phi^2}. \tag{12.29}$$

Finally, the definitions of k and ϕ are substituted into Eq. (12.29) to yield

$$\frac{1}{T} = 1 + \frac{U_0^2}{4E(U_0 - E)} \sinh^2\left(a\sqrt{\frac{2m_e(U_0 - E)}{\hbar^2}}\right). \tag{12.30}$$

It should be obvious to the reader that the reflection probability is simply

$$R = 1 - T. \tag{12.31}$$

From Eq. (12.30), it can be observed that the transmission coefficient approaches unity as the electron energy approaches U_0.

Example 12.1:

For the potential barrier diagram of Fig. 12.12, suppose the following properties exist: $U_0 = 30$ eV, $a = 0.5$ Å, and $E = 5$ eV (for an applied voltage V_0 of 5 volts). Under such conditions, how many electrons strike the barrier per second to produce a tunneling current of 5 mA?

Solution:

Use the substitution $m_e = 511$ keV where $E/c^2 = m$, and from Eq. (12.30),

$$\frac{1}{T} = 1 + \frac{(30\,\text{eV})^2}{4(5\,\text{eV})(30\,\text{eV} - 5\,\text{eV})} \times \sinh^2\left((0.5 \times 10^{-10}\ \text{m})\sqrt{\frac{2(5.11 \times 10^5\ \text{eV})(30\,\text{eV} - 5\,\text{eV})}{(2.998 \times 10^8\ \text{m s}^{-1})^2(6.582 \times 10^{-16}\ \text{eV s})^2}}\right)$$

$$= 1 + (1.8)\sinh^2\left[(0.5 \times 10^{-10}\ \text{m})(2.56 \times 10^{10}\ \text{m}^{-1})\right] = 5.965$$

It is found that $T = 0.1676$. At 5 mA, the number passing through the barrier per second is

$$n_b = \frac{5 \times 10^{-3}\ \text{A}}{1.6 \times 10^{-19}\ \text{C/electron}} = 3.13 \times 10^{16}\ \text{electrons s}^{-1}.$$

The number of electrons n_s striking the potential barrier per second is simply the number tunneling through the barrier per second divided by T and here is found to be

$$n_s = \frac{(3.13 \times 10^{16}\ \text{e}^-\ \text{s}^{-1})}{(0.1676)} = 1.865 \times 10^{17}\ \text{electrons s}^{-1}.$$

Note that potential barriers found in nature are typically not square functions, hence alternative methods to determine the transmission coefficient T are needed. One such method employs the Wentzel-Kramers-Brillouin (WKB) approximation, the details of which can be found in the literature [Gasiorowicz 1974].

12.3.2 Kronig-Penney Model

The electrons surrounding the atoms in a crystal can be thought of as confined in a series of identical potential wells. The functions describing the individual atomic potential wells and the electron confinement are generally quite complex. However, insight about the effect on electrons produced by a periodic series of potentials can be obtained with the idealized assumption that the potentials are a series of square well functions. The resulting quantum mechanical model is referred to as the Kronig-Penney model, and it is fundamental to understanding the behavior of electrons in a semiconductor [Kronig and Penney 1931].

Figure 12.13 shows a one-dimensional infinite series of potential rectangular wells of width a and separated by barriers of width b. Therefore the potential is a one-dimensional periodic function such that $U(n(a+b)) = U(x)$ where n is an integer. It is assumed that the crystal extends to $\pm\infty$; hence one need not be concerned about effects at the termination of the periodicity at the edge of the crystal. Although such a description of the potential an electron experiences in a crystal may strike the reader as unrealistic, it does provide a model for the development of important concepts fundamental to solid state physics, such as *crystal momentum* and carrier *effective mass*. These concepts are introduced in the next section.

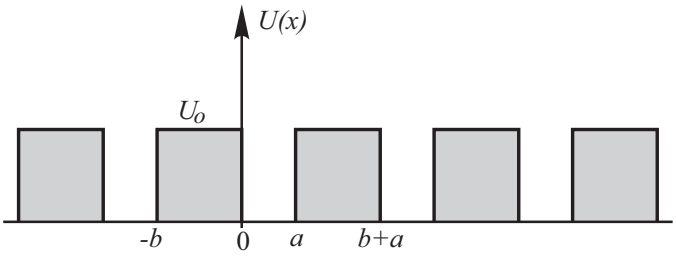

Figure 12.13. The Kronig-Penney model uses a series of rectangular wells to represent the periodicity of the atomic potentials in a crystalline solid. The potential is periodic, i.e., $U(x + a + b) = U(x)$.

It seems reasonable that the wave function describing an electron in the potential of Fig. 12.13 should also be periodic with the period of the crystal $T = a+b$. Indeed, in 1928 Felix Bloch showed that the energy wave function must have the form

$$\psi_k(x) = u_k(x)e^{ikx}, \tag{12.32}$$

where the amplitude $u_k(x)$ also is periodic such that $u_k(x) = u_k(x + T)$ and where k is the wavenumber defined as

$$k = \frac{2n\pi}{a+b}, \quad n = 0, 1, 2, \ldots \quad . \tag{12.33}$$

The one-dimensional Schrödinger wave equation is used to describe an electron of mass m_e in the potential of Fig. 12.13

$$-\frac{\hbar^2}{2m_e}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x). \tag{12.34}$$

Here E is the energy eigenvalue (a positive quantity $< U_o$). The solution for $0 < x < a$ when $U(x) = 0$ (dropping the subscript k for the moment) is

$$\psi(x) = Ae^{igx} + Be^{-igx}, \tag{12.35}$$

in which A and B are arbitrary constants to be found later from the boundary conditions. This solution is the sum of two plane waves, one traveling to the right and the other to the left and has energy

$$E = \hbar^2 g^2/2m_e. \tag{12.36}$$

Within the potential barrier, $-b < x < 0$, the solution of Eq. (12.34) is

$$\psi(x) = Ce^{\gamma x} + De^{-\gamma x}, \tag{12.37}$$

where the positive real number $\gamma^2 = 2m_e(U_o - E)/\hbar^2$. Again C and D are constants to be found from boundary conditions.

Because the wave function must have the Bloch form of Eq. (12.32), the solution $\psi(x)$ for $x \in (a, a+b)$ must be related to the solution for $x \in (-b, 0)$ by

$$\psi(a < x < a+b) = \psi(-b < x < 0)e^{ik(a+b)}. \tag{12.38}$$

From this constraint the wavenumber k is determined and used as an index to the wave function.

The constants A, B, C, and D are chosen to make ψ and $d\psi/dx$ continuous at $x = 0$ and $x = a$. Thus at $x = 0$

$$A + B = C + D \tag{12.39}$$

$$ig(A - B) = \gamma(C - D) \tag{12.40}$$

At $x = a$ with the use of Eq. (12.38) to express $\psi(a)$ in terms of $\psi(-b)$, the boundary conditions require

$$Ae^{iga} + Be^{-iga} = (Ce^{-}\gamma b + De^{\gamma b})e^{ik(a+b)} \tag{12.41}$$

$$ig(Ae^{iga} - Be^{-iga} = \gamma(Ce^{-}\gamma b - De^{\gamma b})e^{ik(a+b)}. \tag{12.42}$$

For the four homogeneous equations for A, B, C, and D to have a non-trivial solution the coefficient matrix for the four constants must vanish. After much algebra, it is found that the determinant vanishes only if

$$\frac{\gamma^2 - g^2}{2\gamma g}\sinh\gamma b \sin ga + \cosh\gamma b \cos ga = \cos k(a+b). \tag{12.43}$$

Because the large potential around a nucleus is located very near the nucleus, i.e., $b \ll a$, the above result can be simplified by approximating the potential as a periodic delta function. Thus let $b \to 0$ and $U_o \to \infty$ such that $P \equiv \gamma^2 ab/2$ remains a finite positive quantity [Kittel 1986]. Thus, in this approximation $\gamma >> g$, $\gamma b << 1$, and $\sinh\gamma b \simeq \gamma b$. Then Eq. (12.43) reduces to

$$\frac{P}{ga}\sin ga + \cos ga = \cos ka. \tag{12.44}$$

Constraints to the solutions of Eq. (12.44) can be inferred from Fig. 12.14 for different values of P, in which the left-hand side of Eq. (12.44) is plotted versus ga. Because the right-hand side of Eq. (12.44) is bounded between ± 1, it is apparent that a solution can exist for the Kronig-Penney model only for those values of ga for which the left-hand side of Eq. (12.44) also is between $\pm$ 1. For all other regions of ga, there are no solutions, and *energy gaps* appear between the regions that have solutions. This situation is analogous to the expected effect of a periodic potential upon electrons in a solid, in which bands of allowed energy states form, and regions also appear in which states are not allowed.

From Eq. (12.44) an *allowed* value of ga on the left-hand side produces a corresponding value of ka from the right-hand side. Because $k \propto 1/\lambda$, where λ is the wavelength of the periodic wave function, then, from de Broglie's relation $p = h/\lambda$ between a particles momentum p and its wave length, it is seen that k is proportional to the electron's momentum. Likewise, from the definition of g in Eq. (12.36), $(ga)^2$ represents the allowed electron energies multiplied by a constant value, $2m_e a^2/\hbar^2$. Therefore, plotting $(ga)^2$ against ka

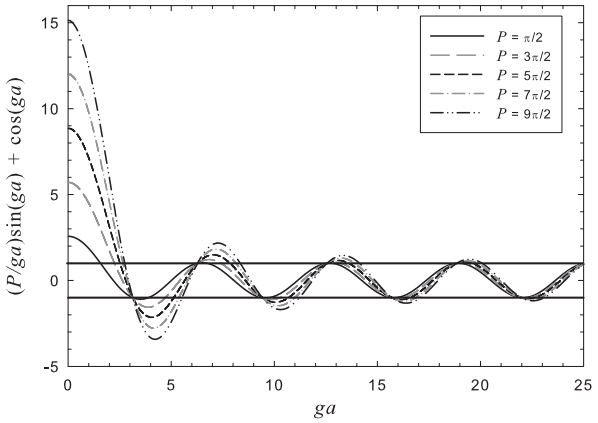

Figure 12.14. Solutions to the Kronig-Penney model for different values of P. Both axes are dimensionless.

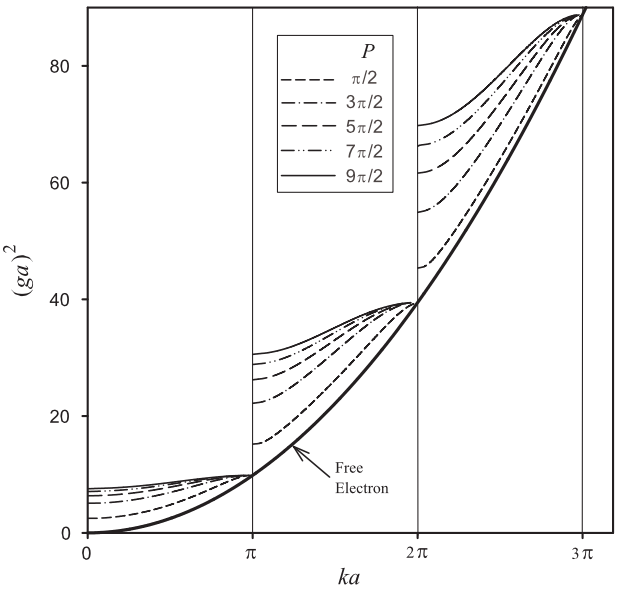

Figure 12.15. Depiction of energy bands from the Kronig-Penney model, showing the relationship between $P, (ga)^2$, and ka. Both axes are dimensionless with ka proportional to the electron's energy and $(ga)^2$ proportional to its momentum.

produces a dimensionless *energy-momentum diagram*. Figure 12.15 shows the results for various values of P for the first three regions of ka where solutions to Eq. (12.44) exist. From this figure, several important features can be seen. Values of ka equal to multiples of π bound momentum regions in which the allowed energies are smoothly continuous. Further, a discontinuity occurs at these boundaries in *k-space*, for which *gaps* between the allowed energy *bands* appear. Notice also that as P increases, the range of the allowed solutions of $(ga)^2$ (or energies) in the band regions decreases. Lastly, this diagram, usually referred to as an E-k diagram, shows that the allowed energies vary from the free electron model,[3] although the basic parabolic shape is still observed.

12.4 Semiconductor Physics

Thus far, the theory developed in the preceding sections applies in general to solid-state crystalline material. Yet, it is the subset of solid-state materials, usually identified as semiconductors, that is generally associated with solid-state radiation detectors. The result for the Kronig-Penney model can be used to understand many concepts in semiconductor physics.

12.4.1 Brillouin Zones

Because of the symmetry in ka of the one-dimensional Kronig-Penney model, Fig. 12.15 can be mirrored upon itself to produce the diagram of Fig. 12.16. The center zone is bounded by $-\pi$ and $+\pi$, and it has a continuum of allowed energy states. This first zone of allowed energies is referred to as the first Brillouin zone in one dimension. The next Brillouin zone is defined by the regions bound between -2π and $-\pi$ and

[3] For a free non-relativistic electron, it can be shown that $(ga)^2 = (ka)^2$.

also between $+\pi$ and $+2\pi$. The third Brillouin zone is bounded by -3π and -2π and also between $+2\pi$ and $+3\pi$, and so on. The total width in k-space is identical for the 1st, 2nd, and 3rd Brillouin zones and all higher Brillouin zones [Brillouin 1953]. At the boundaries of each Brillouin zone is a discontinuity at which an energy gap, or band gap, appears. Hence, Brillouin zones are defined as regions within which a continuum, or more correctly a quasi-continuum, of energy states appear and terminate at the k-space boundaries where the energy gaps appear.

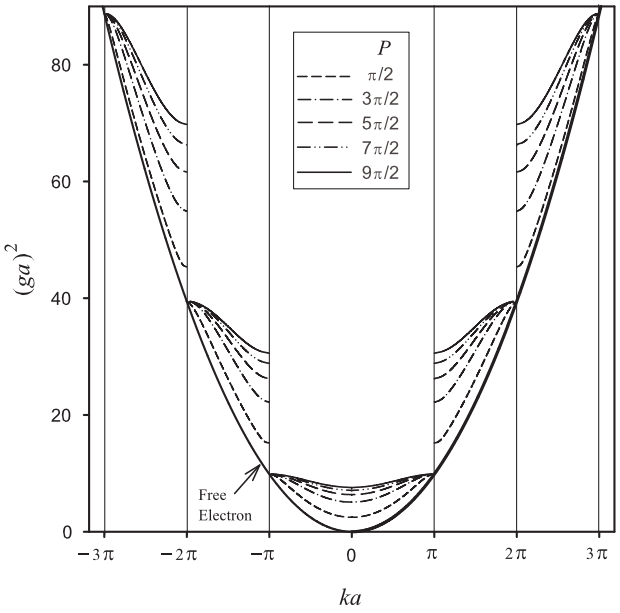

Figure 12.16. Energy band formation and Brillouin zones from the Kronig-Penney model for different values of P.

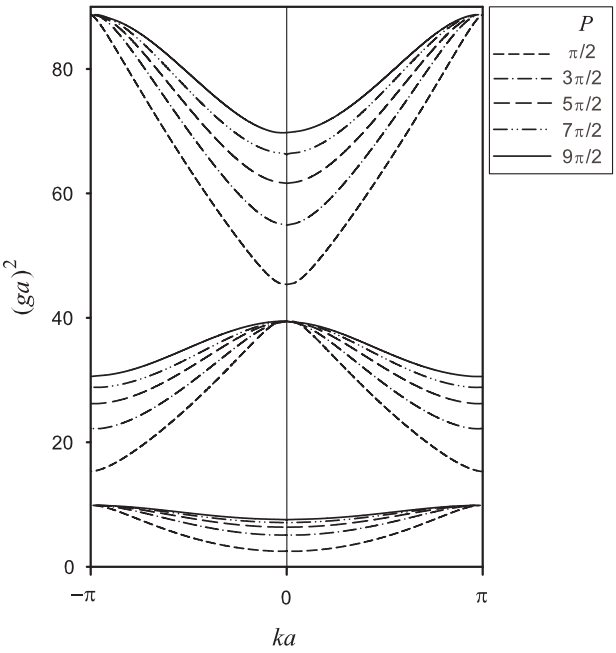

Figure 12.17. Reduced zone diagram, showing the allowed energy bands and forbidden bands for several values of P.

Because one-dimensional Brillouin zones (BZ) all have the same total width in k-space, it is usual to represent Fig. 12.2 in reduced form, as shown in Fig. 12.17. This type of plot is known as the reduced E-k diagram. The plot is created by simply folding each consecutive BZ backwards into the first BZ. The reduced zone diagram is used here to develop basic concepts about electron transport through the periodic potential of a semiconductor. In a three-dimensional solid state crystal, atomic electron orbitals form the energy bands and define the various BZs.

12.4.2 Effective Mass

Consider a wave packet of electrons influenced by an external force. To describe the motion of electrons under such conditions the "group velocity" v_g of the electron wave packet is often used. In general,

$$v_g = \frac{dx}{dt} = \frac{d\omega}{dk}, \tag{12.45}$$

where ω is the "center frequency" of the wave packet, and k is the wavenumber. The frequency is related to energy by $\omega = E/\hbar$ so that

$$v_g = \frac{d}{dk}\left(\frac{E}{\hbar}\right) = \frac{1}{\hbar}\frac{dE}{dk}. \tag{12.46}$$

Application of force (F) to the wave packet, such as occurs when an electric field is placed across the solid, produces a change in energy of the electrons

$$dE = Fdx = Fv_g dt, \tag{12.47}$$

which can be rearranged as

$$F = \frac{1}{v_g}\frac{dE}{dt} = \frac{1}{v_g}\frac{dE}{dk}\frac{dk}{dt} = \hbar\frac{dk}{dt} = \frac{d(\hbar k)}{dt}. \tag{12.48}$$

From Eq. (12.46),

$$\frac{dv_g}{dt} = \frac{1}{\hbar}\frac{d}{dt}\left[\frac{dE}{dk}\right] = \frac{1}{\hbar}\frac{d^2E}{dk^2}\frac{dk}{dt}. \tag{12.49}$$

Substitution of Eq. (12.48) for the force into the above result yields

$$\frac{dv_g}{dt} = \frac{1}{\hbar^2}\frac{d^2E}{dk^2}\frac{d(\hbar k)}{dt} = \left(\frac{1}{\hbar^2}\frac{d^2E}{dk^2}\right)F. \tag{12.50}$$

Finally, Newton's classical relationship $F = ma$ is used to define an "effective mass" m^* for the electrons as

$$F = m_e^*\frac{dv_g}{dt} = \left(\frac{1}{\hbar^2}\frac{d^2E}{dk^2}\right)^{-1}\frac{dv_g}{dt}, \tag{12.51}$$

which, upon rearrangement, gives the electron's effective mass as

$$m_e^* = \left(\frac{1}{\hbar^2}\frac{d^2E}{dk^2}\right)^{-1}. \tag{12.52}$$

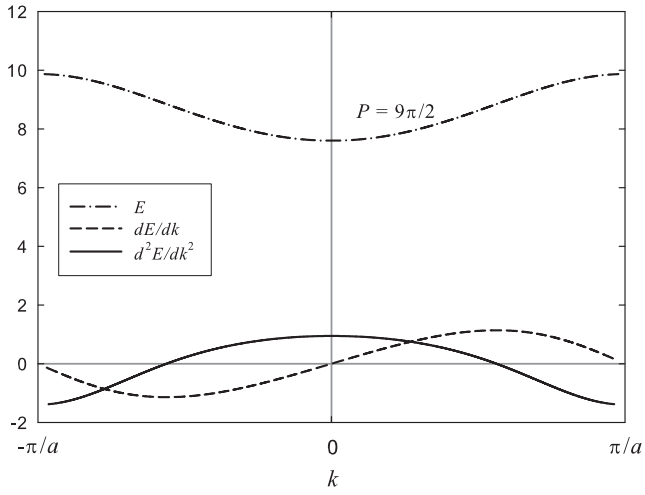

Figure 12.18. The expected values for E, dE/dk, and d^2E/dk^2 of the lowest energy band for the Kronig-Penney model with $P = 9\pi/2$.

This result, of course, does not imply the electron's physical mass has somehow changed, but rather that the periodic potential defined by E and k has changed the influence of an external force upon the electron from that expected upon a free electron. Often the effective mass for electrons in a semiconductor is quoted as a fraction of m_e, the rest mass of a free electron.

A few important concepts can be observed from Eq. (12.52). In order to do so, the result for the lowest energy band in the Kronig-Penney model is used with $P = 9\pi/2$. In Fig. 12.18, allowed energies E of the lowest band, dE/dk, and d^2E/dk^2 are shown as a function of k. Because the effective mass varies inversely with d^2E/dk^2, it is observed that the effective mass can be *negative* whenever the particle moves in the *opposite* direction to that expected for the applied electrical force [Pierret 1989]. This simply means that the particle behaves as though it has the opposite polarity, or in other words, the

electron behaves as a positively charged electron. As a result, the electron moves in the opposite direction of the applied electrical force. It is also observed that the largest magnitude of d^2E/dk^2 occurs in k-space at the top and bottom of the energy band, so that the smallest effective mass occurs at the points of highest curvature with respect to k of the energy band. From Fig. 12.19, in which results for the lowest energy band for different values of P are shown, it is seen that the effective mass decreases as the energy band curvature increases.

The bands, as depicted in Fig. 12.20, are formed from *allowed* energy states, although the available energy states *may not be filled*. The lowest band formed is filled with tightly bound electrons which typically do not share in the chemical bonding process (except for the atoms with very low Z numbers). At higher energies, the band that actively takes part in chemical binding is referred to as the *valence band*. Above the valence band are various partially filled and empty energy bands. The energy gap between the valence band and the next band up, referred to as the *conduction band*, determines, to a large degree, the electronic properties of the solid. For instance, overlapping valence and conduction bands generally form in a conductive material, such as Cu. Those materials with small band-gap energies between the valence and conduction bands, typically no greater than 1.6 eV, generally form a class of materials regarded as *semiconductors*, such as Ge, Si, and GaAs. Larger band gaps, ranging from approximately 1.6 eV to 5 eV compose a class of materials often regarded as *semi-insulators*, which would include CdTe and SiC. Materials with band gaps above 5 eV behave as insulators at room temperature.

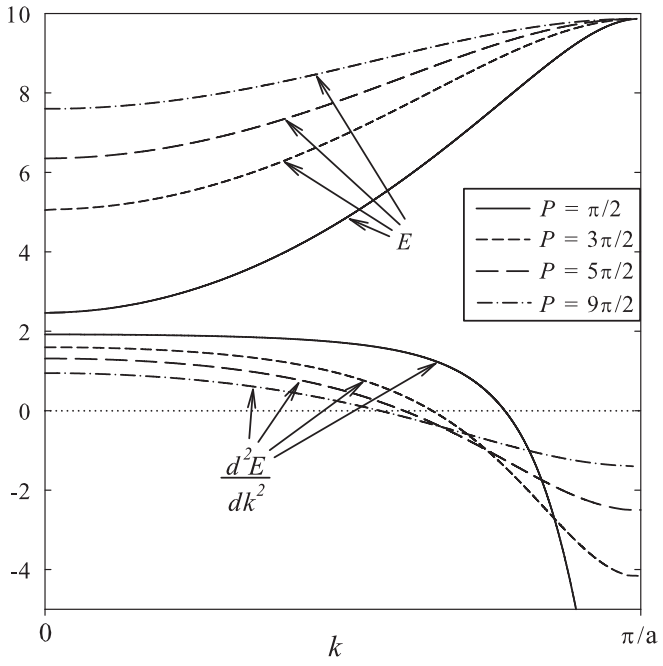

Figure 12.19. E and d^2E/dk^2 for the lowest energy band in the Kronig-Penney model for different values of P. Notice that the largest absolute values of d^2E/dk^2 occur in k space at the top and bottom of the energy bands.

Figure 12.20 depicts a material in which the tightly bound band is filled, the valence band is partially empty, the lower conduction band is partially filled, and the upper conduction band is completely empty. Those electrons populating the upper portions of the bands have negative effective masses, and those electrons populating the lower portions of the energy bands have positive effective masses. Under equilibrium conditions, the electrons in the bands are evenly distributed over k-space such that their net velocities add up to zero. This must be the case because no net current should flow from a simple solid block of semiconductor suspended in space.

Suppose electrical contacts are placed upon the semiconductor block and a voltage is applied. Completely filled bands do not contribute to conduction because there are no empty states in the band for electrons to move into. Conversely, completely empty bands do not contribute to conduction because there are no electrons available. However, for partially filled bands, the force offsets the equilibrium condition so that electrons are displaced in k-space, as depicted in Fig. 12.21. The importance of the effective-mass concept is that those electrons with positive effective masses flow in the direction of the applied electric field force, but those electrons with negative effective masses flow in the *opposite* direction of the applied force.

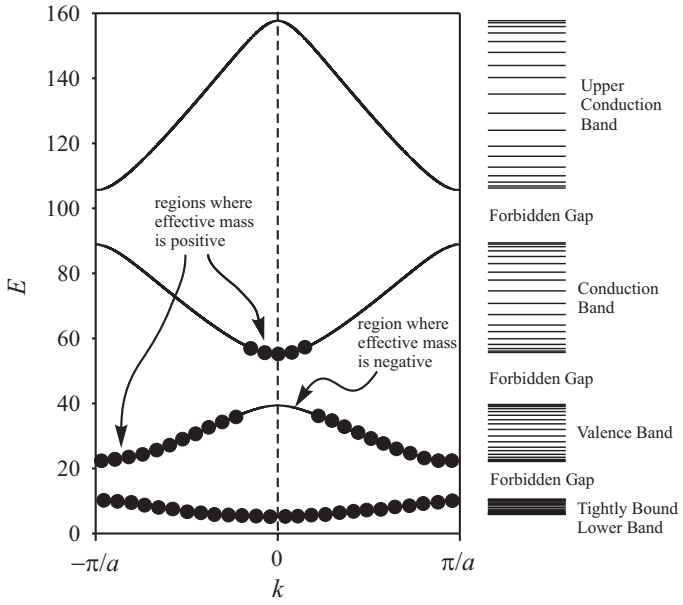

Figure 12.20. The reduced zone diagram depicts energy bands in one dimension. The bands may be completely filled, partially filled, or void of electrons.

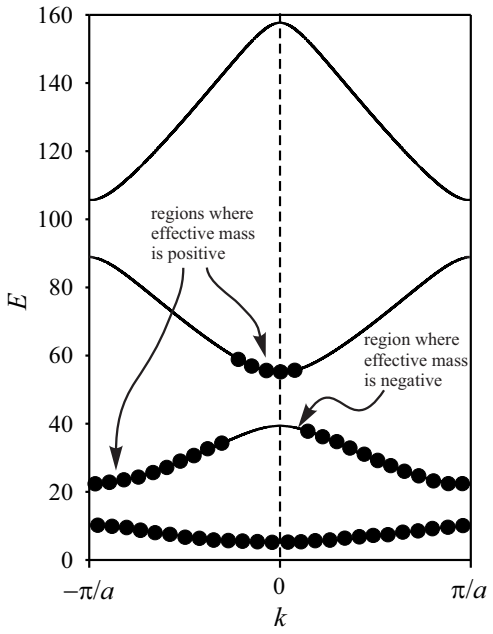

Figure 12.21. A force applied to the periodic structure, such as electric field force, displaces the electron in k-space, thereby perturbing the equilibrium condition.

To determine the current, the total motion of electrons in all of the bands must be taken into consideration [Pierret 1989]. Electric current from contributions in the lower conduction band can be written as

$$I_c = -\frac{q}{d}\sum_{\substack{i \\ \text{filled}}} v_i, \tag{12.53}$$

where the speed contributions from only those states in the conduction band filled with electrons are considered, and d is the width of the semiconductor block between the two contacts. Next, the current contributions from the valence band are found as

$$I_v = -\frac{q}{d}\sum_{\substack{i \\ \text{filled}}} v_i \quad , \tag{12.54}$$

where, again, the speed contributions from only those states in the valence band filled with electrons are used. The summation of currents for the valence band can be difficult because the electrons have both positive and negative effective mass. As a result, positive and negative velocities must also be taken into account. This situation can be greatly simplified by introducing a few approximations. First, note that electrons in the conduction band congregate at the bottom of the band, as occurs in semiconductors operating at ambient temperatures. It can also be assumed that all of the electrons have positive effective mass. To simplify further, it is apparent from Fig. 12.19 that the effective mass, inversely proportional to d^2E/dk^2, is fairly constant near the top and bottom of the energy bands. Hence, those electrons in the conduction band are assumed to have an average constant value for their effective masses. As a result, the evaluation of

Eq. (12.53) requires knowledge only of the number of filled states in the conduction band and the average effective mass at the bottom of the band.

Evaluation of the current from electrons in the valence band is slightly more complicated, but the same assumptions used for the conduction band electrons apply. Here it is assumed that the empty states are all at the top of the band where electrons would have negative effective mass. Again, it is assumed that the effective mass is fairly constant at the top of the band, and that an average effective mass can be used to describe the transport of electrons. Because there is an offset of filled states in k-space, where more positive effective mass states are filled than negative effective mass states, the net electron motion is from electrons moving in the direction of the electric force. That net flow of electrons is simply the difference between the total density of allowed valence band states and the number of valence band filled states. Thus,

$$I_v = \frac{q}{d}\sum_{\substack{i\\ \text{all}}} v_i - \frac{q}{d}\sum_{\substack{i\\ \text{filled}}} v_i = \frac{q}{d}\sum_{\substack{i\\ \text{empty}}} v_i \quad . \tag{12.55}$$

which depends only on the number of empty states, all of which are assumed to be in the negative effective mass region of the valence band. In other words, the number of unfilled states determine the net number of positive effective mass electrons adding to the conduction mechanism. Because the missing electrons at the top of the valence band would have an average negative effective mass, the concept of a *hole* is introduced. A hole is an empty state that behaves like a positively charged particle in the valence band, and mimics the situation in which the valence band is partially filled with positively charged holes that travel in the opposite direction of the negatively charged electrons, as depicted in Fig. 12.22. As a result, the evaluation of Eq. (12.55) requires knowledge of only the number of empty states in the valence band and the average effective mass at the top of the band.

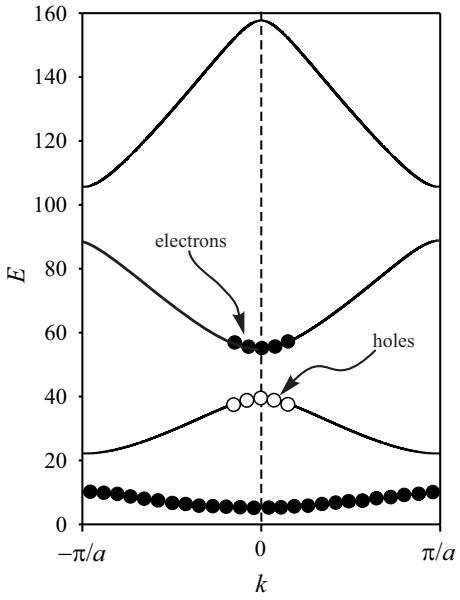

Figure 12.22. The valence band can be thought of as having "positive" charge carriers referred to as "holes" that occupy the empty states. By so doing, the motion of the valence band electrons can be replaced with a simple approximation in which only the motion of holes is considered.

The conduction band of *cubic* semiconductors has three minima, although in some cases all three may not be prevalent. Second, the band gap refers to the energy difference between the lowest point of the conduction band and the highest point of the valence bands. In Fig. 12.23(a), the lowest point in the conduction band is in the [111] direction (the L valley), and is not directly above the highest point of the valence band in k-space. Off-centered band gaps are referred to as *indirect* band gaps. Semiconductors with the Γ valley being the lowest in the conduction band are referred to as having *direct* band gaps because the lowest electron energy is directly across from the highest energy of the valence bands. Third, it should be noted that *three* valence bands form at Γ. Recall that the effective mass in a band decreases as the curvature of the band increases, hence the effective masses for holes in the two upper valence bands are different. The band with narrow curvature is the *light hole* band, and the band with the wider curvature is the *heavy hole* band. The third and lower band is the *split-off band*, and is usually completely filled with electrons, hence has no holes. Typically, the split-off band's effect on free carrier densities is regarded as negligible and is largely ignored in calculations.

So far the discussion has been limited to the one-dimensional case, in which regions of continuous energy in reciprocal space, or k-space, were defined by boundaries of $2\pi/a$. A graphical

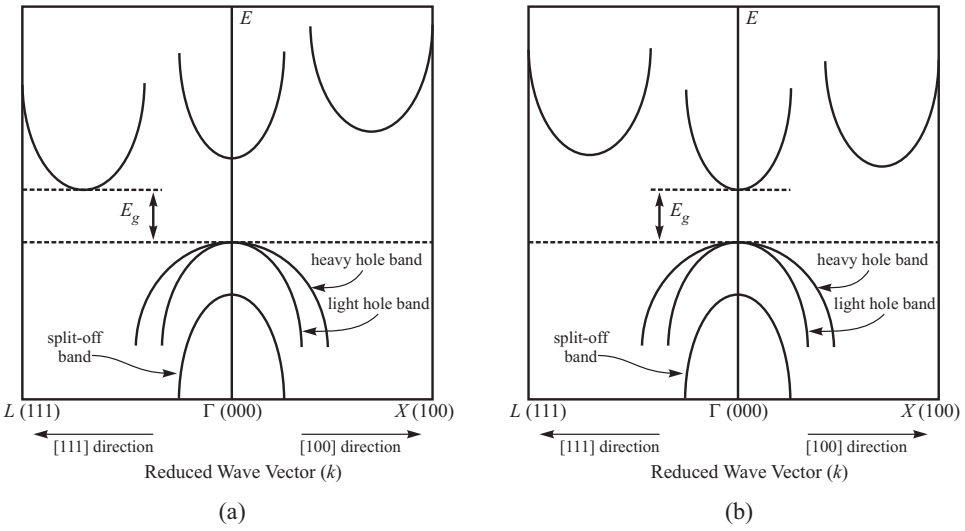

Figure 12.23. Cubic crystals typically have three conduction band minima and three valence band maxima. The conduction band minima are displaced in momentum space. Shown in (a) is an indirect band-gap semiconductor and in (b) a direct band gap semiconductor.

method to develop Brillouin zones from a 2-dimensional (2D) reciprocal lattice is performed as follows. Consider the square lattice depicted in Fig. 12.24. Choose a lattice point, depicted here as the white point in the center. To find the first Brillouin zone, draw straight lines from this point to the closest lattice points, indicated here by the numeral 1. These lines are now bisected by perpendicular lines, shown as dotted lines, and the zone confined in these boundaries is the first Brillouin zone, shown as the white area. These bisecting dotted lines define *Bragg planes*. The second Brillouin zone is found by drawing straight lines from the center to the set of next closest lattice points, indicated here with the numeral 2. These lines are now bisected with perpendicular dotted lines, and the regions confined by these new dotted lines and the previous dotted lines define the second Brillouin zone, shown as the gray area. This procedure is continued for higher order Brillouin zones.

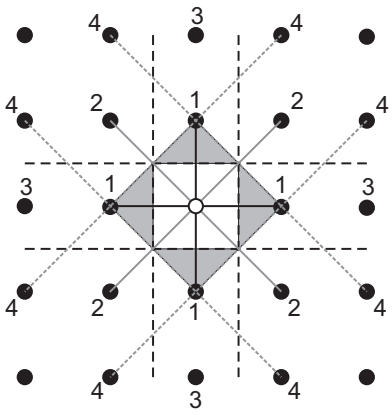

Figure 12.24. Method of developing Brillouin zones from a 2D reciprocal lattice, in this case a square lattice. The first two Brillouin zones are shown for the reciprocal lattice.

These Brillouin zones in two dimensions can also be determined from the reciprocal lattice vector [McKelvey 1966]

$$|\mathbf{G}|^2 + 2\mathbf{k}\bullet\mathbf{G} = 0, \tag{12.56}$$

where $\mathbf{G}$ is 2π multiplied by the reciprocal lattice vector. Hence, in two dimensions, for a square lattice with lattice constant (spacing) of a, the reciprocal lattice is also a square lattice with lattice spacing of $1/a$. Hence it is found that [Kittel 1986],

$$\mathbf{G} = \frac{2\pi}{a}(n_1\hat{\mathbf{x}} + n_2\hat{\mathbf{y}}), \tag{12.57}$$

where n_1 and n_2 are $\pm$ integer values and $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ are unit vectors in the k_x and k_y directions. From Eq. (12.56) and (12.57),

$$-\frac{\pi}{a}(n_1^2 + n_2^2) = k_x n_1 + k_y n_2, \tag{12.58}$$

which produces a family of straight lines in two-dimensional k-space where k_x and k_y are the axes, the boundaries at which Bragg reflection occurs. The intercepts are

$$k_x \text{ intercepts } = -\frac{\pi}{a}\frac{(n_1^2 + n_2^2)}{n_1},$$
$$k_y \text{ intercepts } = -\frac{\pi}{a}\frac{(n_1^2 + n_2^2)}{n_2} \quad .$$

Take the first case, in which $n_1 = 0, n_2 = \pm 1$ and $n_1 = \pm 1, n_2 = 0$. The resulting lines are defined as the boundaries at $k_x = \pm\frac{\pi}{a}, k_y = 0$ and $k_y = \pm\frac{\pi}{a}, k_x = 0$, thereby forming a square in two-dimensional k-space (see Fig. 12.25). This is the *first* Brillouin zone. The second Brillouin zone is found by setting $n_1 = \pm 1, n_2 = \pm 1$, producing the four lines described by $k_x \pm k_y = 2\pi/a$ and $k_x \pm k_y = -2\pi/a$. The reader should notice, just as with the one-dimensional Brillouin zones in which the total length in k-space was always the same, that the total area of the 1st BZ is the equal to the total area of the 2nd BZ. As with the 1-D BZ cases, the 2-D BZs can also be folded back into the first BZ, as shown in Fig. 12.26. The third Brillouin zone is found by setting $n_1 = 0, n_2 = \pm 2$ and $n_1 = \pm 2, n_2 = 0$, which forms the large square with boundaries of $\pm 2\pi/a = k_x, k_y$ shown in Fig. 12.25. Clearly the square formed has more area than the first two constructions, which cannot be. Fact is, there are more boundaries at which Bragg scattering can occur. Hence, to complete the construction of the third Brillouin zone, draw a vertical line from 0 to $k_y = 2\pi$. Rotate the line clockwise and note where the line crosses the next construction lines outside the 2nd BZ, which traces out the third zone. The same procedure is used to form each consecutive BZ. The 2D Brillouin zones form regions of continuous allowed energies, and there are gaps in the allowed energies at the boundaries, much like the result found with 1-D Brillouin zones.

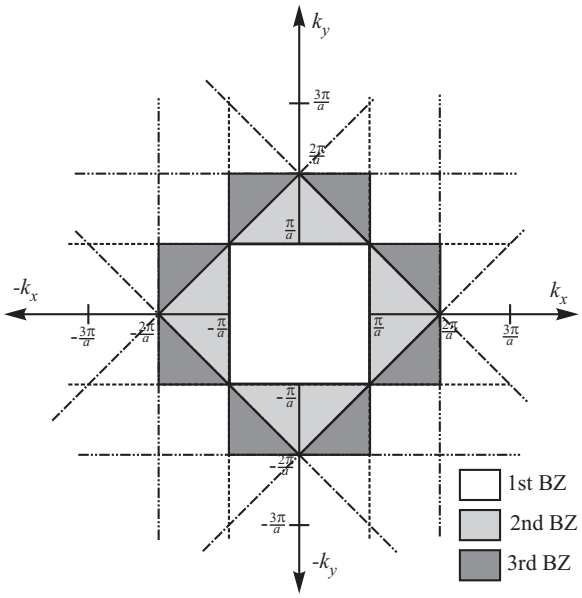

Figure 12.25. Formation of 2D Brillouin zones, showing the 1st, 2nd, and 3rd zones for a square lattice.

These findings can now be extrapolated into three dimensions. The 3D Brillouin zones are *volumes* in reciprocal (k) space, the boundaries of which satisfy the Bragg diffraction condition. As before, each Brillouin zone has the same k-space volume as the 1st Brillouin zone. Using the example for the 2D square, the 1st Brillouin zone for the simple cubic lattice is easily shown to be a cube. The Brillouin zones for the FCC and the BCC lattices are quite different, and are formed in k-space by finding $\mathbf{r}$ for the closest lattice points, and then finding the reciprocal lattice vectors so as to find $\mathbf{G}$. The first Brillouin zone of a BCC lattice is a rhombic dodecahedron, as can best be described, and the first Brillouin zone for the FCC lattice, which are generally of most concern, is a tetrakaidecahedron, which is a 14-faced polyhedron (see Fig. 12.27). The 14 faces consist of 6 planes with normal vectors belonging to the $\langle 100 \rangle$ directions, and 8 planes with normal vectors belonging to the $\langle 111 \rangle$ directions. The formation of the allowed energies and bands is different for

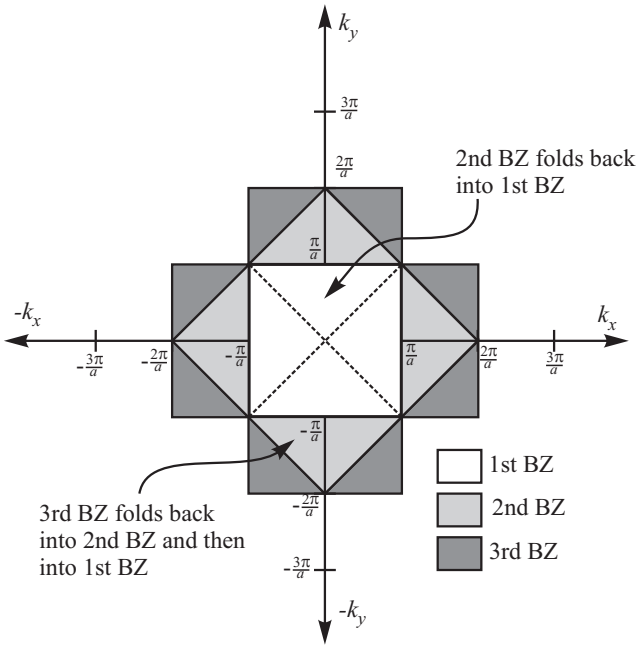

Figure 12.26. As with 1D Brillouin zones, the 2D Brillouin zones each have the same area in k-space, and all can be folded back into the 1st zone.

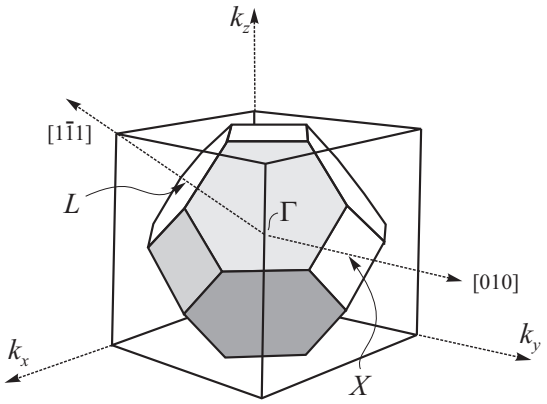

Figure 12.27. The 1st Brillouin zone of the FCC lattice.

the [100] direction than for the [111] direction, most obviously, and from results of the previous sections on the band formation with the Kronig-Penney model, because the distance in k-space to the BZ boundary in the [100] direction, termed X, is not the same as the distance in k space to the BZ boundary in the [111] direction, termed L. Typically, the band diagram for FCC crystals in k space is depicted with the bands formed in the [100] direction to the BZ boundary and the [111] direction to the BZ boundary.

Figure 12.28 depicts a typical FCC E-k diagram showing the energy bands folded back into the 1st Brillouin zone. Only the valence bands and the first conduction band are depicted in the diagram (although other bands may be included as well). The band gap depicted in Fig. 12.28 is indirect, displaced along the [111] direction.

Within the first BZ (see Fig. 12.27) for a FCC semiconductor are regions of constant energy. The regions can be depicted as constant energy *surfaces*. Refer back to Fig. 12.28 and notice again that there are three minima in the conduction band. Free electron carriers accumulate at the lowest energy in one of these bands such that they occupy energies that are quasi-continuous and bound within a region of energy defined by the band curvature. If the Γ valley is the lowest conduction band minima, then the band gap is direct, and electrons need only have an increase in energy to move from the valence bands up to the conduction band, and do not need to change momentum. However, if either the L or X valleys are the lowest conduction band minima, the band gap is indirect, and electrons must both increase in energy and have a change in momentum. The energy bands depicted in Fig. 12.28 are three-dimensional, so that the energy surface within which the electrons are confined is simply the band curvature rotated about the orientation axis, i.e., about [111] for the L valley, and about [100] for the X valley, and about the zone center for the Γ valley. In Chapter 16, modeled results are shown as reported from the literature for several semiconductor energy bands.

From the Γ-valley conduction band depicted in Fig. 12.28, consider a two-dimensional crystal, where the energy is shown as a function of wave vectors k_x and k_y projected along the ⟨100⟩ directions, as shown in

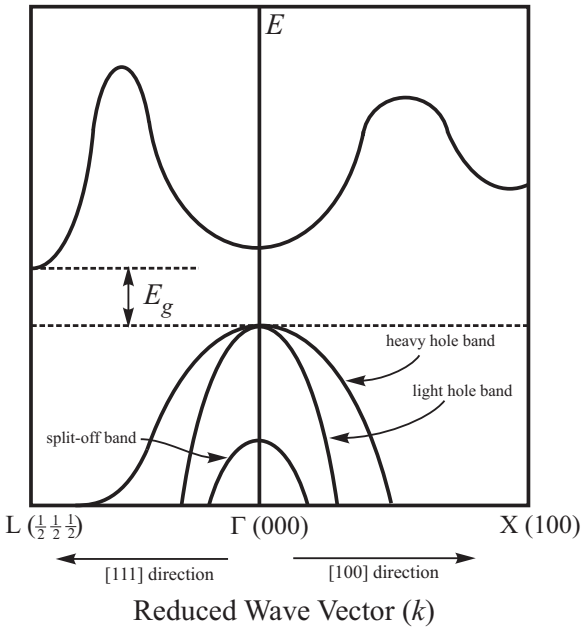

Figure 12.28. A typical E-k diagram for an FCC semiconductor crystal.

Fig. 12.29. Allowed energies are available provided that $E > E_C$. A constant energy, denoted as E_1 for this example, can be depicted as an ellipse around the paraboloid surface. Hence, an ellipse with constant energy around the periphery is described by

$$E_1 - E_C = Ak_x^2 + Bk_y^2, \tag{12.59}$$

where the intercept points along the axes can be identified by,

$$k_x = \pm\sqrt{\frac{E_1 - E_C}{A}},\ k_y = 0, \tag{12.60}$$

$$k_y = \pm\sqrt{\frac{E_1 - E_C}{B}},\ k_x = 0, \tag{12.61}$$

In the case of Fig. 12.29, the ellipse is centered about zone center, meaning that through symmetry the parabolic energy band is identical in the $\pm k_x$ and $\pm k_y$ directions. Consequently, $A = B$, and Eq. (12.59) reduces to the formula for a circle.

If the ellipse is displaced along an axis, as with an indirect band gap (e.g., the X valley in Fig. 12.28), depicted in Fig. 12.30(a) by k_{y1} in the $[0\bar{1}0]$ direction, the constant energy ellipse can now be described by

$$E_1 - E_C = Ak_x^2 + B(k_y + k_{y1})^2, \tag{12.62}$$

where the intercept points along the axes can be identified by,

$$k_x = \pm\sqrt{\frac{E_1 - E_C}{A}},\ k_y = 0, \tag{12.63}$$

$$k_y = \pm\sqrt{\frac{E_1 - E_C}{B}} - k_{y1},\ k_x = 0. \tag{12.64}$$

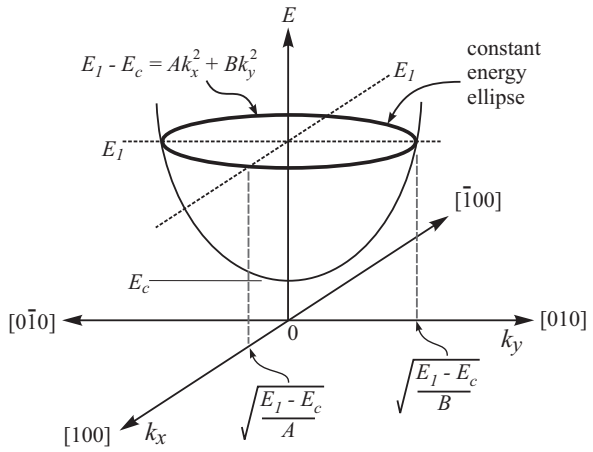

Figure 12.29. Depiction of a constant energy ellipse with energy $E_1 - E_C$ centered at $k_x = k_y = 0$.

However, because the energy band minimum is no longer at zone center, the symmetry between the k_x and k_y directions is lost. Hence, one can expect symmetry about zone center along the $\pm k_y$ directions, finding another energy band minimum at $+k_{y1}$. Also, the energy bands along $\pm k_x$ directions are symmetric about the location $-k_{y1}$ (and also $+k_{y1}$), but not equal to the k_y bands, as depicted in Fig. 12.30(b). Here, $A \neq B$, and the constant energy is depicted by an ellipse. There is a natural consequence to this discovery. Recall from Eq. (12.52) that the effective mass m_e^* is a strong function of the energy band curvature. Because the curvature at the energy minimum is different in the k_x and k_y directions, the electron effective masses are also different. Traditionally, the effective mass along the displaced axis (k_y in the example) is called the

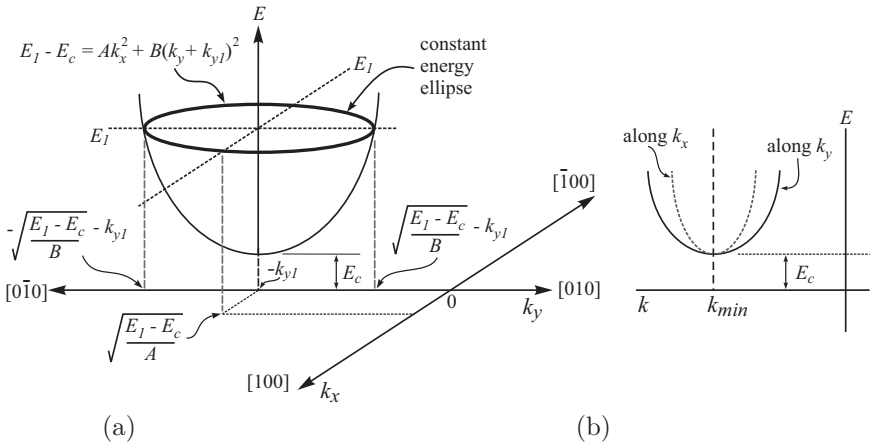

Figure 12.30. (a) Depiction of a constant energy ellipse with energy $E_1 - E_C$ centered at $k_x = 0, k_y = -k_{y1}$. (b) The curvature of the energy bands are different in the k_x and k_y directions.

longitudinal effective mass m_l^* while the effective mass in the perpendicular direction to the long axis (k_x in the example) is called the transverse effective mass m_t^*.

This same concept can now be expanded to three dimensions. Choosing E to lie within the energy ranges populated by the charge carriers in the conduction band, where $E_C \leq E$, the allowed k values form the surface in k-space. Because k is three-dimensional, and providing that the energy E is close to the conduction band edge E_C, the energy of the conduction band surfaces can be approximated by

$$E - E_C \simeq Ak_1^2 + Bk_2^2 + Ck_3^2, \tag{12.65}$$

where A, B and C are constants, and k_1, k_2, and k_3 are k-space coordinates measured from the *center* of an energy band minimum along the principal axis. Eq. (12.65) is the equation for an ellipsoid, meaning that the surface of the ellipsoid in all directions is a constant value.

With cubic crystals, the energy band maxima and minima are nearly parabolic, as was discussed earlier. Also, due to symmetry and expanding on the two-dimensional example, at least two constants in Eq. (12.65) are equal for cubic semiconductors. Hence, the constant energy surface for an indirect band gap, where the energy minimum is displaced from zone center, can be rewritten as

$$E - E_C = Ak_1^2 + B(k_2^2 + k_3^2) \tag{12.66}$$

where A is the axis of revolution.[4] Here, k_1 is the longitudinal axis while k_2 and k_3 are transverse axes. One can imagine spinning the ellipse of Fig. 12.30 about the k_y longitudinal axis to form such an ellipsoid.

For direct band-gap cubic semiconductors, all constants in Eq. (12.65) are equal so that

$$E - E_C = A(k_1^2 + k_2^2 + k_3^2), \tag{12.67}$$

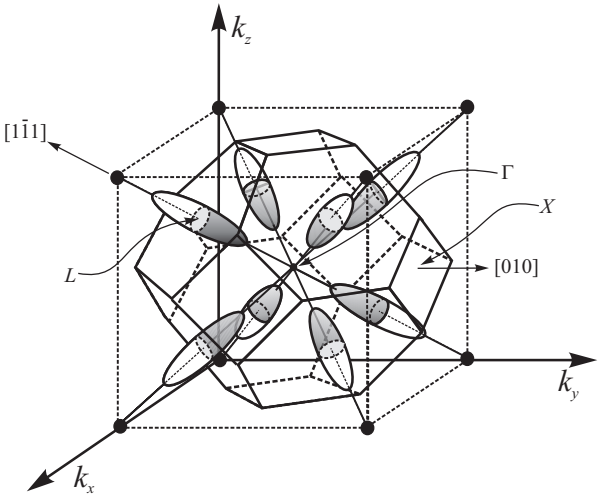

Figure 12.31. First Brillouin zone in the FCC lattice, showing ellipsoids of constant energy for the L valley.

which is the equation of a spherical surface. Hence, it is expected to have a single spherical constant energy surface for direct band-gap cubic semiconductors, six ellipsoidal constant energy surfaces for cubic semiconductors with the lowest band minima at X, and eight ellipsoidal constant energy surfaces for semiconductors with the lowest band minima at L. Figures (12.31), (12.32), and (12.33) depict the first Brillouin zone for the FCC lattice along with the constant energy ellipsoids for the lowest band minima at L, X, and Γ, respectively.

12.5 Charge Transport

To describe the transport of charges in a semiconductor, the concept of effective mass is revisited. The three-dimensional inverse effective mass tensor is described by

$$\frac{1}{\underline{\mathbf{m}}^*} = \begin{pmatrix} \mathbf{m}_{\mathbf{xx}}^{*\,-1} & \mathbf{m}_{\mathbf{xy}}^{*\,-1} & \mathbf{m}_{\mathbf{xz}}^{*\,-1} \\ \mathbf{m}_{\mathbf{yx}}^{*\,-1} & \mathbf{m}_{\mathbf{yy}}^{*\,-1} & \mathbf{m}_{\mathbf{yz}}^{*\,-1} \\ \mathbf{m}_{\mathbf{zx}}^{*\,-1} & \mathbf{m}_{\mathbf{zy}}^{*\,-1} & \mathbf{m}_{\mathbf{zz}}^{*\,-1} \end{pmatrix} \tag{12.68}$$

[4] This type of ellipsoid is called a "spheroid" or "ellipsoid of revolution".

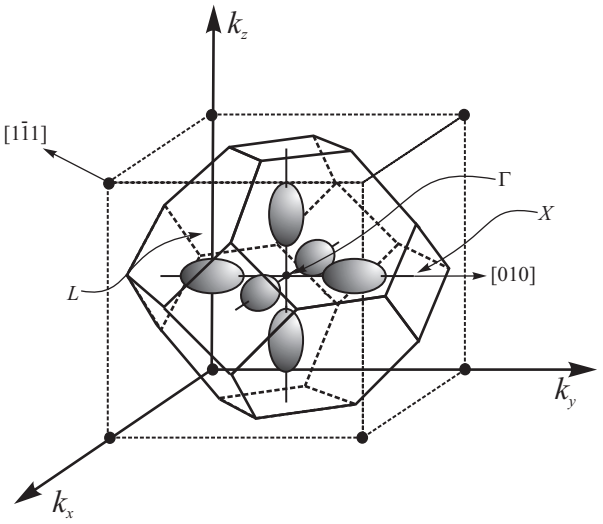

Figure 12.32. First Brillouin zone in the FCC lattice, showing ellipsoids of constant energy for the X valley.

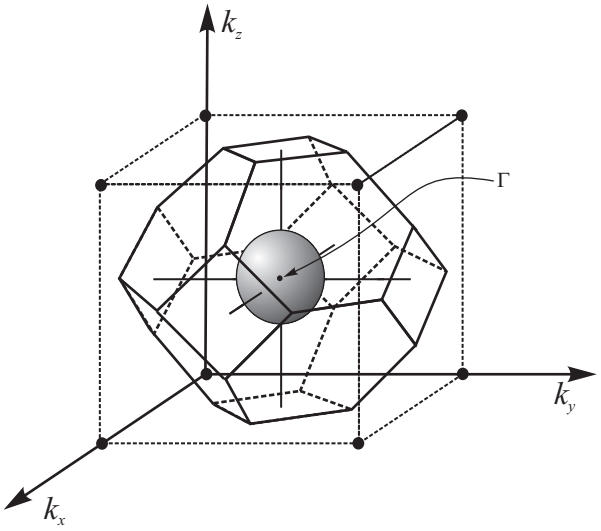

Figure 12.33. First Brillouin zone in the FCC lattice, showing a sphere of constant energy for the Γ valley.

and each inverse effective mass component is

$$\frac{1}{\mathbf{m}^*_{\mathbf{ij}}} = \frac{1}{\hbar^2}\frac{\partial^2 E}{\partial k_i \partial k_j} \quad i,\, j = x,\, y,\, z \quad . \tag{12.69}$$

From Eq. (12.66), the energies in the indirect conduction band valleys are differentiated according to Eq. (12.69) to find, in the case of cubic crystals, that the inverse effective mass tensor reduces to

$$\frac{1}{\underline{\mathbf{m}}^*} = \begin{pmatrix} \mathbf{m}^{*\,-1}_{\mathbf{xx}} & 0 & 0 \\ 0 & \mathbf{m}^{*\,-1}_{\mathbf{yy}} & 0 \\ 0 & 0 & \mathbf{m}^{*\,-1}_{\mathbf{zz}} \end{pmatrix}, \tag{12.70}$$

in which the tensor components $\mathbf{m}^{*\,-1}_{\mathbf{ij}}$ are non-zero only when $i = j$. The conduction mechanism in a semiconductor solid is affected by the total effective mass of the carriers, and can be defined by the relation

$$\mathbf{I} = \underline{\sigma} \bullet \mathbf{E} \tag{12.71}$$

or by

$$\mathbf{E} = \underline{\rho} \bullet \mathbf{I}, \tag{12.72}$$

where $\mathbf{I}$ is the current vector, $\mathbf{E}$ is the electric field vector, $\underline{\sigma}$ is the conductivity tensor and $\underline{\rho}$ is the resistivity tensor. The unit tensor is simply

$$\underline{\sigma} \bullet \underline{\rho} = \begin{pmatrix} \mathbf{1} & 0 & 0 \\ 0 & \mathbf{1} & 0 \\ 0 & 0 & \mathbf{1} \end{pmatrix}, \tag{12.73}$$

from which it is seen that $\underline{\sigma}^{-1} = \underline{\rho}$. The total conductivity is described by

$$\underline{\sigma} = \sum \underline{\sigma}^k \tag{12.74}$$

and

$$\underline{\sigma}^k = (n^k q^2 \tau^*) \begin{pmatrix} \mathbf{m}^{*\,-1}_{\mathbf{xx}} & \mathbf{m}^{*\,-1}_{\mathbf{xy}} & \mathbf{m}^{*\,-1}_{\mathbf{xz}} \\ \mathbf{m}^{*\,-1}_{\mathbf{yx}} & \mathbf{m}^{*\,-1}_{\mathbf{yy}} & \mathbf{m}^{*\,-1}_{\mathbf{yz}} \\ \mathbf{m}^{*\,-1}_{\mathbf{zx}} & \mathbf{m}^{*\,-1}_{\mathbf{zy}} & \mathbf{m}^{*\,-1}_{\mathbf{zz}} \end{pmatrix}, \tag{12.75}$$

where n^k is the number of free electrons in the equivalent ellipsoids in k-space, $\underline{\sigma}^k$ is the conductivity component for ellipsoids in k-space of direction k, q is the unit electronic charge and τ^* is the free carrier mean free drift time. For cubic crystals, the total effective mass always adds up to be the same, regardless of the direction of force applied to the semiconductor. For instance, a block of semiconducting material may have parallel electrodes placed at opposite ends of the block. Regardless of the planes upon which the electrodes are placed, or rather the direction by which an electric field force is applied across the crystal by an external voltage, the summed effective mass, and consequently the conductivity and charge carrier mobility, always sum to the same average value for *cubic lattice* semiconductors. Take for example an indirect band-gap semiconductor with the lowest conduction band minima in the [100] direction, or at X. The free carriers are confined in constant energy ellipsoidal surfaces as depicted in Fig. 12.32.

Suppose an electric field force is applied in the $[0\bar{1}0]$ direction, as shown in Fig. 12.34. The common convention has the electric field vector pointing in the negative direction. As a result, electrons in the ellipsoid surfaces are pushed towards the [010] direction, as depicted in Fig. 12.34. The curvature of the energy bands with respect to k are different in the transverse directions than in the longitudinal directions, hence the effective masses are also different. By invoking symmetry arguments, it can be seen from Fig. 12.34 that the force vector is directed longitudinally along two ellipsoids and transversely along four ellipsoids. The magnitudes of each effective mass tensor component is denoted as m_l^* for longitudinal contributions and m_t^* for transverse contributions.

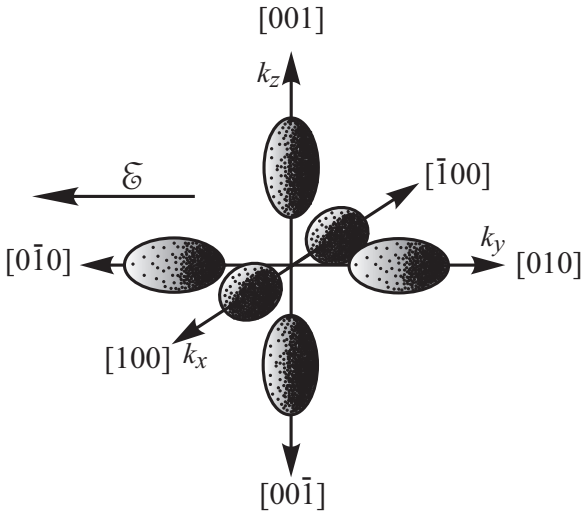

Figure 12.34. Constant energy ellipsoids for the X valley, depicting the effect of an electric field vector applied in the $[0\bar{1}0]$ direction. The small dots are for illustration purposes only, depicting that electrons are distributed preferentially according to the electric field vector.

For the conductivity component along the [100] direction, and by symmetry for the $[\bar{1}00]$ direction,

$$\underline{\sigma}^{[100]} = \underline{\sigma}^{[\bar{1}00]} = (n^{[100]} q^2 \tau^*) \begin{pmatrix} \mathbf{m}_{\mathbf{l}}^{*\,-1} & 0 & 0 \\ 0 & \mathbf{m}_{\mathbf{t}}^{*\,-1} & 0 \\ 0 & 0 & \mathbf{m}_{\mathbf{t}}^{*\,-1} \end{pmatrix}. \tag{12.76}$$

Similarly, for the remaining axial directions,

$$\underline{\sigma}^{[010]} = \underline{\sigma}^{[0\bar{1}0]} = (n^{[010]} q^2 \tau^*) \begin{pmatrix} \mathbf{m}_{\mathbf{t}}^{*\,-1} & 0 & 0 \\ 0 & \mathbf{m}_{\mathbf{l}}^{*\,-1} & 0 \\ 0 & 0 & \mathbf{m}_{\mathbf{t}}^{*\,-1} \end{pmatrix} \tag{12.77}$$

and

$$\underline{\sigma}^{[001]} = \underline{\sigma}^{[00\bar{1}]} = (n^{[001]} q^2 \tau^*) \begin{pmatrix} \mathbf{m}_{\mathbf{t}}^{*\,-1} & 0 & 0 \\ 0 & \mathbf{m}_{\mathbf{t}}^{*\,-1} & 0 \\ 0 & 0 & \mathbf{m}_{\mathbf{l}}^{*\,-1} \end{pmatrix}. \tag{12.78}$$

All six of the $\langle 100\rangle$ ellipsoids are equivalent energy minima, so that the total number of available conduction electrons can be represented by

$$\frac{n_0}{6} = n^{[100]} = n^{[\bar{1}00]} = n^{[010]} = n^{[0\bar{1}0]} = n^{[001]} = n^{[00\bar{1}]}$$

From Eq. (12.74), each conductivity direction tensor is added to find the summed conductivity tensor, which yields

$$\underline{\sigma} = \sum \underline{\sigma}^k = (n_0 q^2 \tau^*) \begin{pmatrix} \frac{1}{3}\left(\frac{2}{\mathbf{m}_t^*} + \frac{1}{\mathbf{m}_l^*}\right) & 0 & 0 \\ 0 & \frac{1}{3}\left(\frac{2}{\mathbf{m}_t^*} + \frac{1}{\mathbf{m}_l^*}\right) & 0 \\ 0 & 0 & \frac{1}{3}\left(\frac{2}{\mathbf{m}_t^*} + \frac{1}{\mathbf{m}_l^*}\right) \end{pmatrix}, \tag{12.79}$$

which can be rewritten as

$$\underline{\sigma} = \left(\frac{n_0 q^2 \tau^*}{3}\right)\left(\frac{2}{m_t^*} + \frac{1}{m_l^*}\right)\begin{pmatrix} \mathbf{1} & 0 & 0 \\ 0 & \mathbf{1} & 0 \\ 0 & 0 & \mathbf{1} \end{pmatrix} = \left(\frac{n_0 q^2 \tau^*}{m_c^*}\right)\underline{\mathbf{1}}, \tag{12.80}$$

where $\underline{\mathbf{1}}$ is the unit tensor and the *conductivity* effective mass is defined as the scalar value

$$\frac{1}{m_c^*} = \left(\frac{1}{3}\right)\left(\frac{2}{m_t^*} + \frac{1}{m_l^*}\right). \tag{12.81}$$

Despite the direction chosen for adding the effective mass tensor components, the result of Eqs. (12.80) and (12.81) for X valley semiconductors are always the same. Hence, regardless of the direction by which an electric field is applied to a cubic lattice semiconductor, the conductivity effective mass, m_c^*, is always the same, implying that mobility and conductivity can be treated as constant values for cubic semiconductors. A similar analysis for L valley semiconductors again produces a constant value for the effective mass, as does the trivial analysis needed for Γ valley semiconductors.

Example 12.2:

The constant energy ellipsoids of L valley cubic semiconductors, such as Ge, are shown in Fig. 12.31. Notice, however, they are aligned along the $\langle 111\rangle$ directions. Determine the conductivity tensor for the [111] direction ellipsoid.

Solution:

A new coordinate system is applied in which one ellipsoid is aligned along a major axis, z' for instance. In such a case, the new coordinate system can be rewritten in terms of the conventional Cartesian coordinate system. Each ellipsoid can then be rewritten in its appropriate coordinate representation.

To simplify matters a bit, note that there are eight ellipsoids in Fig. 12.31, but each ellipsoid terminates in the middle at the Brillouin zone boundary. Therefore, there are only four complete ellipsoids, which can be redrawn as shown in Fig. 12.35. Taking the ellipsoid labeled A, the z' direction is aligned along the longitudinal axis, which, using the diagram of Fig. 12.35, the unit vector can be written as

$$\mathbf{i}_z' = \frac{1}{\sqrt{3}}(\mathbf{i}_x + \mathbf{i}_y + \mathbf{i}_z). \tag{12.82}$$

The unit vectors for the x' and y' directions must be perpendicular to the z' direction and to each other. The plane they must lie in is depicted in Fig. 12.36. Notice that this plane must also intersect three planes, namely the zy, the xy, and the xz planes. Any of these intersections can be chosen for the second unit vector. For the present example, the $k_y k_z$-plane is chosen. Vectors in the $k_y k_z$ plane have no k_x component.

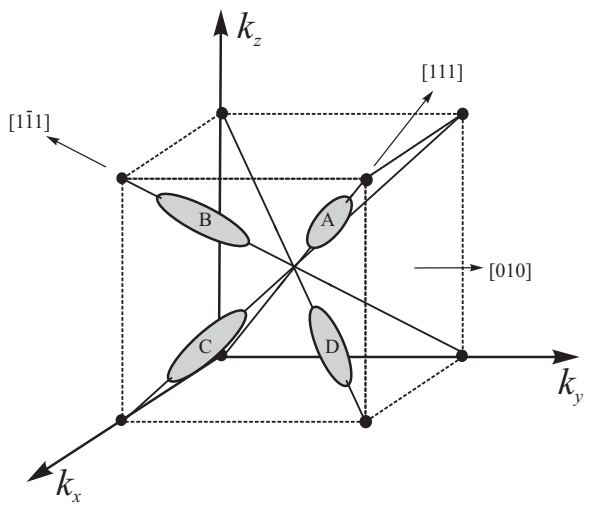

Figure 12.35. For the effective mass calculation, the eight half ellipsoids for the L valley can be rearranged as four complete ellipsoids as shown.

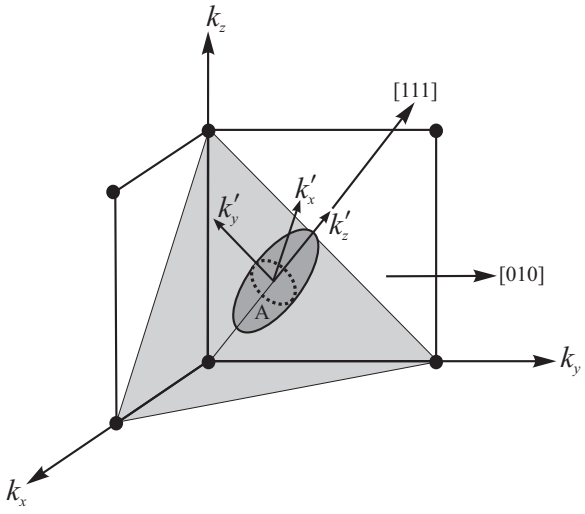

Figure 12.36. Coordinate systems used for the example, showing the relationship between k'_x, k'_y and k'_z to k_x, k_y and k_z.

The dot product of the unit vector in this new vector and Eq. (12.82) must vanish, and is a suitable choice for $\mathbf{i}'_y$.

Hence, the y' unit vector is

$$\mathbf{i}'_y = \frac{1}{\sqrt{2}}(-\mathbf{i}_y + \mathbf{i}_z).$$

The x' direction unit vector is found from the cross product of $\mathbf{i}'_y$ and $\mathbf{i}'_z$,

$$\mathbf{i}'_x = \mathbf{i}'_y \times \mathbf{i}'_z = -\frac{2}{\sqrt{6}}\mathbf{i}_x + \frac{1}{\sqrt{6}}\mathbf{i}_y + \frac{1}{\sqrt{6}}\mathbf{i}_z = \frac{1}{\sqrt{6}}(-2\mathbf{i}_x + \mathbf{i}_y + \mathbf{i}_z).$$

The unit vectors are arranged in matrix form to redefine the x, y and z unit vectors for the [111] ellipsoid A,

$$\begin{pmatrix} -\frac{2}{\sqrt{6}} & \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{6}} \\ 0 & -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} \end{pmatrix} \begin{pmatrix} \mathbf{i}_x \\ \mathbf{i}_y \\ \mathbf{i}_z \end{pmatrix} = \begin{pmatrix} \mathbf{i}'_x \\ \mathbf{i}'_y \\ \mathbf{i}'_z \end{pmatrix}$$

So the system of equations to determine the original Cartesian coordinates is represented by,

$$\begin{pmatrix} -\frac{2}{\sqrt{6}} & 0 & \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{3}} \end{pmatrix} \begin{pmatrix} \mathbf{i}'_x \\ \mathbf{i}'_y \\ \mathbf{i}'_z \end{pmatrix} = \begin{pmatrix} \mathbf{i}_x \\ \mathbf{i}_y \\ \mathbf{i}_z \end{pmatrix}.$$

A method is now available to describe both coordinate systems in terms of the other. Consider an arbitrary vector $\mathbf{k}$ to be described in both coordinate systems, then

$$\mathbf{k} = \sum_j k_j \mathbf{i}_j \ , \ j = x, y, z = \sum_m k'_m \mathbf{i}'_m \ , \ m = x, y, z.$$

Hence,

$$\mathbf{k} = k_x\left(-\frac{2}{\sqrt{6}}\mathbf{i}'_x + \frac{1}{\sqrt{3}}\mathbf{i}'_z\right) + k_y\left(\frac{1}{\sqrt{6}}\mathbf{i}'_x - \frac{1}{\sqrt{2}}\mathbf{i}'_y + \frac{1}{\sqrt{3}}\mathbf{i}'_z\right)$$

$$+k_z\left(\frac{1}{\sqrt{6}}\mathbf{i}'_x + \frac{1}{\sqrt{2}}\mathbf{i}'_y + \frac{1}{\sqrt{3}}\mathbf{i}'_z\right) \quad .$$

Now $\mathbf{k}$ can be written in terms of k'_x, k'_y, k'_z by collecting the terms from the respective unit vectors,

$$k'_x = -\frac{2}{\sqrt{6}}k_x + \frac{1}{\sqrt{6}}k_y + \frac{1}{\sqrt{6}}k_z$$

$$k'_y = -\frac{1}{\sqrt{2}}k_y + \frac{1}{\sqrt{2}}k_z$$

$$k'_z = \frac{1}{\sqrt{3}}k_x + \frac{1}{\sqrt{3}}k_y + \frac{1}{\sqrt{3}}k_z$$

The constant energy surface of ellipsoid A is described by Eq. (12.66)

$$E - E_C = \hbar^2\left[\frac{(k'_z - k'_0)^2}{2m_l^*} + \frac{{k'_x}^2 + {k'_y}^2}{2m_t^*}\right].$$

Upon setting k'_0 to 0, and substitution of the terms for k'_x, k'_y, and k'_z one obtains

$$E - E_C = \frac{\hbar^2}{6m_l^*}\left(k_x^2 + k_y^2 + k_z^2 + 2k_xk_y + 2k_xk_z + 2k_yk_z\right)$$

$$+\frac{\hbar^2}{3m_t^*}\left(k_x^2 + k_y^2 + k_z^2 - 2k_xk_y - 2k_xk_z - 2k_yk_z\right)$$

The conductivity tensor for the [111] direction ellipsoid from Eq. (12.69) is,

$$\underline{\sigma}_{[111]} = \left(\frac{n_0q^2\tau^*}{4}\right)\begin{pmatrix} \frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} + \frac{1}{\mathbf{m_l^*}}\right) & -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) & -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) \\ -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) & \frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} + \frac{1}{\mathbf{m_l^*}}\right) & -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) \\ -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) & -\frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} - \frac{1}{\mathbf{m_l^*}}\right) & \frac{1}{3}\left(\frac{2}{\mathbf{m_t^*}} + \frac{1}{\mathbf{m_l^*}}\right) \end{pmatrix}$$

The remaining three ellipsoid conductivity tensors must now be calculated and summed together with this one to find the total conductivity tensor for the L valley. When performed, which is left as a problem exercise, the result is identical to the result for X valley semiconductors, demonstrating that the conductivity, and consequently mobility, in a cubic semiconductor is the same regardless of the direction of electrical force.

It should be noted that the result in the above example is not necessarily true for other semiconductor crystal systems and lattices. Non-cubic semiconductors, such as HgI_2 and PbI_2, can have quite different conductivities and charge carrier mobilities for different k-space directions.

Next the *density-of-states effective mass* is developed and should not be confused with the *conductivity effective mass*. Centering the indirect energy surface ellipsoids at zero, the relation between effective mass and energy is

$$E - E_C = \frac{\hbar^2}{2m_t^*}(k_1^2 + k_2^2) + \frac{\hbar^2}{2m_l^*}k_3^2. \tag{12.83}$$

where the subscripts 1, 2 and 3 can be interchanged for the x, y and z axes. Substitution of

$$a_1 = \left[\frac{2m_l^*}{\hbar^2}(E - E_C)\right]^{1/2} \qquad \text{and} \qquad a_2 = \left[\frac{2m_t^*}{\hbar^2}(E - E_C)\right]^{1/2}$$

into Eq. (12.83), where $2a_1$ is the length of the major ellipsoid axis and $2a_2$ is the length of the minor ellipsoid axis, and division by $(E - E_C)$ yields

$$1 = \frac{k_1^2 + k_2^2}{a_2} + \frac{k_3^2}{a_1}.$$

The "volume" of the ellipsoid in k-space is

$$V = \frac{4}{3}\pi a_1 a_2^2 \quad .$$

Define m_e^* as the *isotropic effective mass*, which is an average effective mass within all of k-space, along with a spherical constant energy surface bounded by k as shown in Fig. 12.37. The volume of this sphere is

$$V = \frac{4}{3}\pi k_{eff}^3,$$

where

$$k_{eff} = \left[\frac{2m_e^*(E - E_C)}{\hbar^2}\right]^{1/2}.$$

Equating the ellipsoid volumes in k-space to the isotropic effective mass volume yields

$$N_{BZ}\frac{4}{3}\pi a_1 a_2^2 = \frac{4}{3}\pi k_{eff}^3$$

$$N_{BZ}\frac{4}{3}\pi\left[\frac{2m_l^*}{\hbar^2}(E - E_C)\right]^{1/2}\left[\frac{2m_t^*}{\hbar^2}(E - E_C)\right] = \frac{4}{3}\pi\left[\frac{2m_e^*(E - E_C)}{\hbar^2}\right]^{3/2}$$

$$N_{BZ}(m_l^* m_t^{*2})^{1/2} = m_e^{*3/2} \quad ,$$

where N_{BZ} is the number of constant energy ellipsoid surfaces lying within the first Brillouin zone. As a result, the isotropic effective mass for a cubic semiconductor is

$$m_e^* = N_{BZ}^{2/3}(m_l^* m_t^{*2})^{1/3}. \tag{12.84}$$

For the case of Si, there are six ellipsoid surfaces within the first BZ with $N_{BZ} = 6$, whereas for Ge only half of each ellipsoid within the first BZ (see Fig. 12.38), resulting in $N_{BZ} = 4$.
Their effective masses can be described by,

$$m_e^* \text{ (Si)} = 6^{2/3}(m_l^* m_t^{*2})^{1/3} \qquad \text{and} \qquad m_e^* \text{ (Ge)} = 4^{2/3}(m_l^* m_t^{*2})^{1/3}.$$

For direct band-gap semiconductors there is only one spherical constant energy surface, and $m_t^* = m_l^*$, hence,

$$m_e^* \text{ (GaAs)} = (m_l^* m_t^{*2})^{1/3} = m_e^*,$$

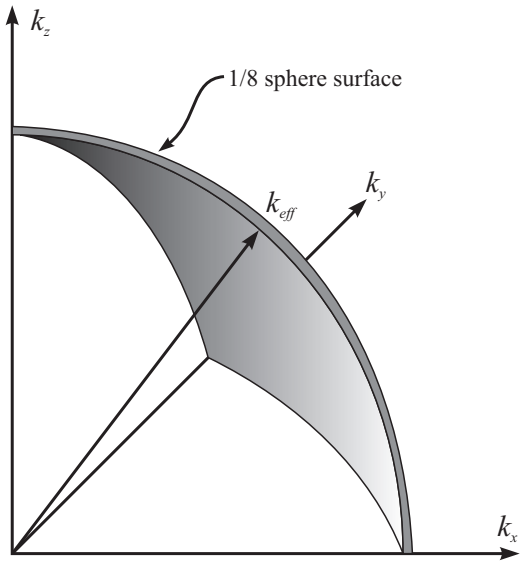

Figure 12.37. A sphere of constant energy in k-space with radius of k_{eff} is used to define m_e^*.

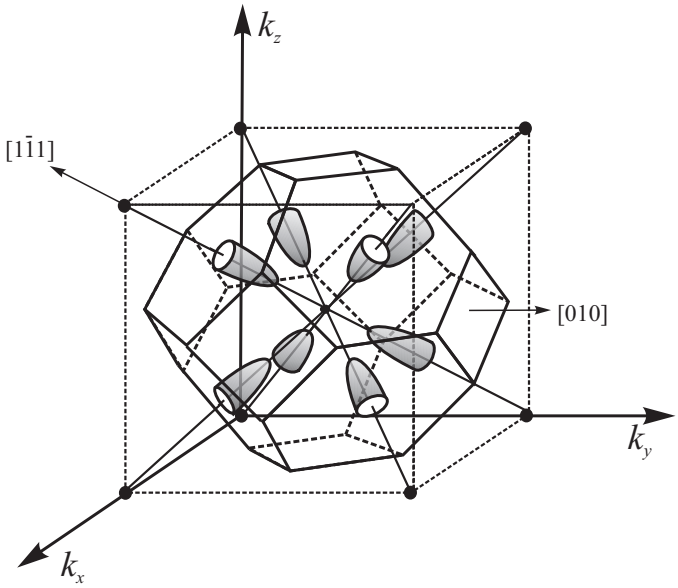

Figure 12.38. Constant energy ellipsoids for the L valley, depicting that only half of each ellipsoid lies within the first Brillouin zone.

where m_e^* is the radial effective mass in all directions, because m_l^* and m_t^* are essentially the same. Overall, a method of defining an isotropic effective mass is developed, which is commonly referred to as the *density-of-states* effective mass.

Next, the effective mass for the holes is addressed. Notice again in Fig. 12.28 that there are three valence band maxima, of which only two are considered to play an important part in hole conduction. Assuming that the upper portion of the heavy hole and light hole bands are parabolic and have spherical energy surfaces, it is usual to write an equivalent effective mass as

$$m_h^{*\,3/2} = m_{lh}^{*\,3/2} + m_{hh}^{*\,3/2} \tag{12.85}$$

or

$$m_h^* = (m_{lh}^{*\,3/2} + m_{hh}^{*\,3/2})^{2/3}. \tag{12.86}$$

Equation (12.86) is only an approximation, because (1) the bands are not actually parabolic at zone center, nor are the energy surfaces perfectly spherical, and (2) the split-off band may in fact contribute holes to the conduction process.

12.5.1 Charge Carrier Mobility

The motion of a charge carrier can be influenced by diffusion, scattering, trapping, magnetic fields and electric fields. The strength of this influence is characterized by the carrier mobility, described as [Sze 1981]

$$\mu_i = \frac{q\,\tau_{ci}}{m_i^*}, \qquad i = n \text{ or } p, \tag{12.87}$$

where τ_c is the average time between scattering collisions and m^* is the effective mass of the hole or electron.[5] Note that mobility increases with decreasing effective mass. The valence and conduction bands have different periodic potentials, and for this reason electron mobility in the conduction band is different than hole mobility in the valence band. Electron mobility is denoted μ_e and hole mobility is denoted μ_h.

The speed of a charge carrier can be approximated with

$$v_i = \mu_i \mathcal{E}, \tag{12.88}$$

where $\mathcal{E}$ is the electric field magnitude. Equation (12.88) is a good approximation provided that the electric field is below the *saturation* field strength (typically below about 2×10^3 V cm^{-1}). Above the saturation field the charge carrier velocities begin to asymptotically approach a limiting or saturation speed. Carrier velocities for indirect band-gap semiconductors are often described by the empirical formula [Sze 1981],

$$v \simeq v_s \left[1 + \left(\frac{\mathcal{E}_o}{\mathcal{E}}\right)^{\gamma}\right]^{-1/\gamma}, \tag{12.89}$$

where v_s is the saturation speed and E_o is an experimentally determined constant. Although Eq. (12.89) may be useful for some semiconductors, such as Si and Ge, it is altogether incorrect for semiconductors such as GaAs and InP in which more than one band gap may play an important function in the free carrier population. What is important to understand is that speeds for electrons and holes saturate, usually somewhere between 6×10^6 cm s^{-1} and 2×10^7 cm s^{-1}, depending on the type of semiconductor and dopant concentration. Consequently, the usefulness of Eq. (12.88) is limited.

12.5.2 Material Resistivity and Capacity

The ability of a semiconductor to conduct electrons is referred to as the material resistivity, with units of ohm centimeter. The resistivity of a semiconductor is

$$\rho = \frac{1}{q(\mu_e n + \mu_h p)}, \tag{12.90}$$

where q is the unit electronic charge, n and p and the free electron and hole densities, respectively, and μ_e and μ_h are the electron and hole mobilities, respectively. If $n \gg p$, then Eq. (12.90) reduces to

$$\rho \simeq \frac{1}{q\mu_e n}, \tag{12.91}$$

and if $p \gg n$, then Eq. (12.90) reduces to

$$\rho \simeq \frac{1}{q\mu_h p}. \tag{12.92}$$

The resistance of a right parallelepiped block of the semiconductor is

$$R = \rho \frac{d}{A}, \tag{12.93}$$

where d is the detector width or length, and A is the contact area. The parallel plate capacitance for a bar of semiconductor is found by

$$C = \frac{\epsilon_o \kappa A}{d}, \tag{12.94}$$

[5] Often in the literature the subscripts n and p, used to indicate *negative* and *positive* charge carriers, are replaced by e and h to refer, equivalently, to *electrons* and *holes*.

where ϵ_o is the permittivity of free space and κ is the semiconductor dielectric constant. The RC time constant of the material, commonly referred to as the *dielectric relaxation time*, is

$$RC = \frac{\rho d}{A}\frac{\epsilon_o \kappa A}{d} = \rho \epsilon_o \kappa. \tag{12.95}$$

This is the time needed by a semiconductor to return to electrical neutrality after injection or extraction of charge carriers.

12.5.3 Intrinsic Semiconductors

Semiconductors that are mostly void of impurities and defects that can alter the electrical characteristics of the pure material are referred to as *intrinsic semiconductors*. The term does not necessarily mean a perfect semiconductor, because materials are intrinsic if the *intrinsic properties* dominate over *extrinsic properties*. The conductivity in an intrinsic semiconductor is dominated by free charge carriers excited directly across the band gap rather than carriers excited from energy sites appearing in the band gap from crystal defects. Because the electrons excited into the conduction band come from the valence band, there must be an equal density of empty states in the valence band. To determine the conductivity of the semiconductor, the density of filled states in the conduction band and the density of empty states in the valence band must be determined.

Density of Energy States

To determine the density of energy states, revisit the problem of an electron trapped in a potential well, discussed in Section 12.3.4, but now with a slight change. The electron is now trapped in a *three*-dimensional potential box. The potential box is bounded in the x, y, and z directions by dimensions a, b and c. The three-dimensional Schrödinger wave equation that describes the possible states of the particle is [Nussbaum 1962],

$$-\frac{\hbar^2}{2m_e}\nabla^2\psi(x,y,z) + U(x,y,z)\psi(x,y,z) = E\psi(x,y,z), \tag{12.96}$$

with $0 < x < a$, $0 < y < b$, and $0 < z < c$.

The particle is trapped within the box, from which infinite energy is required to escape, i.e., the particle has zero potential energy so that $U(x,y,z) = 0$ within the box. With this simplification, Eq. (12.96) can be rewritten as

$$\nabla^2\psi(x,y,z) + k^2\psi(x,y,z) = 0, \tag{12.97}$$

where

$$k = \sqrt{\frac{2m_e E}{\hbar^2}} \qquad \text{and} \qquad E = \sqrt{\frac{\hbar^2 k^2}{2m_e}}. \tag{12.98}$$

To solve Eq. (12.97) employ the method of separation of variables, in which the three-dimensional wave function is expressed as

$$\psi(x,y,z) = X(x)Y(y)Z(z). \tag{12.99}$$

Substitute for ψ in Eq. (12.97) and divide by XYZ to obtain

$$\frac{1}{X(x)}\frac{d^2X(x)}{dx^2} + \frac{1}{Y(y)}\frac{d^2Y(y)}{dy^2} + \frac{1}{Z(z)}\frac{d^2Z(z)}{dz^2} + k^2 = 0. \tag{12.100}$$

For Eq. (12.100) to be valid for a point (x,y,z) in the box, each of the first three terms must equal a constant, i.e.,

$$\frac{1}{X(x)}\frac{d^2X(x)}{dx^2} = -k_x^2, \quad 0 < x < a, \tag{12.101}$$

$$\frac{1}{Y(y)}\frac{d^2Y(y)}{dy^2} = -k_y^2, \quad 0 < y < b, \tag{12.102}$$

$$\frac{1}{Z(z)}\frac{d^2Z(z)}{dz^2} = -k_z^2, \quad 0 < z < c, \tag{12.103}$$

in which

$$k^2 = k_x^2 + k_y^2 + k_z^2. \tag{12.104}$$

The solution of Eq. (12.101), Eq. (12.102), and Eq. (12.103) is subject to the boundary conditions that $X(x)$, $Y(y)$, and $Z(z)$ must vanish on the surfaces of the potential box. For example, because $X(0) = X(a) = 0$ the only solutions of Eq. (12.101) are $X(x) = A\sin(k_x x)$, where $k_x = n_x\pi/a$, $n_x = \pm1, \pm2 \pm 3, \ldots$. Similar results are obtained for $Y(y)$ and $Z(z)$. In this manner, the solution of Eq. (12.97) is

$$\psi(x, y, z) = A\sin(k_x x)\sin(k_y y)\sin(k_z z) \tag{12.105}$$

with

$$k_x = \frac{n_x\pi}{a}, \qquad k_y = \frac{n_y\pi}{b}, \quad \text{and} \quad k_z = \frac{n_z\pi}{c}. \tag{12.106}$$

where n_x, n_y, and n_z are integers $\pm1, \pm2, \pm3, \ldots$.

From this solution one can calculate the number of allowed electronic states, per unit volume defined by the dimensions a, b and c. Recall in reciprocal lattice space, the reciprocal-space unit-cell volume is defined by

$$\text{cell volume} = \left(\frac{\pi}{a}\right)\left(\frac{\pi}{b}\right)\left(\frac{\pi}{c}\right) = \frac{\pi^3}{abc} \tag{12.107}$$

and represents one state or solution. Hence, the number of solutions per reciprocal space volume is

$$\frac{\text{no. of solutions}}{\text{unit cell volume}} = \frac{1 \text{ state}}{\pi^3/abc} = \frac{abc}{\pi^3}. \tag{12.108}$$

Note that the number of solutions per reciprocal space volume does not equal the number of allowed states. From Eq. (12.98) and Eq. (12.101) the energy of an allowed state depends on (n_x^2, n_y^2, n_z^2) so the 8 possible solutions $\psi_{\pm n_x, \pm n_y, \pm n_z}(x, y, z)$ all have the same energy level. Hence, for each unit volume of reciprocal space, the number of solutions must be divided by the 8 possible combinations of $(\pm n_x, \pm n_y, \pm n_z)$ to get the density of allowed states. However, because the particles can have 2 values of spin, the allowed states must then be multiplied by 2. As a result, the density of allowed states within a reciprocal space unit volume becomes

$$\frac{\text{no. of allowed states}}{\text{unit cell volume}} = \frac{abc}{4\pi^3}. \tag{12.109}$$

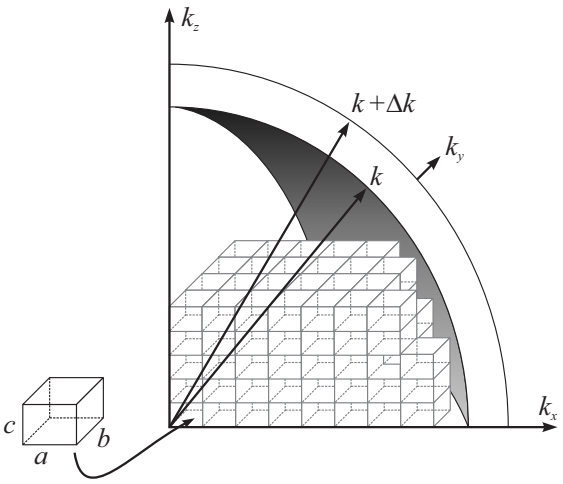

Figure 12.39. The number of allowed states can be modeled as quantum well boxes inside a spherical shell in k-space.

To determine the density of allowed states per unit volume in real space, consider a spherical shell in reciprocal space, as shown in Fig. 12.39, in which the axes are defined by k_x, k_y and k_z. For any particular value of $k = (k_x^2 + k_y^2 + k_z^2)^{1/2}$, the volume in dk about k is

$$\text{volume} = 4\pi k^2 dk. \tag{12.110}$$

Thus, the number of allowed states within this volume can be estimated as

$$\text{no. of allowed states} = \left(4\pi k^2 dk\right)\left(\frac{abc}{4\pi^3}\right) = \frac{(abc)k^2 dk}{\pi^2}. \tag{12.111}$$

From Eqs. (12.98),

$$dk = \frac{1}{\hbar}\sqrt{\frac{m_e}{2}}\frac{dE}{\sqrt{E}}, \qquad \text{where} \qquad dE = \frac{\hbar^2 k dk}{m_e}. \tag{12.112}$$

Substitution of these results into Eq. (12.111) gives the density of allowed states $N(E)dE$ with energies between E and $E + dE$, namely

$$N(E)dE = \frac{abc}{\pi^2}\frac{\sqrt{2}m_e^{3/2}}{\hbar^3}\sqrt{E}dE. \tag{12.113}$$

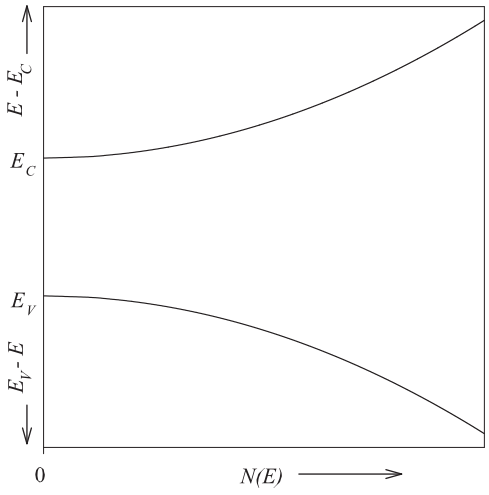

Figure 12.40. The density of states for the conduction and valence bands. In the band gap, there are no states, hence $N_C(E) = N_V(E) = 0$.

The density of states $N(E)$, per unit volume and per unit energy about E, is then obtained by dividing the number of states $N(E)dE$ by the unit volume per state in dE about E, i.e.,

$$N(E) = \frac{abc}{\pi^2}\frac{\sqrt{2}m_e^{3/2}}{\hbar^3}\sqrt{E}dE\left[\frac{1}{V dE}\right] = \frac{\sqrt{2E}m_e^{3/2}}{\pi^2\hbar^3}, \tag{12.114}$$

where $V = abc$.

Finally, because there are no allowed states permitted in the band gap, substitution of the effective masses for electrons and holes in Eq. (12.114), yields densities of allowed states for the conduction and valence bands, namely

$$N_C(E) = \frac{\sqrt{2(E - E_C)}m_e^{*3/2}}{\pi^2\hbar^3}, \quad E \geq E_C, \tag{12.115}$$

and

$$N_V(E) = \frac{\sqrt{2(E_V - E)}m_h^{*3/2}}{\pi^2\hbar^3}, \quad E \leq E_V, \tag{12.116}$$

where $N_C(E)$ is the density of states in the conduction band and $N_V(E)$ is the density of states in the valence band. Here m_e^* and m_h^* are the effective mass of an electron or hole, respectively. The variation of these densities with $E - E_C$ and $E_V - E$ is shown in Fig. 12.40.

Charge Carrier Concentration

Because electrons are fermions, they must obey the Pauli exclusion principle so each state at energy E can contain at most 1 electron with a given spin. Further, the probability an electron has energy E is governed by Fermi-Dirac statistics and states that the number $n(E)$ of electrons in quantum states in unit energy about E per unit volume is given by

$$n(E) = g(E)f_{\mathcal{FD}}(E), \tag{12.117}$$

where the degeneracy parameter $g(E)$ is the number of states in unit energy about E per unit volume available to an assembly of electrons and $f_{\mathcal{FD}}(E)$ is the Fermi function, named after its discoverer,

$$f_{\mathcal{FD}}(E) = \frac{1}{1 + \exp\left[\dfrac{E - E_F}{kT}\right]}. \tag{12.118}$$

Here k is Boltzmann's constant, T is the absolute temperature, and E_F is the Fermi energy. The Fermi energy is defined as the energy level, at 0 K temperature, for which all states below it are filled and all above it are empty. Equation (12.118) can be used to determine the density of electrons in the conduction band, i.e., for $E \geq E_C$. From Eq. (12.118), it is seen that the probability an electron crosses the band gap to the conduction band increases with increasing temperature. The Fermi-Dirac distribution is shown in Fig. 12.41.

The free electron density n in the conduction band is that of the *negatively* charged carriers, and the free hole density p in the valence band is that of the *positively* charged carriers. The empty states in the valence band are treated as positive charge carriers called "holes", a concept which greatly simplifies calculations. For a pure material, the density of electrons in the conduction band must equal the density of holes in the valence band, i.e., $n = p$. Such a situation is referred to as the *intrinsic* case.

The free electron density can be found by integrating the product of the conduction band density of states function and the Fermi-Dirac distribution function, namely

$$n = \int_{E_C}^{E_{top}} N_C(E) f_{\mathcal{FD}}(E) dE, \tag{12.119}$$

where E_{top} is the top of the first conduction band. Almost all charge carriers in the conduction band are located near the bottom of the band with none of the states at the top filled; hence integration from E_C to E_{top} is equivalent to integration from E_C to ∞.

Substitution of Eq. (12.115) and Eq. (12.118) into Eq. (12.119), with the upper integration limit replaced by ∞, gives

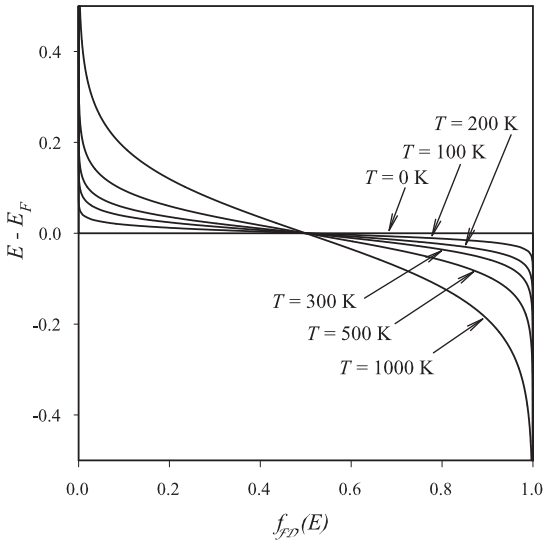

Figure 12.41. The Fermi-Dirac probability distribution function. At 0 K, the distribution indicates that all energy states above the Fermi energy are empty and all states below the Fermi energy level are filled. As the temperature is increased, the probability of states being filled above the Fermi energy increases.

$$n = \frac{\sqrt{2} m_e^{*3/2}}{\pi^2 \hbar^2} \int_{E_C}^{\infty} \frac{\sqrt{E - E_C}}{1 + \exp[(E - E_F)/(kT)]} \, dE. \tag{12.120}$$

To evaluate this integral, let $\xi = (E - E_C)/(kT)$, define $\eta_c \equiv (E_F - E_C)/(kT)$, recall that $\hbar = h/(2\pi)$, and recall $\Gamma(1 + \frac{1}{2}) = \sqrt{\pi}/2$ [Pierret 1989]. Eq. (12.120) then reduces to

$$n = 2 \left[\frac{2\pi m_e^* kT}{h^2} \right]^{3/2} \frac{1}{\Gamma(1 + 1/2)} \int_0^{\infty} \frac{\xi^{1/2}}{1 + \exp[\xi - \eta_c]} \, d\xi,$$

$$= N_C \frac{2}{\sqrt{\pi}} F_{1/2}(\eta_c) = N_C \mathcal{F}_{1/2}(\eta_c). \tag{12.121}$$

Here $N_C \equiv 2[2\pi m_e^* kT]/h^2]^{3/2}$ is energy-independent and referred to as the *effective* density of states in the conduction band. The quantity $F_{1/2}$ is the Fermi-Dirac integral of 1/2 order, while $\mathcal{F}_{1/2}$ is the Fermi-Dirac integral function of order 1/2.[6]

[6] This particular integral is one of the more important integrals encountered in semiconductor physics and belongs to a general set of Fermi-Dirac integral functions defined by [Blakemore 1985]

$$\mathcal{F}_j(t) = \frac{1}{\Gamma(1 + j)} \int_0^{\infty} \frac{\xi^j}{1 + \exp[\xi - t]} \, d\xi.$$

The density of empty states in the valence band must equal the density of filled states in the conduction band. Because $f_{\mathcal{FD}}(E)dE$ is proportional to the probability of filled states with energy in dE about E in the conduction band, then the probability of empty states in dE about E in the valence band must be proportional to $[1 - f_{\mathcal{FD}}(E)]dE$. Because the empty states are near the top of the valence band, the density p of empty states (or holes) in the valence band is

$$p = \int_{E_{bot}}^{E_V} N_V(E)[1 - f_{\mathcal{FD}}(E)]\, dE, \tag{12.122}$$

in which the integral is taken from the bottom of the valence band E_{bot} to the valence band edge at E_V. Because the empty states are near the top of the valence band with no unfilled states at the band bottom, the lower limit of integration may be replaced by $-\infty$. Substitution of Eq. (12.116) and Eq. (12.118) into Eq. (12.122), with the lower integration limit replaced by $-\infty$, gives

$$\begin{aligned} p &= \frac{m_p^{*3/2}\sqrt{2}}{\pi^2\hbar^3} \int_{-\infty}^{E_V} \frac{\sqrt{E_V - E}}{1 + \exp[(E - E_F)/(kT)]}\, dE \\ &= 2\left[\frac{2\pi m_h^* kT}{h^2}\right]^{3/2} \frac{2}{\sqrt{\pi}} F_{1/2}(\eta_v) = N_V \mathcal{F}_{1/2}(\eta_v), \end{aligned} \tag{12.123}$$

where $\eta_v = (E_V - E_F)(kT)$. The energy independent term N_V is the *effective* density of states in the valence band. It is important to note that the use of the Fermi-Dirac distribution function and the results of Eq. (12.121) and Eq. (12.123) are valid for all positions of the Fermi energy level, E_F.

Unfortunately, there are no closed-form analytical expressions for any Fermi function of positive order. Hence, closed form expressions for Eq. (12.121) and Eq. (12.123) are not available. Numerical integration may be used to evaluate $\mathcal{F}_{1/2}(\eta)$ or some approximate expression is used. There are several approximations for the Fermi-Dirac integral, some far more complex than others. One relatively simple approximation for the Fermi-Dirac integral of order $j = 1/2$ is [Pierret 1989]

$$\mathcal{F}_{1/2}(\eta) \simeq \exp(\eta) - 0.3\exp(2\eta) + 0.06\exp(3\eta) \tag{12.124}$$

with less than $\pm 0.75\%$ error for negative values of η and less than $\pm 1.5\%$ error for positive values of η no greater than 0.5.

The results of Eqs. (12.121) and (12.123) are quite general and apply to any semiconductor, doped or undoped, under the restriction that any added dopants or impurities do not appreciably change the band structure of the original semiconductor, i.e., the density of states functions of Eqs.(12.115) and (12.116) are not changed.

Approximations for the Charge Carrier Concentrations

A useful approximation for the non-degenerate case, in which the Fermi energy level is within the band gap and at least $3kT$ away from either the conduction or valence band edges, is to approximate the Fermi-Dirac distribution function $f_{\mathcal{FD}}(E)$ by the Boltzmann distribution $f_{\mathcal{B}}(E)$, i.e., if $E \geq E_C$ and $E_C - E_F \geq 3kT$

$$f_{\mathcal{FD}}(E) \equiv \frac{1}{1 + \exp\left[\dfrac{E - E_F}{kT}\right]} \simeq \exp\left[\frac{E_F - E}{kT}\right] \equiv f_{\mathcal{B}}(E). \tag{12.125}$$

With this approximation and Eq. (12.115), the concentration of free charge carriers (electrons) in the conduction band is found to be

$$n = \int_{E_C}^{\infty} N_C(E) f_{\mathcal{B}}(E)\, dE = \int_{E_C}^{\infty} \frac{m_e^{*3/2}\sqrt{2}}{\pi^2\hbar^3} \sqrt{E - E_C}\exp\left[\frac{E_F - E}{kT}\right] dE$$

$$= 2\left(\frac{2\pi m_e^* kT}{h^2}\right)^{3/2} \exp\left[\frac{E_F - E_C}{kT}\right],$$

which yields the following useful relation

$$\boxed{n = N_C \exp\left[\frac{E_F - E_C}{kT}\right].} \tag{12.126}$$

In a similar manner the concentration of free charge carriers (holes) in the valence band can be found approximately with Boltzmann's approximation. Here an approximation is needed for $1 - f_{\mathcal{FD}}(E)$ when $E \leq E_V$ and $E_F - E_V > 3kT$. In this case

$$1 - f_{\mathcal{FD}}(E) = \frac{1}{1 + \exp\left[\dfrac{E_F - E}{kT}\right]} \simeq \exp\left[\frac{E - E_F}{kT}\right]. \tag{12.127}$$

With this approximation and Eq. (12.116) the concentration p of holes in the valence band is

$$p = \int_{-\infty}^{E_V} N_V(E)[1 - f_{\mathcal{FD}}(E)]\, dE \simeq \int_{-\infty}^{E_V} \frac{m_h^{*\,3/2}\sqrt{2}}{\pi^2\hbar^3}\sqrt{E_V - E}\exp\left[\frac{E - E_F}{kT}\right] dE$$

$$= 2\left(\frac{2\pi m_h^* kT}{h^2}\right)^{3/2} \exp\left[\frac{E_V - E_F}{kT}\right],$$

from which the following useful relation is obtained

$$\boxed{p = N_V \exp\left[\frac{E_V - E_F}{kT}\right].} \tag{12.128}$$

Comparison of Eq. (12.126) to Eq. (12.121) and Eq. (12.128) to Eq. (12.123), shows that

$$\mathcal{F}_{1/2}(\eta) \simeq e^{\eta} \tag{12.129}$$

provided $E_C - E_F \geq 3kT$ (or $\eta_c \leq -3$) and $E_F - E_V \geq 3kT$ (or $\eta_v \leq 3$).

WARNING: Eq. (12.126) and Eq. (12.128) are only approximations and should not be used for degenerate semiconductors![7] If the material is intrinsic, i.e., the background impurities have negligible effect upon the semiconductor properties, then the following must be true for the free carrier concentrations,

$$n_i = n = p = N_C \exp\left[\frac{E_i - E_C}{kT}\right] = N_V \exp\left[\frac{E_V - E_i}{kT}\right], \tag{12.130}$$

[7] A degenerate semiconductor is a heavily doped semiconductor whose Fermi level may no longer be in the energy band gap.

where n_i is the *intrinsic* free carrier concentration and E_i is the *intrinsic* Fermi energy level.[8] From this result it is apparent that

$$\boxed{np = n_i^2.} \tag{12.131}$$

Equation (12.131) is the so-called *mass-action* law, and, because it was derived with the Boltzmann approximation, it is only valid for non-degenerate semiconductors. Equation (12.131) can be used to derive the intrinsic free carrier concentration of a semiconductor,

$$n_i^2 = np = N_C \exp\left[\frac{E_F - E_C}{kT}\right] N_V \exp\left[\frac{E_V - E_F}{kT}\right]$$

$$= N_C N_V \exp\left[\frac{E_V - E_C}{kT}\right] = N_C N_V \exp\left[\frac{-E_g}{kT}\right].$$

where E_g is the band-gap energy. Thus the intrinsic carrier concentration is

$$\boxed{n_i = \sqrt{N_C N_V} \exp\left[\frac{-E_g}{2kT}\right].} \tag{12.132}$$

Notice that the free charge carrier concentration increases exponentially with absolute temperature. Notice also that the band gap of a semiconductor largely affects the free carrier concentration, in which large band-gap materials has higher electrical resistivity than small band-gap materials, a property that is important for semiconductor radiation detectors.

In Fig. 12.42 the Fermi-Dirac function is shown along with the density of states functions, $N_C(E)$ and $N_V(E)$, and the distribution of charge carriers in the conduction and valence bands. Notice in Fig. 12.42(a), that the Fermi-Dirac distribution is symmetric about the Fermi energy level, i.e., there are just as many filled states above E_F as there are empty states below E_F. Notice also that the density of states function increases with $\sqrt{E}$ from the band edges, as required by Eqs. (12.115) and (12.116), and that there are no states in the band gap. As a result, the product, $f_{\mathcal{FD}}(E)N_C(E)$, or $[1 - f_{\mathcal{FD}}(E)]N_V(E)$ is zero in the band gap. Further, as $N_C(E)$ or $N_V(E)$ increases with E, the probability of a state being filled decreases with increasing E. Hence, the product $f_{\mathcal{FD}}(E)N_C(E)$ is non-linear, as is the distribution of free charge carriers in the conduction band and the valence band, as shown in Fig. 12.42(c).

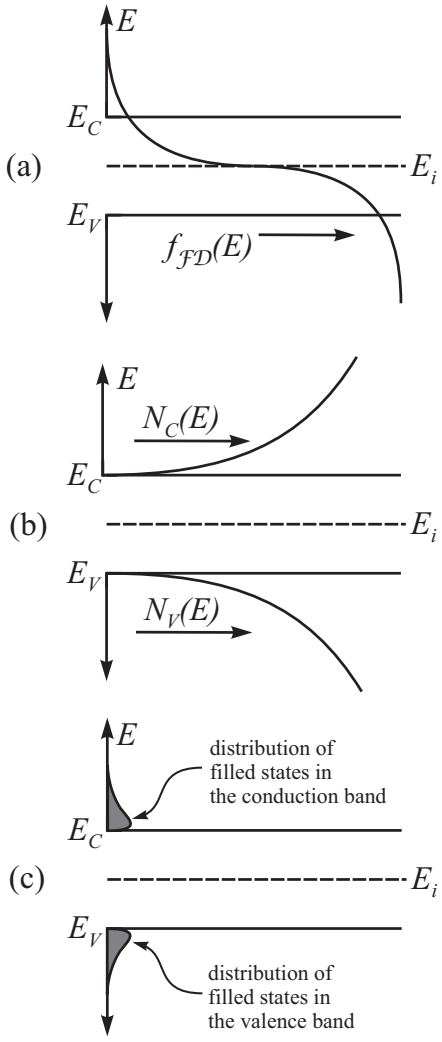

Figure 12.42. Shown are (a) the Fermi-Dirac function for an intrinsic semiconductor, (b) the density of states functions, and (c) the distribution of free charge carriers, electrons and holes, in the conduction and valence bands, respectively.

The total number of free carriers excited from the valence band to the conduction band per unit time in a semiconductor crystal depends upon the band gap energy, temperature, and the actual volume of the crystal.

[8] The intrinsic Fermi level E_i is a constant for a given semiconductor and equals the actual Fermi level E_F if impurities are negligible. However, as impurities or dopants are added the Fermi level changes although the intrinsic Fermi level remains constant.

Hence, one can quickly surmise that, given a limit on allowable leakage current, wide band-gap materials have lower leakage currents from thermal generation of charge carriers than narrow band-gap materials. Further, under ideal conditions, wide band-gap materials can be fashioned into larger devices than narrow band-gap materials, and they can still exhibit low leakage currents. Lastly, for narrow band-gap materials, the operating temperature of the material can be reduced so as to lower the leakage current, as is usually done with Ge and large Si devices.

12.5.4 Impurities and Extrinsic Semiconductors

One of the more useful properties of semiconductors is that their electrical conductivities can be altered with the simple addition of various impurities. Depending on the valence of the impurity atoms and the host semiconductor, the electrical conductivity can be dominated by hole motion or electron motion. Further, with proper concentrations, impurities can be added to an unintentionally contaminated (doped) semiconductor to make it behave much like an intrinsic semiconductor.

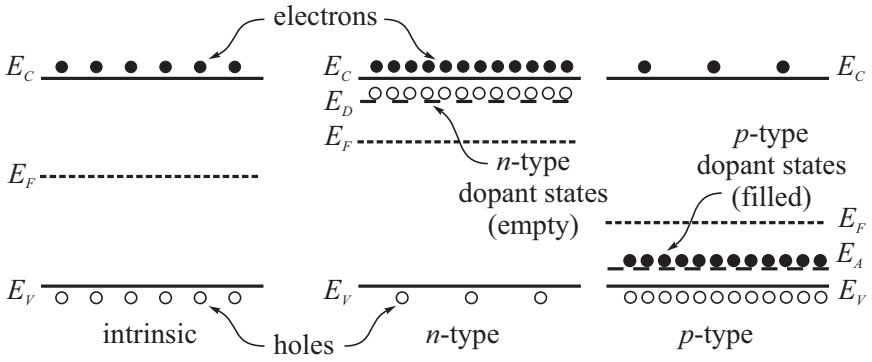

Figure 12.43. The simplified energy band structures for intrinsic, n-type, and p-type materials. The electron and hole carrier concentrations are equal for the intrinsic case. Materials doped n-type have an excess of electrons in the conduction band, and materials doped p-type have an excess of holes in the valence band.

Dopant Impurities

Dopant impurities are often added to a semiconductor to control its electrical properties. Dopants that add excess electrons to the chemical binding are called *donors*, because they need only a slight amount of thermal energy to transfer these excess electrons into the conduction band. Dopants that lack an electron to complete the valence bonding are called *acceptors*, because they need only a slight amount of energy to accept electrons from the valence band into their unfilled states. The simplified energy band structures for intrinsic, n-type, and p-type materials are depicted in Fig. 12.43. The concentration of donor atoms is denoted by N_D with energy level E_D, and the concentration of acceptor atoms is denoted by N_A with energy level E_A. If donors are added to the semiconductor, then the concentration of holes is reduced. The opposite occurs if acceptors are added to the semiconductor. Because dopants are generally used in such a small concentration that the energy band structure is unaffected, the general relationship between the free electron concentration and the free hole concentration is given by Eq. (12.131).

Background

In the preparation and the growing of crystals, there are many ways contaminant atoms can enter the crystal even after rigorous purification processes. Typically, a variety of processes are used to remove contaminants from the starting crystal material. These include vapor distillation, zone melting, and zone refinement. All

of these methods depend upon an ability to diffuse impurity ions from one region of the starting material to another. Often the segregation coefficients of impurities is not conducive to such processes and the impurities are, therefore, hard to remove. Ge and Si can be purified to levels below one ppb with zone refinement and float zone refinement. However, inadequate handling techniques can reintroduce impurities from chemicals used for growth preparations, crucibles and ampoules used during the growth process, heating coils and liners in the growth furnaces, as well as human introduced impurities such as Na and K. These undesirable impurities are commonly referred to as *background impurities*.

Although the presence of impurities generally affects the electronic performance of a semiconductor material, the effect can vary widely. For instance, some impurities may introduce scattering centers that can affect the free carrier mobility, but may not be electrically active, i.e., they do not introduce free charge carriers to the conduction or valence bands. For example, boron impurities in GaAs, in high concentrations, can affect the mobility of the charge carriers, but they are electrically inactive. As a result, pyrolitic BN is often used as the crucible for GaAs bulk crystal growth. By contrast carbon, sources of which are present in practically all steps of the GaAs materials preparation and crystal growth, is an electrically active shallow acceptor and behaves as a p-type dopant. Hence, carbon affects mobility and electrical conductivity.

If the background impurities, primarily those that are electrically active, can be kept to levels below the intrinsic free carrier concentration of the semiconductor of interest, then the material still behaves intrinsically. However, extrinsic behavior is observed for impurity concentrations approaching or exceeding the intrinsic concentration. Often impurities of opposite electrical behavior are purposely added during the crystal growth process to counteract the effect of background impurities, a process referred to as *compensation*. Dopants may also be added during post-growth processes, such as implantation and diffusion, so as to intentionally *dope* a semiconductor to behave as n-type or p-type. Under such processes, select regions of a semiconductor sample may be doped n-type while other regions of the same sample are doped p-type. Selective doping allows for the formation of rectifying and ohmic junctions.

Extrinsic semiconductors are those materials whose electrical properties are dominated by impurity atoms and intrinsic defects. Typically, there is a temperature range in which extrinsic semiconductors demonstrate such behavior, beyond which the thermal excitation of charge carriers directly from the valence band causes the material to behave intrinsically. At the top of Fig. 12.44 are depictions of the free carrier concentrations for intrinsic material (n_i), lightly doped material (n or p), and highly doped material (n^+ or p^+). At low temperatures, the shallow donor and acceptor sites are not fully ionized, a region referred to as the *freeze-out* region.

As shown in the bottom of Fig. 12.44, as the temperature is increased, more of the impurities become ionized, until they are all ionized. In the extrinsic region, few electrons are excited from the valence band to the conduction band, hence the extrinsic carrier concentration from impurities far exceeds the free carrier concentration excited from the valence band. At this point the material behaves *extrinsically*, i.e., the conductivity remains largely unchanged and is dominated by the concentration of impurities present in the semiconductor. An important aspect to impurity doping is that it allows the device designer to control the semiconductor electrical conductivity over a wide temperature range, something that cannot be done with intrinsic materials in which the free carrier concentration changes exponentially with temperature.

As the temperature is increased further, thermal generation increases the density of free carriers excited from the valence band to the conduction band until they surpass the free carrier density excited from impurity sites, and the material behaves *intrinsically*. The temperature at which the crossover from extrinsic to intrinsic behavior is located increases as the impurity concentration increases. Hence, highly doped materials retain extrinsic behavior at higher temperatures than do lightly doped materials.

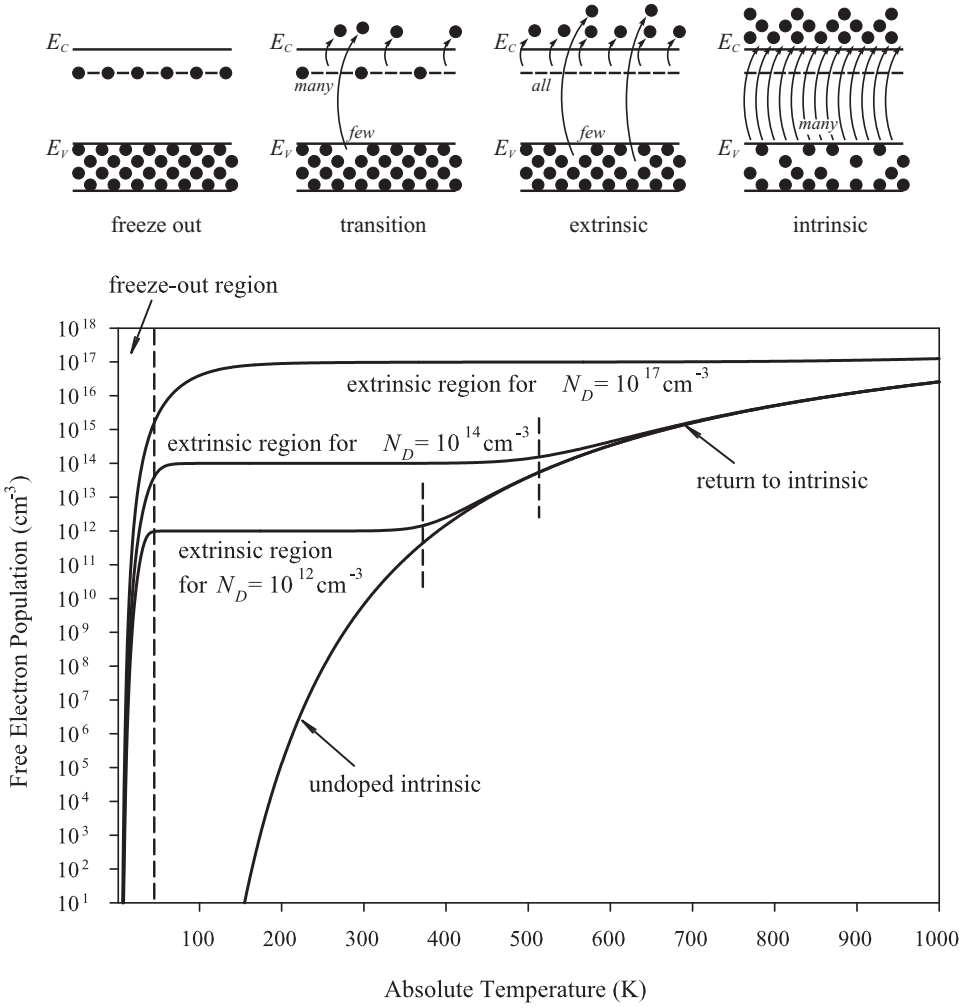

Figure 12.44. At low temperature, the impurities do not have enough thermal energy to become fully ionized, a temperature region known as *freeze-out*. As the temperature is increased, there is a transition in which the shallow impurities become ionized. At a high enough temperature, the thermal energy fully ionizes the shallow impurities, although the thermal energy is not enough to promote significant electron excitation from the valence to conduction bands. As a result, in the extrinsic region, the conductivity of the semiconductor is controlled, and limited, by the impurity concentration. At higher temperatures, the concentration of electrons excited from the valence band exceeds the impurity concentration, and the conductivity is controlled by the intrinsic free carrier concentration.

Degeneracy Factors

In the earlier use of the Fermi-Dirac distribution it was assumed that each available state could be occupied by only one electron. However, an electron occupying states in the band gap, whether donor or acceptor sites, can have either spin-up or spin-down, so that there are two different methods by which the state might be filled. As a result, the donor state is said to have a *degeneracy* g_D of 2. Typically, only one conduction band plays a dominant role in charge conduction, hence the Fermi-Dirac function is corrected for degeneracy,

and the ionized donor concentration is

$$N_D^+ = N_D[1 - f_{\mathcal{FD}}(E_D)] = N_D - \frac{N_D}{1 + \frac{1}{g_D}\exp\left[\frac{E_D - E_F}{kT}\right]} = \frac{N_D}{1 + 2\exp\left[\frac{E_F - E_D}{kT}\right]}. \tag{12.133}$$

Recall that there are two active valence bands in cubic semiconductors; hence, there is a degeneracy of 2 for the spin states multiplied by a degeneracy of 2 for the overlapping heavy hole and light hole bands from which the electrons can fill the acceptor states. Typically, the hole degeneracy of a band-gap state, g_A, is assumed to be 4, thereby yielding

$$N_A^- = N_A f_{\mathcal{FD}}(E) = \frac{N_A}{1 + g_A\exp\left[\frac{E_A - E_F}{kT}\right]} = \frac{N_A}{1 + 4\exp\left[\frac{E_A - E_F}{kT}\right]}. \tag{12.134}$$

With these results one can now determine free carrier concentrations and conductivities for shallow dopant impurities.

Degeneracy values for deep levels in a band gap are far more difficult to determine, because impurity atoms can give rise to numerous energy states in a band gap. Typically, for deep donors, deep acceptors and traps, the ionized concentrations are written as

$$N_{DD}^+ = \frac{N_{DD}}{1 + g_{DD}\exp\left[\frac{E_F - E_{DD}}{kT}\right]}, \quad N_{AA}^- = \frac{N_{AA}}{1 + g_{AA}\exp\left[\frac{E_{AA} - E_F}{kT}\right]} \quad \text{and} \quad N_T^* = \frac{N_T}{1 + g_T\exp\left[\frac{E_F - E_T}{kT}\right]}.$$

where the subscripts DD and AA are used for deep donors and deep acceptors, respectively, and the subscript T is used for charge carrier traps. Depending on the lattice site into which an impurity atom falls, the impurity may act as a donor or an acceptor, complicating matters more. It is usual for a degeneracy of 1 to be assigned to deep donors, deep acceptors and traps; however, one should be aware that such an assumption could be seriously incorrect.

Shallow Dopant and Shallow Impurity Energy Levels

Atoms in a semiconductor crystal that are purposely introduced are commonly referred to as *dopant atoms*; whereas, those impurities that are inadvertently present as a consequence of the starting material or growth and handling processes are usually referred to as *background impurities*. In either case, the impurities can alter the electrical behavior of the host semiconductor, whether it is through changes in electrical conductivity, charge carrier mobility, or charge carrier mean free drift times. Ge, Si, and GaAs energy levels have been studied extensively, and energy levels associated with impurities and defects are shown in Tables 12.3, 12.4, and 12.5. Numerous other semiconductors used for radiation detectors have also been studied, yet the energy levels and associated impurities and defects are still under investigation.

A block of semiconductor material, whether it is intrinsic, n-type or p-type, must have the same number of negative and positive charges, because the material must have zero overall charge. This charge neutrality arises because any free electron with negative charge has an original host atom that became a positive ion, and for every free hole, there is an acceptor atom that became a negative ion. Additionally, every negative electron excited from the valence band to the conduction band leaves behind a positive hole in the valence band. This charge neutrality condition can be written, with the use of Poisson's equation, as

$$\nabla\mathcal{E} = \frac{\rho}{\kappa\epsilon_o} = \frac{q}{\kappa\epsilon_o}\left[p - n + N_D^+ - N_A^-\right] = 0, \tag{12.135}$$

Table 12.3. Energy levels (eV) reported as donors and acceptors for Ge (E_g = 0.66 eV). Donors are referenced from the conduction band edge ($E_C - E_D$) and acceptors are referenced from the valence band edge ($E_A - E_V$). Data are from [Milnes 1973] and [Sze 1981].

* EL2 means "energy level 2", associated with an intrinsic anti-site defect As_{Ga}.
** Has at times been confused with the EL2 level.

where n is the free electron concentration, p is the free hole concentration, N_D^+ is the ionized donor concentration and N_A^- is the ionized acceptor concentration. Substitution of Eq. (12.126), Eq. (12.128), Eq. (12.133), and Eq. (12.134) into Eq. (12.135) yields

$$N_V \exp\left[\frac{E_V - E_F}{kT}\right] - N_C \exp\left[\frac{E_F - E_C}{kT}\right] + \frac{N_D}{1 + 2\exp\left[\dfrac{E_F - E_D}{kT}\right]} - \frac{N_A}{1 + 4\exp\left[\dfrac{E_A - E_F}{kT}\right]} = 0. \quad (12.136)$$

For any specified temperature T, the concentrations, N_D^+, N_A^-, N_C, and N_V can be calculated. With these values p and n can be found as shown below. Finally, numerical iteration of Eq. (12.126) can be used to determine an exact value for the Fermi energy level E_F.

For the situation in which donors are the *majority* impurities, so that $N_D \gg N_A$, then with the use of Eq. (12.126),

$$n \simeq N_D^+ = \frac{N_D}{1 + g_D \exp\left[\dfrac{E_F - E_D}{kT}\right]} = \frac{N_D}{1 + g_D \left(\dfrac{n}{N_C}\right) \exp\left[\dfrac{E_C - E_D}{kT}\right]} = \frac{N_D}{1 + \dfrac{n}{N_{\xi d}}}, \quad (12.137)$$

where

$$N_{\xi d} = \left(\frac{N_C}{g_D}\right) \exp\left[-\frac{(E_C - E_D)}{kT}\right]. \quad (12.138)$$

Equating the first and last terms of Eq. (12.137) and with some algebraic rearrangement, one obtains

$$n^2 + nN_{\xi d} - N_{\xi d} N_D = 0, \quad (12.139)$$

whose solution for positive n is

$$n = -\frac{N_{\xi d}}{2} + \left[\frac{N_{\xi d}^2}{4} + N_{\xi d}N_D\right]^{1/2} = \frac{N_{\xi d}}{2}\left[\left(1 + \frac{4N_D}{N_{\xi d}}\right)^{1/2} - 1\right]. \tag{12.140}$$

In a similar fashion, it can be shown that when $N_A \gg N_D$,

$$p = \frac{N_{\xi a}}{2}\left[\left(1 + \frac{4N_A}{N_{\xi a}}\right)^{1/2} - 1\right], \qquad \text{with} \qquad N_{\xi a} = \left(\frac{N_V}{g_A}\right)\exp\left[-\frac{(E_A - E_V)}{kT}\right]. \tag{12.141}$$

Example 12.3: Suppose Si is doped with shallow donors at a concentration of $N_D = 10^{16}$ cm^{-3}. It is known that the donor site is 0.04 eV below the conduction band energy E_C. What is the electron free carrier concentration at 77 K and at 300 K?

Solution:
From Eq. (12.84) and the effective mass m_l^* and m_t^* values in Table 16.4 for Si at 4 K, the density of states effective mass at 77 K is estimated to be,

$$m_e^* \simeq 6^{2/3}(m_l^* m_t^{*2})^{1/3} = 6^{2/3}((0.9163)(0.1905)^2)^{1/3} = 1.062m_e$$

where m_e is the mass of a free electron. Then from Eq. (12.120)

$$N_C = 2\left[\frac{2\pi m_e^* kT}{h^2}\right]^{3/2} = 2\left(\frac{2\pi(1.062m_e k)(77\,\text{K})}{h^2}\right)^{3/2} = 3.57\times10^{18}\ \text{cm}^3.$$

Substitution into Eq. (12.141) gives

$$N_{\xi d} = \frac{3.57\times10^{18}\ \text{cm}^3}{2}\exp\left[\frac{-0.04\ \text{eV}}{(77\,\text{K})(8.617\times10^{-5}\,\text{eV K}^{-1})}\right] = 4.3\times10^{15}\ \text{cm}^3.$$

Finally, substitution of these values into Eq. (12.140) gives the free carrier concentration

$$n(77\ \text{K}) = \frac{4.3\times10^{15}}{2}\left[\left(1 + \frac{4(10^{16}\ \text{cm}^{-3})}{4.3\times10^{15}\ \text{cm}^3}\right)^{1/2} - 1\right] = 4.75\times10^{15}\ \text{cm}^3.$$

From this result it is seen, at the cryogenic temperature of 77 K, 47.5% of the shallow donor atoms are ionized; hence, the material is still conductive and behaving extrinsically. If one wishes to design a detector with low free-carrier densities, as is needed for large-volume low-leakage current devices, it is often not enough to simply cryogenically cool the material; the semiconductor must also be purified so that only low concentrations of background impurities are present.

With the same calculations as above, the following results are obtained for $T = 300$ K: $m_e^* = 1.084m_e$, $N_C = 2.83\times10^{19}$ cm^{-3}, $N_{\xi d} = 3\times10^{18}$ cm^{-3}, and $n(300\ \text{K}) = 9.97\times10^{15}$ cm^{-3}. These values indicate that, at room temperature, almost all (99.7%) of the shallow donor states are ionized. Hence, at room temperature $N_D^+ \simeq N_D$.

The result in the above example can be used to simplify calculations for the free carrier concentrations. In the case that one dopant impurity concentration far exceeds the other type, it can be assumed that, at room temperature,

$$n \simeq N_D \quad \text{if} \quad N_D \gg N_A \qquad \text{or} \qquad p \simeq N_A \quad \text{if} \quad N_A \gg N_D. \tag{12.142}$$

For shallow dopants and impurities, the donor and acceptor states are almost completely ionized at room temperature. The free electron and hole concentrations, n and p, can be obtained from the condition of charge neutrality, i.e.,

$$p - n + N_D^+ - N_A^- = 0. \tag{12.143}$$

Then from the mass-action law of Eq. (12.131), $p = n_i^2/n$, and Eq. (12.143) can be rewritten as

$$n^2 - n(N_D^+ - N_A^-) - n_i^2 = 0. \tag{12.144}$$

This quadratic equation for n is readily solved for $n > 0$ as

$$n = \left(\frac{N_D^+ - N_A^-}{2}\right) + \left[\left(\frac{N_D^+ - N_A^-}{2}\right)^2 + n_i^2\right]^{1/2}. \tag{12.145}$$

In a similar fashion, the hole concentration is found to be

$$p = \left(\frac{N_A^- - N_D^+}{2}\right) + \left[\left(\frac{N_A^- - N_D^+}{2}\right)^2 + n_i^2\right]^{1/2}. \tag{12.146}$$

In the *extrinsic region*, where $N_D^+ \gg n_i$ then Eq. (12.145) reduces to

$$n = 2\left[\frac{N_D^+ - N_A^-}{2}\right] \simeq N_D^+ \simeq N_D \quad \text{when} \quad N_D \gg N_A. \tag{12.147}$$

Similarly, where $N_A^- \gg n_i$, Eq. (12.146) reduces to

$$p = 2\left[\frac{N_A^- - N_D^+}{2}\right] \simeq N_A^- \simeq N_A \quad \text{when} \quad N_A \gg N_D \quad . \tag{12.148}$$

In the *intrinsic region*, where $n_i \gg N_D^+$ or $n_i \gg N_A^-$, then Eq. (12.145) and Eq. (12.146) reduce to

$$n \simeq n_i \qquad \text{and} \qquad p \simeq n_i. \tag{12.149}$$

From the previous analysis, one can also determine the location of the Fermi level E_F. If $N_D = 0$ and $N_A = 0$ then $n = p = n_i$ and $E_F = E_i$. Then from Eqs. (12.126) and (12.128)

$$N_C \exp\left[\frac{E_F - E_C}{kT}\right] = N_V \exp\left[\frac{E_V - E_F}{kT}\right]. \tag{12.150}$$

Upon setting $E_F = E_i$ and taking the logarithm of both side of this equation, one obtains

$$\ln\left(\frac{N_C}{N_V}\right) = \frac{E_V + E_C - 2E_i}{kT}, \tag{12.151}$$

from which the intrinsic Fermi level is found to be

$$E_i = \left(\frac{E_V + E_C}{2}\right) + \frac{kT}{2}\ln\left(\frac{N_V}{N_C}\right). \tag{12.152}$$

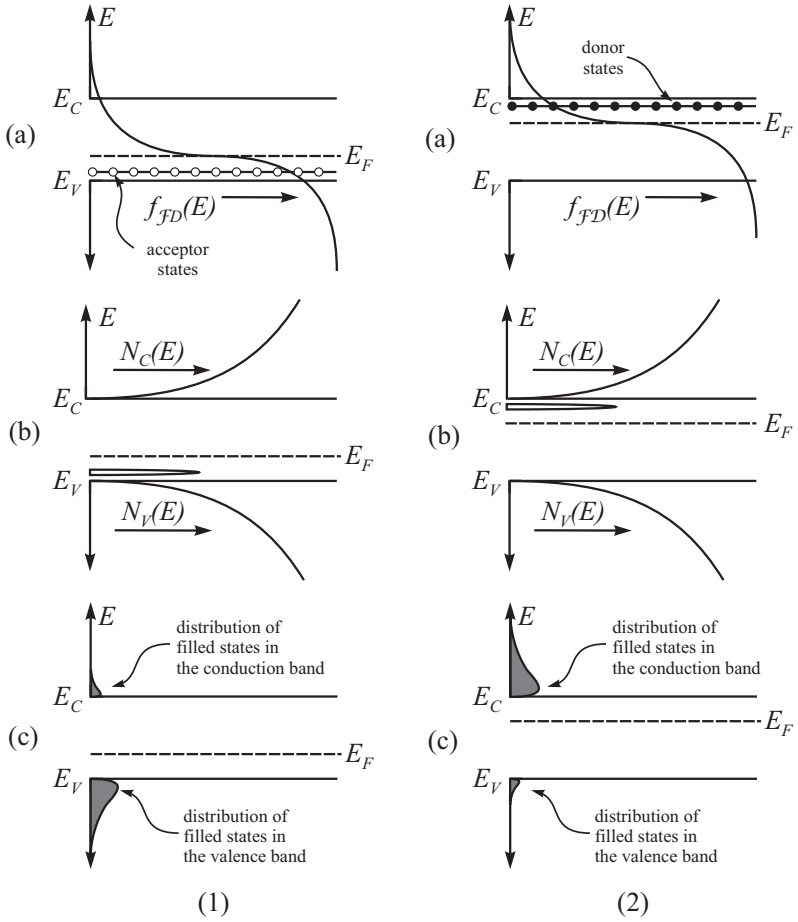

Figure 12.45. Shown are (a) the Fermi-Dirac distributions for extrinsic semiconductors, (b) the density of states functions, and (c) the distribution of free charge carriers, electrons and holes, in the conduction and valence bands, respectively. The distributions in column (1) are for p-type material and the distributions in column (2) are for n-type material.

From Eqs.(12.121) and (12.123), it is seen that $N_V/N_C = (m_h^*/m_e^*)^{3/2}$ so that

$$E_i = \left(\frac{E_V + E_C}{2}\right) + \frac{3kT}{4}\ln\left[\frac{m_h^*}{m_e^*}\right]. \tag{12.153}$$

In the *freeze-out region*, one can equate Eq. (12.126) and Eq. (12.140) and solve for E_F to obtain

$$E_F = E_C + kT\ln\left\{\frac{N_{\xi d}}{2N_C}\left[\left(1 + \frac{4N_D}{N_{\xi d}}\right)^{1/2} - 1\right]\right\}. \tag{12.154}$$

Similarly, from Eqs. (12.128) and (12.141), one finds

$$E_F = E_V - kT\ln\left\{\frac{N_{\xi a}}{2N_V}\left[\left(1 + \frac{4N_A}{N_{\xi a}}\right)^{1/2} - 1\right]\right\}. \tag{12.155}$$

Finally, in the *extrinsic region* one must first relate the intrinsic Fermi level E_i to the actual Fermi level. From Eq. (12.130) one has $N_C = n_i \exp[(E_C - E_i)/kT]$. Substitution of this result into Eq. (12.126) gives

$$n = n_i \exp\left[\frac{E_F - E_i}{kT}\right]. \tag{12.156}$$

Similarly from Eq. (12.130), it is seen that $N_V = n_i \exp[(E_i - E_V)/kT]$. Substitution into Eq. (12.128) then gives

$$p = n_i \exp\left[\frac{E_i - E_F}{kT}\right]. \tag{12.157}$$

The solution of these two equations for E_F in terms of n or p is

$$E_F = E_i + kT \ln(n/n_i) = E_i - kT \ln(p/n_i). \tag{12.158}$$

For the case $N_D \gg N_A$ and $N_D \gg n_i$, Eq. (12.158) reduces to

$$E_F = E_i + kT \ln(N_D/n_i), \tag{12.159}$$

and for the case $N_A \gg N_D$ and $N_A \gg n_i$

$$E_F = E_i - kT \ln(N_A/n_i). \tag{12.160}$$

The Fermi levels and charge carrier distributions for p-type and n-type materials are depicted in Fig. 12.45.

Deep Dopant, Impurity and Defect Energy Levels

Impurities and dopant atoms, as well as intrinsic defects such as antisites, vacancies, and interstitials, can introduce energy levels deep in the band gap of a semiconductor. Deep donors, acceptors, and traps are usually characterized as having an energy level greater than 0.1 eV from either band edge within the band gap. Unlike shallow energy levels, deep levels *should not* be assumed to be fully ionized at room temperature, and the Fermi-Dirac distribution function must be used to determine the fraction of deep states that are filled or empty.

Suppose a semiconductor exists in which there is only one deep level distributed throughout a material with a concentration of N_{DD} and a shallow acceptor level, N_A, of minimal concentration. The electron concentration is given by

$$n = \frac{N_C}{1 + \exp\left[\dfrac{E_C - E_F}{kT}\right]} \simeq N_C \exp\left[\frac{E_F - E_C}{kT}\right], \tag{12.161}$$

and the density of neutral deep donor sites is

$$N_{DD}^0 = \frac{N_{DD}}{1 + \dfrac{1}{g_{DD}} \exp\left[\dfrac{E_D - E_F}{kT}\right]}, \tag{12.162}$$

where N_{DD}^0 is the filled or *neutral* deep donor concentration. With the assumption that the shallow levels are fully ionized, and because the semiconductor total charge density must be neutral, the following balance relation holds

$$N_{DD} - N_{DD}^0 - N_A - n + p = 0. \tag{12.163}$$

The density of ionized deep donors is

$$N_{DD}^{+} = n + N_A - p = N_{DD} - N_{DD}^{0} = N_{DD}\left[1 - \frac{1}{1 + \frac{1}{g_{DD}}\exp\left[\frac{E_D - E_F}{kT}\right]}\right] = \frac{N_{DD}}{1 + g_{DD}\exp\left[\frac{E_F - E_D}{kT}\right]}. \tag{12.164}$$

To find the free electron concentration n, first consider the quantity $R \equiv nN_{DD}^{+}/(N_{DD} - N_{DD}^{+})$. Because the hole concentration is negligibly small, Eq. (12.163) gives

$$R = \frac{nN_{DD}^{+}}{N_{DD} - N_{DD}^{+}} = \frac{n(n + N_A)}{N_{DD} - n - N_A}. \tag{12.165}$$

From Eq. (12.161) and Eq. (12.164) one also finds

$$R = \frac{nN_{DD}^{+}}{N_{DD} - N_{DD}^{+}} = \frac{N_C}{g_{DD}}\exp\left[\frac{E_{DD} - E_C}{kT}\right]. \tag{12.166}$$

Equating these two expressions for R leads to a quadratic equation in n whose solution for positive n can be written as

$$n = 2(N_{DD} - N_A) \times \left[\left(1 + \frac{g_{DD}N_A}{N_C}\exp\left[\frac{E_C - E_{DD}}{kT}\right]\right) + \left\{\left(1 + \frac{g_{DD}N_A}{N_C}\exp\left[\frac{E_C - E_{DD}}{kT}\right]\right)^2 + \frac{4g_{DD}(N_{DD} - N_A)}{N_C}\exp\left[\frac{E_C - E_{DD}}{kT}\right]\right\}^{1/2}\right]^{-1} \tag{12.167}$$

Equation (12.167) can be simplified further by assuming N_A to be negligibly small such that $N_A \simeq 0$,

$$n \simeq 2N_{DD}\left[1 + \left(1 + \frac{4g_{DD}N_{DD}}{N_C}\exp\left[\frac{E_C - E_{DD}}{kT}\right]\right)^{1/2}\right]^{-1}. \tag{12.168}$$

Equation (12.168) provides a simple expression for the expected free electron concentration in the presence of a dominating deep donor level.

The opposite case is true if a deep acceptor is present with concentration N_{AA} and with a negligible number of shallow levels, either for N_D and N_A. Use of the same arguments used above to find n gives the hole concentration under the constraint that $N_{AA} \gg N_D$, namely,

$$p = 2(N_{AA} - N_D)\left[\left(1 + \frac{g_{AA}N_D}{N_V}\exp\left[\frac{E_{AA} - E_V}{kT}\right]\right) + \left\{\left(1 + \frac{g_{AA}N_D}{N_V}\exp\left[\frac{E_{AA} - E_V}{kT}\right]\right)^2 + \frac{4g_{AA}(N_{AA} - N_D)}{N_V}\exp\left[\frac{E_{AA} - E_V}{kT}\right]\right\}^{1/2}\right]^{-1} \tag{12.169}$$

Equation (12.169) can be simplified if it is assumed that N_A is negligibly small so that $N_A \simeq 0$,

$$p \simeq 2N_{AA}\left[1 + \left(1 + \frac{4g_A N_{AA}}{N_V}\exp\left[\frac{E_{AA} - E_V}{kT}\right]\right)^{1/2}\right]^{-1}. \tag{12.170}$$

Notice that the deep donor and acceptor impurities may not be completely ionized at room temperature (300 K); hence, the actual ionized concentrations must be calculated when determining the free carrier densities and material resistivities.

Deep Level Compensation

In the case of wide band-gap semiconductors, the free carrier concentration is typically low for the intrinsic material. Almost all wide band-gap semiconductors are compound materials with the exception of diamond which has a band gap of 5 eV. As a result, purification of wide band-gap semiconductors can be complicated. For example, Si and Ge are widely used semiconductors for radiation detectors. Both are materials composed of a single element and both can be prepared from a melt process in which a single crystal is grown by changing it directly from the liquid to solid state. Hence, both Ge and Si can be purified and processed as a single element. Zone refined Ge and Si has the impure regions removed after purification processes, remelted and grown into single crystals.

However, the case is not so simple for CdTe, which is a far more complex compound semiconductor. Both starting materials, Cd and Te, are typically purified separately. Afterwards, the purified materials must be reacted to form the compound CdTe, which unfortunately is never quite complete because there is always a small percentage of free Cd and free Te left in the molten material. The situation is further complicated by noting that segregation coefficients for some impurities in Cd may be negligible in Te. Hence, when the two are mixed, an impurity efficiently removed from one (Cd, for instance) may be introduced by the other element (Te in this example). Further, during growth, a Cd atom may fall into a Te location or vice versa, thus forming antisites that behave as electrically active impurities, a condition that does not occur for Si or Ge.

It is also important to be able to control the electrical properties of semiconductors that are to be used for radiation detectors. After purification, if the background doping levels remain too high, often impurities are added that act as *deep* impurities. Deep impurities have energy levels that fall deep in the band gap of a semiconductor, typically greater than 0.1 eV from the band edge. Often the most effective deep dopants have energy levels near the middle of the band gap.

Two-Level Model: In the case of two levels present in the semiconductor, for instance one shallow acceptor level and one deep donor level, a simplified compensation model can be developed for the free electron density in the conduction band [Lindquist and Ford 1982],

$$n \simeq \left(\frac{1}{x-1}\right) N_C \exp \frac{(E_A - E_C)}{kT}, \tag{12.171}$$

where $x = N_A/N_{DD}$.

Three-Level Model: Suppose one wants to compensate a material that has been unintentionally doped with p-type dopants from background contamination. In addition, suppose there is a residual concentration of n-type dopants as well, such that $N_A > N_D$. It is desired to add the correct amount of deep level donors to the semiconductor with the goal of making the material have a high resistivity. Hence, the goal is to force the Fermi energy level to the middle of the band gap, as shown in Fig. 12.46. For this example, the *three level model* is used in which $N_{DD} > N_A > N_D$ [Blanc and Weisberg 1960; Lindquist and Ford 1982]. Charge neutrality and Eq. (12.131) require

$$n = p + N_D^+ + N_{DD}^+ - N_A^- = \frac{n_i^2}{n} + N_D^+ + N_{DD}^+ - N_A^-. \tag{12.172}$$

At room temperature $N_D^+ \simeq N_D$ and $N_A^- \simeq N_A$. Hence, with the use of Eq. (12.162),

$$n = N_{DD}(1 - f(E_C - E_{DD})) - (N_A - N_D) + \frac{n_i^2}{n} = \frac{N_{DD}}{1 + g_{DD}\exp\left[\dfrac{E_F - E_{DD}}{kT}\right]} - (N_A - N_D) + \frac{n_i^2}{n}. \quad (12.173)$$

If it is assumed that $n \gg n_i$, the last term in the above result can be neglected. Then substitution of Eq. (12.126) into Eq. (12.173), with the last term set to zero, gives

$$(N_A - N_D) + n = \frac{N_C N_{DD}\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}{ng_{DD} + N_C\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}. \quad (12.174)$$

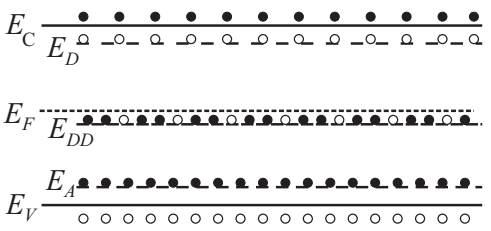

Figure 12.46. The basic three-level compensation model with two shallow levels and one deep level. Depicted is the case in which $N_{DD} > N_A > N_D$, in which the deep levels are only partially ionized. In such a case, the Fermi energy level is "*pinned*" near the middle of the band gap, thereby producing a relatively higher resistivity material.

If the condition exists such that $N_A - N_D \gg n$, then

$$(N_A - N_D) \simeq \frac{N_C N_{DD}\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}{ng_{DD} + N_C\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}. \quad (12.175)$$

The solution of this equation for ng_{DD} gives

$$ng_{DD} \simeq \frac{N_C(N_{DD} - 1)\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}{(N_A - N_D)}. \quad (12.176)$$

Finally, if $N_{DD} \gg 1$, then the above result reduces to

$$n \simeq \frac{N_C N_{DD}\exp\left[-\dfrac{E_C - E_{DD}}{kT}\right]}{g_{DD}(N_A - N_D)}, \quad (12.177)$$

which gives an approximation for the expected free electron concentration in the conduction band for deep donor compensated material.

Using a similar argument, compensation with deep acceptor levels is achieved if $N_{AA} > N_D > N_A$. Through a similar, but opposite, system of equations, the resulting concentration of free holes is,

$$p \simeq \frac{N_V N_{AA}\exp\left[-\dfrac{E_{AA} - E_V}{kT}\right]}{g_{AA}(N_D - N_A)}. \quad (12.178)$$

Example 12.4:

The semiconductor GaAs is a moderately wide band-gap material (eV = 1.42 eV) that has been used for radiation detector development. Bulk grown material even in its purest form often has background impurities. Typically, GaAs is compensated by purposely incorporating excess As in the melt to give rise to the intrinsic anti-site defect, As_{Ga}, which produces a deep donor level in the material 0.75 eV below the

conduction band edge (denoted EL2). Carbon, a shallow acceptor, appears as a background contaminant in concentrations near 10^{15} cm^{-3}, with shallow n-type materials appearing in concentration near 10^{14} cm^{-3}. What is the room temperature free electron concentration if the EL2 concentration is 10^{16} cm^{-3}?

Solution:

Substitution of given values into Eq. (12.177) with $g_{DD} = 2$ yields

$$n \simeq \frac{(4.7 \times 10^{17}\ \text{cm}^{-3})(10^{16}\ \text{cm}^{-3}) \exp\left[-\dfrac{0.75\ \text{eV}}{(300\ \text{K})(8.617 \times 10^{-5}\ \text{eV K}^{-1})}\right]}{2(10^{15}\ \text{cm}^{-3} - 10^{14}\ \text{cm}^{-3})} = 9.482 \times 10^{4}\ \text{cm}^{-3}.$$

With $\mu_e \simeq 8000$ cm^2 V^{-1} s^{-1}, this free electron concentration thus results in a resistivity from Eq. (12.91) of approximately $\rho = 8.24 \times 10^9$ ohm cm.

12.6 Summary

Solid state materials used for radiation detectors are generally composed of crystalline materials. A crystalline material is defined by a basis of atoms arranged upon a periodic lattice. There are 14 possible Bravais lattice systems. The periodic arrangement of atoms causes the appearance of periodic potentials. This potential periodicity causes bands of allowed states to form, producing quasi-continua of energy states in these bands. The density of allowed energy states in these bands is defined by the density of states function. Gaps between these bands are referred to as energy gaps. The energy band that plays the part of atomic bonding is the valence band, and the energy band that plays the part in electron conduction is the conduction band. The energy gap between the valence band and the conduction band is referred to as the band gap.

Energy bands have maxima and minima when defined by energy and crystal momentum in what are known E-k diagrams. Empty states in the valence band are treated as positive particles called "holes". Because electrons need only lose energy to recombine with a hole in direct band gap semiconductors, the charge carriers have high recombination probabilities, thereby causing short charge carrier lifetimes. Electrons must change both momentum and energy to recombine with holes for semiconductors with indirect band gaps; hence, the charge carrier lifetimes are generally longer than observed for direct band-gap materials. Bands with sharp curvature d^2E/dk^2 cause the charge carrier effective mass for electrons or holes to decrease. Small effective mass increases the charge carrier mobility. The electrical behavior of semiconductors can be controlled by introducing dopant impurities. Deep dopants can be added into material to increase resistivity and reduce leakage currents in such a way that the material performs in a similar fashion as intrinsic material. The introduction of excess impurities or defect centers causes a reduction in charge carrier lifetime.

PROBLEMS

1. For the structure shown in Fig. 12.47, what are the Miller indices for the listed planes?

(a) BSFT, (b) HMNP, (c) OTHO, (d) JVCW, (e) OKGR, (f) LTEL, (g) KSFO, (h) HTBP, (i) OTSO, (j) LFEL, (k) OKHP, (l) HFSP

2. For the structure shown in Fig. 12.47, what are the direction indices for the following directions?

(a) OT, (b) LV, (c) SJ, (d) NK, (e) OJ, (f) LF, (g) SM, (h) NT

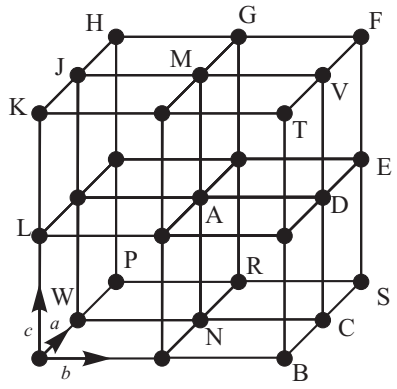

Figure 12.47. Lattice structure.

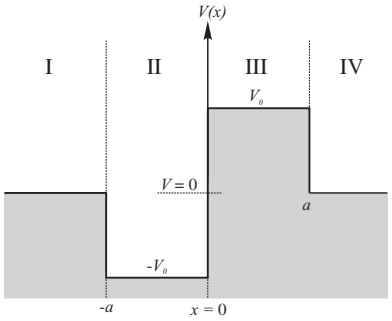

Figure 12.48. Potential well and barrier.

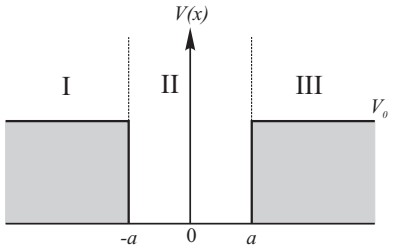

Figure 12.49. Potential well.

3. For a cubic unit cell, find the angles between the normals to the pairs of planes defined by the following Miller indices

(a) (100)(010), (b) (100)(111), (c) (100)(210), (d) (110)(210)

4. For the cubic lattice systems, determine the reciprocal lattice vectors $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$ for the FCC lattice and the BCC lattice.

5. For the potential shown in Fig. 12.48, solve for the reflection and transmission coefficients.

6. Quantum well cavities can be formed by growing consecutive layers of varying semiconductors that have different band-gap energies. For instance, a quantum well can be defined by epitaxially growing a layer of AlGaAs, with a band gap of 1.71 eV, followed by GaAs, with a band gap of 1.42 eV, followed by another AlGaAs layer. Typically, such films are only a few tens to hundreds of angstroms thick, and are grown on semiconductor buffer layers with protective contacts on top. Fig. 12.49 shows a square well where $a = 50$ Å, $V_0 = 0.3$ eV, and $m^* = 0.06\, m_0$. Find the following: (a) Find the allowed energies of the states in the well. (b) Find the wave functions and coefficient values. (c) Plot the wave functions for the allowed energies. (d) Determine the probabilities that an electron is located at the allowed energies.

7. Show that the solution to the Kronig-Penney model can be reduced to Eq. (3.58). Here is a hint to make matters simpler: Assume that the barrier is a delta function such that $\phi \gg k$ such that $d^2u/dx^2 \gg du/dx$ in the region, and simplify.

8. For a 2-dimensional square lattice, draw the first 4 Brillouin zones and clearly show their boundaries. Perform the same exercise for a 2-dimensional hexagonal lattice.

9. Determine the conductivity effective mass for cubic lattice L valley semiconductors by completing the example problem 12.2.

10. A silicon sample is doped with boron at a concentration of 5×10^{15} cm^{-3}. What is the expected resistivity of the material at a temperature of 194 K? What is it at a temperature of 300 K?

11. A silicon sample is doped with a concentration of 10^{16} cm^{-3} phosphorus atoms. At 300 K, what are the concentrations of free electrons and holes?

12. InP ($E_g = 1.35$ eV) is often doped with Fe ($E_C - E_{AA} = 0.66$ eV) to increase resistivity. With $N_A = 3 \times 10^{14}$ cm^{-3}, $N_D = 2.5 \times 10^{15}$ cm^{-3}, and $N_{AA} = 1.5 \times 10^{16}$ cm^{-3}, what is the expected resistivity?

Chapter 13

Scintillation Detectors and Materials

In a few minutes there was no doubt about it. Rays were coming from the tube which had a luminescent effect upon the paper. I tried it successfully at greater and greater distances, even at two meters. It seemed at first a new kind of invisible light. It was clearly something new, something unrecorded.

Wilhelm C. Röntgen

13.1 Scintillation Detectors

Because Röntgen used a scintillating platinobarium cyanide plate to discover x rays in 1895, scintillation radiation detectors hold the distinction of being the first type of radiation detector ever invented. However, the emission of light was basically a qualitative measure of radiation interactions and not so much a quantitative measure. The fluorescence of the material indicated the presence of penetrating ionizing radiation, yet the actual intensity of radiation was not easily gauged.

Materials that scintillate are generally separated into two classes, namely inorganic and organic. The method by which either produces scintillation light is physically different, hence the distinction. Inorganic scintillators can be found as crystalline, polycrystalline, or microcrystalline materials. Organic scintillators come in many forms, including crystalline materials, plastics, liquids and even gases.

The scintillation principle is quite simple. Radiation interactions in a scintillator cause either the atomic or molecular structure in the scintillator to become excited such that electrons are increased in potential energy. These excited electrons then spontaneously de-excite with the decrease in potential energy emitted as radiant light energy. These light emissions can then be detected with light sensitive instrumentation.

Although simple in concept, there are certain attributes that a material must possess to be a useful scintillator. First, the material must be capable of absorbing the radiation of interest. Second, the subsequent energy released from the scintillator must be largely radiative, i.e., a large percentage of the absorbed energy is converted to photons. Third, the light emission must be spontaneous such that the scintillator *fluoresces* rather than *phosphoresces*.[1] Fourth, the scintillator must be transparent to its own scintillation light. Finally and fifth, the fluorescent light must be of a wavelength that can be detected with conventional

[1] Phosphorescence is a process in which light emission continues after the source of radiation is removed

light detecting systems, such as photomultiplier tubes or semiconductor photodiodes. There are many materials that scintillate, but only a select few have all of the necessary properties listed above. In fact, many scintillators were discovered and used in a limited sense for the first 50 years after Röntgen's discovery of x rays.

Many early discoveries depended on the observation of scintillation light. Wilhelm Röntgen used such light to discover x rays and Ernest Rutherford counted, through a microscope, flashes of light produced in a scintillating screen from alpha particle interactions in it.[2] Although scintillators were well known to be sensitive to radiation, their relatively low light yields made them difficult to use as practical detectors. Further, light detection devices needed to detect the scintillations were inadequate at the time. As a result, gas filled detectors dominated the detector industry prior to the 1940s.

An attempt to couple special Geiger-Müller counter tubes with scintillators is described by Krebs [1934, 1941] (also see [Daggs et al. 1952]), who used a thin window GM counter as a light detection device. A screen coated with zinc sulphide (ZnS) was the scintillator used by Krebs, and over the following years many other scintillators were also investigated by Krebs and other researchers [Mandeville and Scherb 1950, Krebs 1955]. However, GM tubes do not preserve energy deposition information, and these types of scintillation detectors served only as radiation counters.

In 1941, RCA introduced the first commercial *photo-multiplier tube* (PMT), a highly light-sensitive electron-amplification vacuum tube that could detect tiny amounts of visible light. In was the PMT that enabled scintillating materials to become practical radiation spectrometers. With improvements in stability and spectral response, eventually it was the PMT that became the light detector of choice for scintillators.

In 1944, Curran and Baker and later Broser and Kallman [1947a, 1947b] and Coltman and Marshall [1947] successfully used PMTs coupled to scintillators to measure alpha, beta, and gamma radiation. Broser and Kallman [1947b] and Deutsch [1948] used the organic scintillator naphthalene, because it was transparent to its own light emissions, to measure ionizing radiations.[3] In 1948 Robert Hofstadter discovered NaI:Tl, probably the most important scintillator in use over the last 65 years. The first efficient gamma-ray scintillation counters and spectrometers were demonstrated when a NaI:Tl crystal and a PMT were coupled together [Hofstadter 1948, 1949; McIntyre and Hofstadter, 1950; Hofstadter and McIntyre, 1950].

A typical scintillation spectrometer consists of a scintillating material hermetically sealed in an internally light-reflecting canister. Typical canisters are cylindrical, with an optically transparent window at one end of the cylinder and all remaining surfaces are Lambertian reflectors.[4] The optically transparent window is coupled to a light collection device, such as a PMT, with an optical compound. The optical compound helps match the indices of refraction between the scintillation canister and the light collection device so as to reduce reflective losses. The PMT provides a voltage output that is linear with respect to the light emitted from the scintillator. Hence, the voltage output "spectrum" is a linear indication of the radiation energy spectrum deposited in the detector. It is typical for commercial vendors to provide the scintillation canister and the PMT as one complete unit, although they can be acquired separately. Properties of commonly used inorganic scintillator materials are listed in Table 13.1.

13.2 Inorganic Scintillators

Inorganic scintillators depend primarily on the crystalline energy band structure of the material for the scintillation mechanism. In Fig. 13.1 an energy band diagram is shown for a typical inorganic scintillator.

[2] This fatiguing process led Hans Geiger and Rutherford to invent the Geiger gas-filled detector.

[3] Hofstadter notes in his 1975 review paper that "all nuclear physics laboratories smelled of mothballs" shortly after Broser and Kallman [1947b] published their work.

[4] A Lambertian surface, named after Johann Heinrich Lambert, has luminance independent of the angle of view. Typically these reflectors are white and *not* glossy or mirror-like.

Table 13.1. Widely used inorganic scintillator materials with some of their properties.

Scintillator	Density (g/cm^3)	Refractive Index (at λ_{max})	λ_{max} (nm)	Decay Time (ns)	Light Yield (photons per MeV)	Bi-Alkali PMT Response WRT NaI(Tl)	Reference

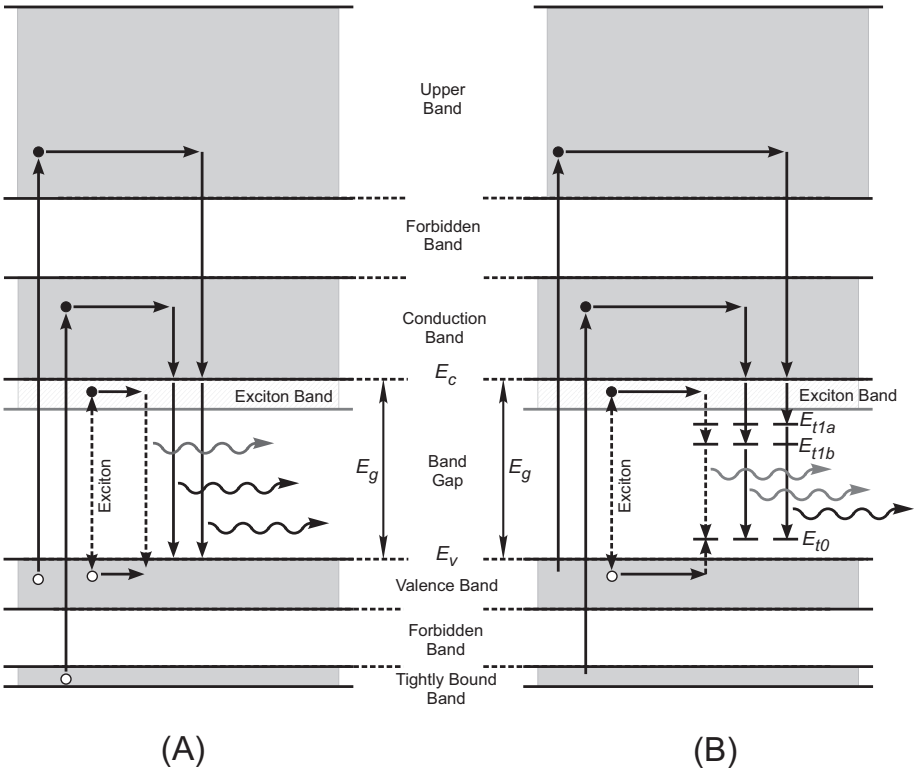

Figure 13.1. Shown are two basic methods by which an inorganic scintillator produces light, (A) is the intrinsic case and (B) is the extrinsic case.

A lower energy band, referred to as the valence energy band, has a reservoir of electrons. It is this band of electrons that participates in the binding of atoms. The next higher band is usually referred to as the conduction band, which for inorganic scintillators is usually devoid of electrons. Between the two bands is a forbidden region where electrons are not allowed to exist, typically referred to as the energy band gap.

If a radiation particle, such as a gamma ray or charged particle, interacts in the scintillation material, it can excite numerous electrons from the valence band and the tightly bound bands up into the conduction bands as shown in Fig. 13.1(A). These electrons rapidly lose energy and fall to the conduction band edge E_C. As they de-excite and drop back into the valence band, they can lose energy through light emissions. Unfortunately, because the radiated energy of the photons is equivalent to the band-gap energy, these same photons can be reabsorbed in the scintillator and again excite electrons into the conduction band. Hence, the scintillator usually is opaque to its own light emissions. There are exceptions in which intrinsic scintillators work well. For example, bismuth germanate (BGO) releases light through optical transitions of Bi^{+3} ions, which release light that is lower in energy than the band gap, hence is relatively transparent to its own light emissions.

However, if an *impurity* or *dopant* is added to the crystal, it can produce allowed states in the band gap, as depicted in Fig. 13.1(B). Such a scintillator is referred to as *activated*. In the best of cases, the impurity atoms are uniformly distributed throughout the scintillator. When electrons are excited by a radiation event, they migrate through the crystal and many subsequently drop into the excited state of the impurity atom. Upon de-excitation, a photon is produced equal in energy to the difference between the impurity atom's excited and ground states. Hence, it is unlikely to be reabsorbed by the scintillator material. Careful

selection of the proper impurity *dopant* can allow the light emission wavelength to be tailored specifically to match the sensitivity of the light collection device.

13.2.1 Theory of Scintillation for Inorganic Scintillators

The scintillation process is described elsewhere as consisting of five distinctive stages [Rodyi 1997], namely

1. Radiation absorption and subsequent excitation of electron-hole pairs.
2. Relaxation of primary electron-hole pairs.
3. Thermalization of the low-energy of charge carriers.
4. Energy transfer to luminescent centers.
5. Photon emission from the luminescent centers.

It is difficult to observe the separate processes of stages 1 through 3 and stages 4 and 5. Instead, these processes are usually categorized as electron-hole production followed by photon emission. But, for the sake of completeness, all five stages are presented here.

Already presented in Chapter 4 are the basic processes by which radiation interacts in matter, and they are the same for scintillators. An ionizing particle excites multiple electron-hole pairs (see Chapter 12) by multiple ionizing processes including photoionization, elastic and inelastic scattering, Coulombic scattering, fission, and neutron transmutation. If the discussion is restricted to photon interactions, then the probability of exciting a K-shell electron is generally higher than exciting electrons from outer shells (L or M). The process by which the holes relax is either from radiative transitions, in which an outer shell electron falls into the empty state by releasing a photon (a characteristic x ray), or by a non-radiative transition (i.e., Auger electron emission). These subsequent emissions can be reabsorbed by outer shell electrons of nearby atoms, thereby producing more electron-hole pairs.

Meanwhile, the liberated energetic electrons travel through the crystal lattice and lose energy through Coulombic interactions and, thus, liberate more electron-hole pairs. The process continues until the resultant electrons and holes no longer have sufficient energy to produce more ionization. Overall, electrons and holes move to their respective band edges, electrons at the conduction band edge and holes at the valence band edge, within about 10^{-15} to 10^{-13} seconds.

Excited electrons still bound to their respective holes through Coulombic forces are also formed at this stage. This condition causes the electron-hole pair to have slightly lower energy than a free electron-hole pair. Thus, the pair exists at an energy below the band gap energy and can be represented as a temporary energy band perturbation traditionally called the exciton band, through which the electron-hole pair diffuse together as an electrically neutral quasiparticle called an *exciton*.

The intrinsic case (A) has no added activator dopants. Absorbed radiation energy excites electrons from the valence and tightly bound bands up into the higher energy conduction bands. These electrons quickly de-excite to the lowest conduction band edge E_C. As they drop to back to the valence band, they release light photons. Some intrinsic scintillators emit light through optical transitions from ionized elemental constituents, which can be of lower energy than the band gap. The extrinsic case (B) has activator dopants that produce energy levels in the band gap. Absorbed radiation energy excites electrons from the valence and tightly bound bands up into the higher conduction bands. These electrons quickly de-excite to the lowest conduction band edge E_C as in case (A). However, many drop into the upper activator site energy state E_{t1}. As they then drop to the activator ground state E_{t0}, they release light photons of lower energy than the scintillator band gap.

Emission Spectra

The emission spectrum is largely affected by the band-gap energy of the scintillator and the energy levels of the activator. Moreover, the emission spectrum is usually spread over a continuous range of energies

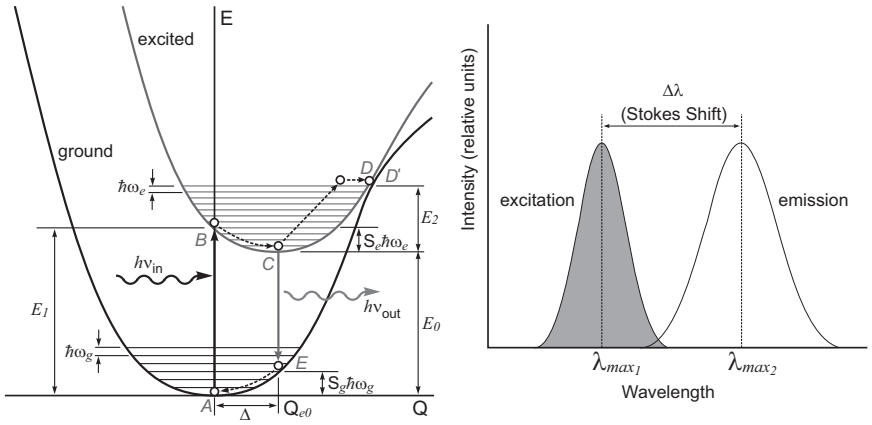

Figure 13.2. Configuration coordinate diagram for a luminescent center depicting luminescence with a Stokes shift and also a form of non-radiative de-excitation. The ordinate is energy E and the abscissa is the average distance Q between the luminescent center and the surrounding ions.

rather than concentrated at discrete energies. As shown in Fig. 13.2, an electron can be excited from the lowest energy state of a fluorescent center by a photon, it may capture a free electron, or it may capture an exciton to produce an excited electron at B. When produced by the absorption of a photon, this electron excitation is a vertical transition and, according to the Franck-Condon principle, occurs nearly instantaneously (femtoseconds). Because electrons are significantly less massive than the surrounding nuclei, the electron transition probabilities can be calculated with the assumption that the nuclear positions appear stationary during the transition. However, after the transition, thermal motion and the relocation of electron spatial positions cause vibrational states to appear, represented as horizontal lines in Fig. 13.2.

In inorganic scintillators, the photon assisted transitions are broadened, which, in turn, results in a widening of the luminescent bands [Rodnyi 1997]. If the luminescent center and its nearest ion neighbor can be modeled by Hooke's Law,[5] then the total energy of the ground state can be modeled as [Yamamoto 2007],

$$U_g = k_g \frac{Q^2}{2} \tag{13.1}$$

and the total energy of the excited state is,

$$U_e = k_e \frac{(Q - Q_{e0})^2}{2} + E_0, \tag{13.2}$$

where k_g and k_e are force constants of the chemical bonds, Q_{e0} is the interatomic distance when the ground state is at equilibrium, and E_0 is the total energy at $Q = Q_{e0}$. At location B, the total energy can be represented by

$$U_e = k_e \frac{(\Delta)^2}{2} + E_0. \tag{13.3}$$

where $\Delta = Q_A - Q_{e0} = -Q_{e0}$.

Elevation of an electron from the ground state to an excited state moves the electron into a different orbital. Consequently, spatial occupancy and the electron wavefunction changes with this transition from

[5] In classical physics, Hooke's Law describes the stored energy in a spring as a function of displacement, $U = kx^2/2$.

the ground state to the excited state. The electron also affects its neighboring atoms differently in its excited state, resulting in a change in the chemical binding (and force constant k), and the position of lowest energy changes from A to Q_{e0} (shown in Fig. 13.2). Further, the potential energy curve of the excited state is wider, thereby allowing the ground state to come close or overlap the excited state potential energy curve at point $D \rightarrow D'$.

An excited electron moves from point A to point B. This excited electron rapidly loses energy and moves to location C. It can now drop directly to the ground state at location E, thereby releasing a photon. The electron then loses energy, by non-radiative processes, to once again fall to location A. Ground state transitions are possible from the several vibrational energy states in the excited state. Consequently, there is usually a wide range of energies contributing to the emission spectrum, which appears as a continuous broad spectrum rather than discrete energy emissions.

The excitation energy ($A \rightarrow B$) is larger than the emission energy ($C \rightarrow E$). This change causes the resultant absorption spectrum of a luminescent center to be different than the emission spectrum because the absorption spectrum is centered about shorter wavelengths than is the centroid of the emission wavelengths. This shift in wavelength is known as the *Stokes shift*,

$$\Delta\lambda = \lambda_{max_{em}} - \lambda_{max_{ab}}, \tag{13.4}$$

where the subscripts em and ab indicate emission or absorption, respectively. If the Stokes shift is adequately large, photon emissions have too little energy to be reabsorbed by the scintillation crystal or other luminescent centers.

The vibrational states can be modeled as a harmonic oscillator bound by the energy wells depicted in Fig. 13.2, in which discrete energy states appear within the energy wells. The solutions give rise to vibrational energy states separated by the phonon energy $\hbar\omega$,[6] where ω is the vibrational mode angular frequency [Rodyni 1997], with even and odd wave functions for both of the wells,

$$E_{n_{g,e}} = (n + \frac{1}{2})\hbar\omega_{g,e}, \quad n = 0, 1, 2, \ldots, \tag{13.5}$$

where the g and e subscripts indicate either the ground or excited potential wells.

In Fig. 13.2, the case is shown in which the number of vibrational states involved with transition $A \rightarrow B \rightarrow C$, denoted by S_e, is different than the number of vibrational states involved with transition $C \rightarrow E \rightarrow A$, denoted by S_g. The energy and number of phonons involved with the relaxation from $B \rightarrow C$ are

$$S_e\hbar\omega_e = k_e\frac{(Q_{e0} - Q_A)^2}{2}. \tag{13.6}$$

In a similar fashion,

$$S_g\hbar\omega_g = k_g\frac{(Q_A - Q_{e0})^2}{2}. \tag{13.7}$$

Note that in Fig. 13.2, $Q_A = 0$. Suppose that the vibrational frequencies and force constants are the same for the ground and excited states, such that $k_g = k_e$ and $\omega_g = \omega_e$, then $S_e = S_g$ and the total energy difference between the transition $A \rightarrow B$ and the transition $C \rightarrow E$ is

$$\Delta E = \hbar\omega(S_g + S_e) = 2S\hbar\omega, \tag{13.8}$$

[6]Here $\hbar \equiv h/(2\pi)$ and is widely used to avoid repeated factors of 2π in quantum calculations.

where S is the number of phonons involved with the absorption or emission of photons, named the Huang-Rhys factor S [Huang and Rhys 1950]. The Stokes shift becomes,

$$\Delta\lambda = \frac{4\pi S\omega c\hbar^2}{E_o^2 - (2\hbar\omega)^2}. \tag{13.9}$$

At a given temperature T, the transition probability for phonon absorption is [Yamamoto 2007],

$$W_{ab}(\hbar\omega) = \frac{1}{\sqrt{2\pi\sigma_{ab}}} \exp\left[\frac{-(\hbar\omega - E_1)^2}{2\sigma_{ab}^2}\right], \tag{13.10}$$

where k is Boltzmann's constant,

$$E_1 = E_0 + \frac{k_e Q_{e0}^2}{2}, \qquad \text{and} \qquad [\sigma_{ab}(T)]^2 \approx 2S_e kT\frac{(\hbar\omega_e)^3}{(\hbar\omega_g)^2}. \tag{13.11}$$

Here the spectral absorption width is defined as the FWHM of the Gaussian distribution, $w_{ab} = 2.355\sigma_{ab}$.[7] For emission, the terms become [Ridley 1982],

$$W_{em}(\hbar\omega) = \frac{1}{\sqrt{2\pi\sigma_{em}}} \exp\left[\frac{-(\hbar\omega - E_3)^2}{2\sigma_{em}^2}\right], \tag{13.12}$$

where

$$E_3 = E_0 - \frac{k_g Q_{e0}^2}{2} = E_0 - S_g\hbar\omega_g \qquad \text{and} \qquad [\sigma_{em}(T)]^2 \approx 2S_g kT\frac{(\hbar\omega_g)^3}{(\hbar\omega_e)^2}. \tag{13.13}$$

If $\omega_e \approx \omega_g$, then the variance as a function of temperature is,

$$[\sigma_{em}(T)]^2 \approx 2S_g kT\hbar\omega, \tag{13.14}$$

which defines the spectral broadening of the emission spectrum, $w_{em} = 2.355\sigma_{em}$. From Eq. (13.14), it is observed that the variance of the emission spectrum increases with S_g, ω, and the absolute temperature T.

It is important that the choice of scintillator matches well to the choice of light sensing device. Perhaps the most common device employed to detect the relatively low light emissions from a scintillation is a photomultiplier tube, or PMT (covered in the following chapter). In Fig. 13.3, there are numerous emission spectra from common scintillator materials along with two comparison sensitivity responses for two types of PMTs. There is at least one characteristic that must be considered when coupling a PMT to a scintillator, mainly, that the spectra match well. For example, the emission spectrum from thallium doped NaI (or NaI:Tl) matches well to both the S-11 and the K-bialkali PMT responses. However, neither the responses from the S-11 or K-bialkali PMT match to the CsI:Tl emission spectrum.

Often the potential energy curves depicted in Fig. 13.2 either intersect or come into close proximity along the Q direction, represented as points D and D'. With thermal agitation, the electron can move to the ground state without releasing a photon. This process can be understood with the assistance of Fig. 13.2, in which electrons are excited from the ground state of a luminescent center to an excited state ($A \rightarrow B$). The electron quickly moves to the lowest potential energy of the excited state C. If the excited electron acquires thermal energy equivalent to E_2, it can be raised to point D and transfer to point D', thereby allowing the

[7] The spectral absorption width is defined here as the FWHM of the Gaussian distribution, or $2\sqrt{2\ln(2)}\sigma_{ab}$. However, the spectral width has been defined elsewhere as w where $W_{ab}(E_1)/q = W_{ab}(E_1 + w)$. Hence, under this alternative definition, $w_{ab} = \sqrt{2}\sigma_{ab}$ [Yamamoto 2007].

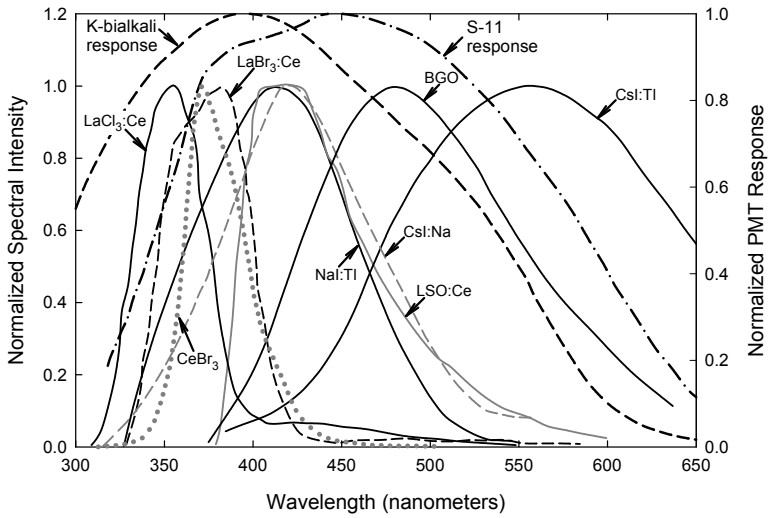

Figure 13.3. The emission spectra from several popular inorganic scintillators. Also shown is an overlaying sensitivity comparison to the normalized responses of two common photomultipliers (K-bialkali and S-11). Scintillation spectral response data from [Lindow et al. 1978, Shah et al. 2005; Valais et al. 2007, and Saint-Gobain 2016]. PMT response data from [Engstrom 1980].

electron to pass directly from the excited state into the ground state without releasing a photon. The excess energy is lost to thermal lattice vibrations (phonons). Ultimately, these electrons are lost to the luminescent process and do not contribute to the fluorescent light yield. The loss of these electrons, acting as information carriers, and the consequential light reduction is called *quenching*.

There are other competing processes that reduce the fraction of electrons contributing to the overall fluorescent scintillation spectrum. Electrons may fall into energy states that produce metastable states, whose transitions to the ground state are forbidden. With some additional energy, these electrons may move to higher allowed energy states and, thereby complete the radiative process. For instance, thermal energy from the ambient environment may be enough to cause these transitions. If these delayed transitions take a relatively long time, beyond several decay times for fluorescent photons, then the radiant decay is called *phosphorescence* or *afterglow*. Phosphorescence becomes a form of background noise in scintillation detectors. These afterglow light emissions can be detected, but the time delay for the emission decouples its correlation to the radiation event that caused the initial electron excitations. Note that some light-emitting materials use phosphorescent decay for benefit, such as the thermoluminescent detectors (TLDs) discussed in Chapter 19.

13.2.2 General Properties of Inorganic Scintillators

Price [1964] suggests that the charge measured at the output of the light collection device be represented by,

$$Q = Mqn_e, \tag{13.15}$$

where M is the multiplication factor of the light collection device (see Chapter 14), q is the electron charge, and

$$n_e = E_n F_n C_{np} T_p F_p S_m f F_c, \tag{13.16}$$

where E_n is the energy of the radiation quantum, F_n is the fraction of energy deposited in the scintillation medium, C_{np} is the conversion efficiency of energy to fluorescent light, T_p is the transparency of the scintillator to its own light emission spectrum, and F_p is the fraction of light photons that reach the light collection sensor. The terms $S_m f F_c$ pertain to the conversion efficiency of the light sensor, where S_m is the light to photoelectron conversion, f is a factor that corrects for spectral mismatch of the light output to the light sensor photoresponse, and F_c the photoelectron collection efficiency. Equation 13.15 can be rewritten as,

$$Q = q(MS_m f F_c)(E_n F_n C_{np})(T_p F_p) = qN_e L_p L_c. \tag{13.17}$$

The term N_e (charge production) is mostly addressed in Chapter 14, whereas the terms L_p (light production) and L_c (light collection) are addressed in this chapter.

Radiation Absorption Efficiency

The radiation absorption efficiency is a strong function of the atomic number and density of the material constituents. For gamma-ray detection, the three most important radiation interactions in a scintillator are photoelectric absorption, Compton scattering, and pair-production. For these three interactions, high Z values produce more efficient results than low Z values. There are some materials that have one moderately high Z constituent and one or more low Z constituents. Yet it is still the concentration of high Z elements that largely determines the absorption coefficient. For instance, the absorption coefficient for CsI (55/53) is only slightly higher than that for NaI (11/53) by about a factor of two or less.

Photoelectric absorption edges should also be considered when selecting a scintillator material for low energy gamma-ray detectors. Within some energy regions, a scintillator with a relatively large Z constituent may actually have lower absorption than another scintillator with lower Z constituents. For instance, the highest K edge for LSO (lutetium orthosilicate) is located at 63.3 keV below which its absorption coefficient drops from 66.87 cm^{-1} to 12.86 cm^{-1}. By comparison, the highest K edge for NaI is located at 33.16 keV. Consequently, the gamma-ray absorption efficiency is actually higher for NaI than LSO between 33.16 keV and 63.3 keV.

The exponential attenuation of uncollided gamma rays entering a scintillating crystal is given by Eq. (4.4), namely

$$I(x) = I_o e^{-\mu_t(E)x}, \tag{13.18}$$

where I_o is the initial gamma-ray intensity intersecting the material surface and x is the distance into the crystal material. Recall from Chapter 4 that the total interaction coefficient is given by

$$\mu_t(E) = \sum \mu_i(E) \approx \mu_{pe} + \mu_{cs} + \mu_{pp} \tag{13.19}$$

where the subscripts pe, cs, and pp refer to photoelectric, Compton scattering and pair-production, respectively. Note that other gamma-ray interactions are possible, as described in Chapter 4, but are less important to general gamma-ray detection. In the detector community, the ratio $I(x)/I_o$ is called the *interaction efficiency* and is the probability a photon interacts in some manner in the material while traveling a distance x in it.

Note the interaction efficiency describes the probability of an interaction, and *not* the amount of energy absorbed. A gamma ray absorbed through the photoelectric effect passes its energy (minus the electron binding energy) to a photoelectron. As the ionized atom de-excites, bound electrons fall into lower energy levels giving off x rays. These x rays may be reabsorbed in the medium from electrons in higher energy levels (L and M shells), or may in fact escape the material altogether. Gamma rays that interact through Compton scattering do not deposit their total energy. In fact, the fractional amount of energy deposited per scatter decreases as the gamma-ray energy increases. These concepts are described in detail in Chapter 4 and

their consequences for radiation detection in Chapter 20. In summary, the absorption efficiency describes the probability of a photon interaction and *not* the probability that gamma rays are fully absorbed.

For other radiations, lower Z materials may be of more importance. For instance, the backscatter probability increases with Z for both α and β particles. Thus for a high Z material these radiations have a good chance of reflecting off the material rather than entering the detector and being detected. Hence, scintillators used for charged particle detectors are usually fabricated from low Z materials, such as organic scintillators. For fast neutrons, low Z materials facilitate higher energy loss per collision. Hence, organic scintillators, such as plastic scintillators, are usually used for fast neutron detectors. When doped with reactive materials with high absorption cross sections in the thermal region, these scintillators can be used for slow neutron detection. There are special scintillators with constituent materials that offer excellent thermal neutron absorption, such as lithium iodide (LiI) and gadolinium oxysulfide (Gd_2O_2S).[8]

Light Yield

Light yield is the number of fluorescent photons produced per energy unit absorbed in a scintillating medium. The *absolute* light yield is the total number of fluorescent photons released per unit absorbed energy, typically reported as photons per MeV. The absolute light yield is usually reported for a specific energy, such as 662 keV (^{137}Cs), 835 keV (^{54}Mn), or 1.836 MeV (^{88}Y), although in some cases a multitude of gamma-ray energies may have been used for the calibration (see for example [Holl et al. 1988]). For statistical reasons, a high absolute light yield is desirable for good gamma-ray energy resolution. In other words, the brighter the scintillator, the better the energy resolution. The absolute light yields of several common inorganic scintillators are listed in Table 13.1.

The *relative* light yield is the number of photons emitted per unit energy at different energies, reported as normalized at a specific energy. Recent publications have used energies near 450 keV as the normalization energy [Mengesha et al. 1998, Swiderski et al. 2009a, Payne et al. 2011]. The relative light yield is a measure of the fluorescent response linearity to absorbed energy. Ideally, the relative light yield should be constant; however, several physical factors can affect the light yield of scintillators, especially in the lower energy region below 500 keV [Jaffe et al. 2007].

Although the cause of non-linear light yield is not fully understood, progress has been made in recent years with predictive modeling. Discussions on different models that elucidate the non-linearity of light emission can be found in the literature [Payne et al. 2009, Payne et al. 2011, Moses et al. 2012]. An important factor affecting non-proportionality is the ionization density produced by an interacting charged particle (electron). From the Bethe-Bloche expression for electron energy loss in matter (see Chapter 4), the ionization density increases as the electron velocity (or energy) decreases. For most scintillators, there is a notable decrease in relative light yield in the low energy region, as shown in Fig. 13.4 and Fig. 13.5, which indicates that light yield for these scintillators decreases as ionization density increases. However, for several alkali-metal/halogen scintillators, there is a notable decrease in light yield also in the high energy region (see Fig. 13.4), an indication that the relative light yield is decreasing for low ionization densities. This ionization density is dependent upon the initial excitation energy of the ejected electron produced by Compton scattering, pair production, or the photoelectric effect. Further, the deexcitation processes, radiative or non-radiative, are also dependent on the incident particle energy. Over the past several decades, there have been numerous models proposed to predict or explain the relative light yield of inorganic scintillators, three of which are described here [Moses et al. 2012].

The "minimalist model" uses numerous simplifying assumptions to arrive at a manageable model. Foremost, it is assumed that luminous emissions are produced solely from exciton recombination at luminous defect centers. Further, it is assumed that free electrons and holes do not contribute to light emissions,

[8] Also known as GOS or Gadox.

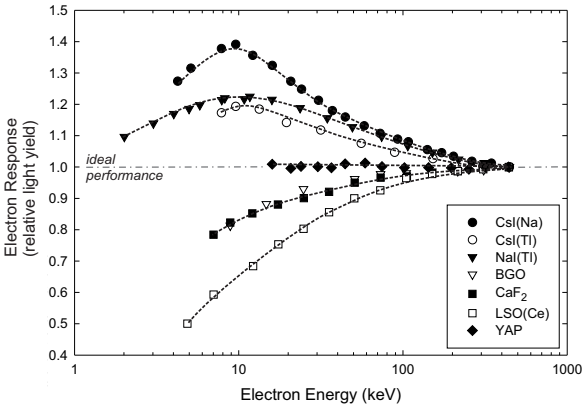

Figure 13.4. Relative light yield for several inorganic scintillating materials, all normalized at 440 keV. Data are from [Mengesha et al. 1998].

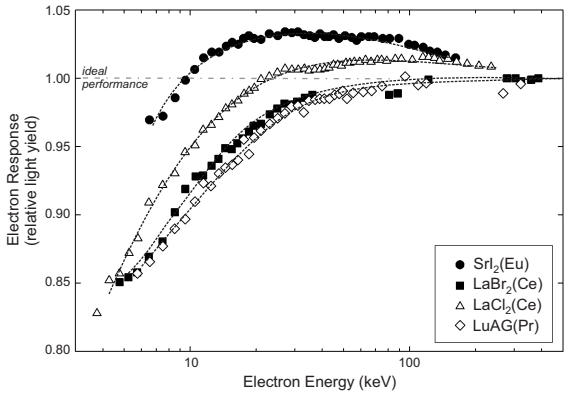

Figure 13.5. Relative light yield for several inorganic scintillating materials, normalized at 450 keV. Data are from [Swiderski et al. 2009a, Payne et al. 2011].

but instead recombine non-radiatively. It would, therefore, be the loss of excitons to competing processes that causes a reduction in relative light yield. The minimalist model seeks to explain this phenomenon as losses due to collisions between excitons in which one exciton pair is changed into an electron-hole pair that de-excites by non-radiative transitions but the other is ultimately preserved. The probability of this event increases with the square of the charge carrier density and, hence, becomes dominant for low energy photon interactions. Also assumed is that at higher energies, the electron and hole densities are less and are also spatially separated. Only those electrons and holes within the *Onsager* radius R_O can form mobile excitons.[9] Based on the non-linear behavior described by Birks [1964], the light yield thus becomes,

$$L = \frac{1 - \eta_{eh} \exp\left[-\dfrac{dE/dx}{(dE/dx)_{R_O}}\right]}{1 + kB\dfrac{dE}{dx}}, \tag{13.20}$$

where η_{eh} is the fraction of electrons and holes that do not form excitons, $(dE/dx)_O$ is the energy loss where the average spatial separation between electrons and holes is R_O, and kB is the quenching parameter described by Birks [1964]. Payne et al. [2011] successfully apply Eq. (13.20) to effectively model the response of numerous scintillator materials. Unfortunately, the minimalist model fails to predict relative light yield from first principles, and is more akin to an empirical data curve fitting method.

The "kinetic model" includes phenomena that are known to occur and affect scintillation yield, but are disregarded in the minimalist model. These effects include radiative emission from trap assisted electron-hole recombination and the reduction of charge carrier density as recombination progresses. Through either a rigorous system of mathematical rate equations, or through Monte-Carlo techniques, these kinetic models attempt to track changes in the electron-hole-exciton cloud as a function of time. The analytical techniques can be complicated, and attempt to include all processes that affect scintillation light yield. The stated advantage is that this modeling method provides much insight into the scintillation mechanism of a material. The disadvantage is the complexity involved with the model.

[9] The Onsager radius R_O is the physical distance between an electron and hole at which the electro-static energy is equal to the thermal energy, i.e., $q^2/(\epsilon R_O) = kT$, where ϵ is the dielectric constant and q is the unit electronic charge. At $R < R_O$, the electron (or hole) cannot escape from the Coulombic force field. [Payne et al. 2009].

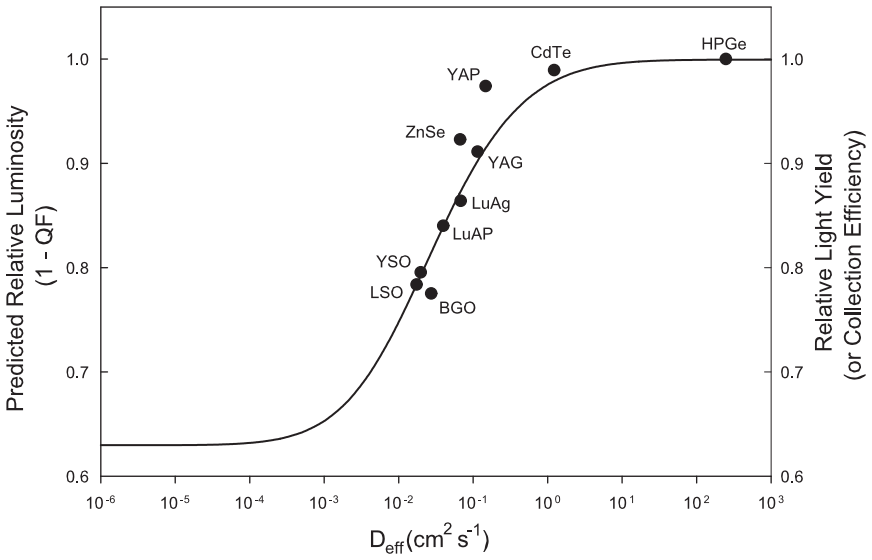

Figure 13.6. Measured light yield from several common scintillators compared to predicted results from a transport model. The responses are shown as functions of diffusion coefficients. The term (1 - QF) is the fraction of carriers that survive at least 10 ps after the charge cloud is formed. CdTe and HPGe are semiconductors, and the measured metric is the charge carrier collection efficiency. Data are from [Li et al. 2011].

The "diffusion model" includes the effect of electron and hole mobility, as well as ambipolar diffusion of excitons. Electrostatic forces and thermal diffusion affect the density of electrons and hole in a charge cloud. Recombination is a strong function of the product np and the trap density (covered in Chapter 15). As electrons and holes separate from diffusion, the probability of direct or trap assisted recombination decreases. Excitons are treated as neutral particles, affected only by thermal diffusion. The overall result can be used to modify the kinetic model. This carrier transport method has at least three major implications [Moses et al. 2012]. First, if one charge carrier type diffuses much faster than the other, for instance $\mu_e \gg \mu_h$, then these differing charge carriers become physically separated and, thus, significantly decreases recombination. Second, for materials with similar electron and hole diffusion coefficients, electrons and holes diffuse with similar spatial distributions, thereby producing a high light yield by efficient recombination. Third, charge carriers (and excitons) with high mobilities rapidly separate, thereby diminishing the carrier density and reducing light loss from quenching. Consequently, it is expected that scintillation materials with relatively high charge carrier mobilities have proportional light output, while the opposite is true for materials with low charge carrier mobilities. The diffusion model has been successfully used to predict luminosity from several common scintillators [Li et al. 2011] as shown in Fig. 13.6.

A scintillator is said to have a *linear response* if the light yield scales as

$$\langle N \rangle = kE + b \tag{13.21}$$

where $\langle N \rangle$ is the mean number of information carriers, E is the absorbed radiation energy, k is a proportionality constant, and b is a constant. For the case of scintillators, $\langle N \rangle$ is the average number of photons produced per event at energy E. In such a case, the scaling of a scintillator is predictable, but the average energy needed to produce a photon is a function of energy and is not constant ($w = E/\langle N \rangle \neq$ constant). If

the constant b is zero, the scintillator is said to have a *proportional response*, in which case $w = E/\langle N\rangle =$ constant. Regardless of the value of b, the differential change in information carriers per differential change in energy is constant, or $d\langle N\rangle/dE = 1/k =$ constant for both linear and proportional responses.

Non-linear (or non-proportional) light yield response as a function of energy complicates energy calibration [Jaffe et al. 2007]. Ideally, the relative light yield (photons/MeV) should be constant, or at least proportional, for all energies. Consequently, pulse height spectral features do not appear in channels predicted with a linear formula. For instance, the relative light yield for NaI deviates from 1 (at 662 keV) to 1.25 (at 10 keV), whereas YAP has minimal deviation in relative light yield as shown in Fig. 13.4. With predictive modeling, a calibration can be developed to provide a reasonably accurate scaled response.

Example 13.1: You are using a NaI:Tl scintillator to measure gamma rays from different sources having energies of 59.5 keV and 662 keV. If system gain puts the 662 keV gamma ray at channel 1000, in what channel does the 59.5 keV gamma-ray center appear? Which channel should it appear in if the relative light yield was constant at all energies?

Solution:

Although the 59.5-keV gamma ray is lower in energy than the 662-keV gamma ray, it produces more light per unit energy. From Fig. 13.4, the relative light yield at 60 keV is about 1.15. To find the energy per channel:

$$E/Ch = 662 \text{ keV}/1000 = 0.662 \text{ keV/channel}.$$

The channel in which the 59.5-keV gamma ray appears, corrected for the increase in light yield from 1.00 to 1.15,

$$Ch = (1.15)(59.5 \text{ keV})/(0.662 \text{ keV/ch}) = \text{channel } 104.$$

rounded to the nearest channel. The 59.5-keV gamma ray should appear in channel 90 if the relative light yield was constant.

Large deviations in relative light yield as a function of energy also adversely affect the energy resolution by causing further statistical spread in the photon yield [Valentine et al. 1998]. Two factors identified by Valentine et al. that contribute to energy resolution broadening are (1) multiple interaction events resulting in one or more energetic primary electrons prior to photoelectric absorption and (2) the resulting electron cascade sequence that follows photoelectric absorption which produces Auger electrons and x-ray emissions. For instance, gamma rays of energy near 662 keV interact most often by Compton scattering in a medium and, hence, deposit only a fraction of their energy in the scintillator at a Compton scatter location. For each subsequent interaction, be it another Compton scatter event or photoelectric absorption, a different amount of energy is deposited in the scintillator until either the photon is absorbed through the photoelectric effect or the photon escapes the detector. Multiple events occur as the empty energy states created by Compton scattering of photoelectric absorption are filled, which includes a cascade of Auger electrons and x-ray emissions. These emissions can also be re-absorbed in the scintillation material. The overall light yield is the sum from all of these events, starting from the initial Compton scatter interaction, all of which produce an energetic electron of different initial energy. Because these energetic initial electrons are of different energies, they also produce a different relative light yield. The variance in light yield about the average light produced from this process must be added to the statistical variance in the average number of electron-hole pairs (and excitons) produced. For ideally proportional scintillators, this variance contribution to the light yield reduces to zero, although the fluctuations in the number of charges created from Poisson statistics remains.

Example 13.2: You are using a NaI:Tl scintillator to measure gamma rays from ^{137}Cs with gamma-ray emissions of 662 keV. Suppose that one gamma ray undergoes photoelectric absorption ejecting a photoelectron from the K shell of iodine. A second gamma ray produces a Compton electron of 150 keV, a second Compton electron of 200 keV, and is then captured by the photoelectric effect. Determine the difference in relative light yield and absolute light yield for these two events.

Solution:

The K-shell binding energy of iodine is 33.164 keV. Therefore, the first photoelectron is ejected with an energy of

$$662 \text{ keV} - 33.164 \text{ keV} = 628.84 \text{ keV}.$$

From Fig. 13.4, the relative light yield for the first gamma-ray absorption correlates to a relative light yield of 1.0.

The remaining energy is preserved by numerous cascades of electrons through atomic energy levels, but assume, to a first approximation, that a characteristic x ray from a $K\alpha_I$ emission is produced, which subsequently ejects a L_{II} electron. Note that a variety of transitions are possible, but the differences in these energy transitions are small. Hence,

$$28.61 \text{ keV(at } K\alpha_I) - 4.856 \text{ keV(binding energy at } L_{II}) = 23.75 \text{ keV}.$$

From Fig. 13.4, the relative light yield for the 23.75-keV Auger electron is about 1.2. The remaining energy (approximately 9.41 keV) is absorbed through various Auger electron transitions. Because two L electrons are missing, two allowed transitions from the M shell are chosen, namely $L\alpha_1$ and the $L\beta_1$. Auger electrons can be produced if these x rays are absorbed by the M shell. There are numerous possibilities, but we choose M_{II} or M_{III} electrons, then free electrons of energy 3.06 keV and 3.29 keV, respectively. From Fig. 13.4, these emissions would produce a relative light yield of approximately 1.15 each. The remaining 3.06 keV energy is regained by electrons relaxing into the M shell, producing free electrons with energies on the order of 0.50 keV to 0.88 keV. Regardless of the transitions, extrapolation from Fig. 13.4 gives a relative light yield near 1.0. If the relative light yield is tabulated in terms of fractions, then

$$\text{RLY} = \frac{628.64 \text{ keV}}{662 \text{ keV}}(1.0) + \frac{23.75 \text{ keV}}{662 \text{ keV}}(1.2) + \frac{3.06 \text{ keV} + 3.29 \text{ keV}}{662 \text{ keV}}(1.15) + \frac{3.06 \text{ keV}}{662 \text{ keV}}(1.0) = 1.0083.$$

The expected absolute light yield is,

$$43,000 \text{ photons/MeV} \left(\frac{1 \text{ MeV}}{1000 \text{ keV}} \right) (662 \text{ keV})(1.0083) = 28,702 \text{ photons}.$$

The same analysis can be done for the Compton scattered photons. The main difference is the ejection of a 150-keV Compton electron (relative light yield of 1.06), a 200-keV Compton electron (relative light yield of 1.03), and the subsequent absorption of the 312-keV Compton scattering photon, which produces a 278.8-keV photoelectron (relative light yield of 1.01). With a similar Auger electron cascade scheme, one arrives at the total relative light yield of 1.0345. The expected absolute light yield is,

$$43,000 \text{ photons/MeV} \left(\frac{1 \text{ MeV}}{1000 \text{ keV}} \right) (662 \text{ keV})(1.0345) = 29,448 \text{ photons}.$$

The total percent difference between the single photoelectric absorption and the Compton scattered example is

$$(100)\frac{1.0345 - 1.0083}{1.0083} = 2.6\%.$$

Decay Time and Pulse Formation

Suppose a radiation particle interacts in a material and excites N^* electron-hole pairs. Of these N^* electrons, an average fraction of electrons fall into luminescent centers, represented by $N = fN^*$. The rate at which these free electrons fall into luminescent centers can be represented as a decay rate,

$$\frac{dN(t)}{dt} = -\lambda_r N(t) = -\frac{N(t)}{\tau_r}, \tag{13.22}$$

where $N(t)$ is the population of free electrons that eventually fall into luminescent centers, λ_r is the probability, per unit differential time, that an electron falls into a luminescent center from its mobile state and τ_r is the mean decay time in which the subscript r designates 'rise'. The rate at which electrons, once in luminescent centers, decay and release a photon is given by

$$\frac{dN_c(t)}{dt} = -\lambda_d N_c(t) = -\frac{N_c(t)}{\tau_d}, \tag{13.23}$$

where λ_d is the probability, per unit differential time, that an electron falls into a luminescent center from its mobile state and τ_d is the mean decay time. Here the subscript d designates 'decay'. Hence, the rate of change in luminescent center population, immediately after a radiation interaction event, is

$$\frac{dN_c(t)}{dt} = \frac{N(t)}{\tau_r} - \frac{N_c(t)}{\tau_d}. \tag{13.24}$$

From the solution of this equation, the luminescent center population immediately after a radiation interaction is,

$$N_c(t) = N\frac{\tau_d}{\tau_r - \tau_d}\left(e^{-t/\tau_r} - e^{-t/\tau_d}\right). \tag{13.25}$$

The light emission rate, in photons per unit time, is expressed as a function of the decay time,

$$L(t) = \frac{N_c(t)}{\tau_d} = \frac{N}{\tau_r - \tau_d}\left(e^{-t/\tau_r} - e^{-t/\tau_d}\right). \tag{13.26}$$

Note that if the population 'rise time' is extremely short ($\leq$ a few ns), which it usually is, then Eq. (13.26) reduces to,

$$L(t) \simeq \frac{N}{\tau_d}\left(e^{-t/\tau_d}\right). \tag{13.27}$$

The solution of Eq. (13.26) is derived with the assumption that a single decay time can adequately represent the light emission rate of a scintillation material. The decay times listed in Table 13.1 are average values obtained from an experiment. Many luminescent states may play a part in the emission sequence. Often these decay times for separate energy levels are similar enough that an average decay time adequately defines the light emission behavior. However, there are many scintillators that have multiple decay times that are notably different. Some also have different emission wavelengths. As seen from Table 13.1, CsI:Na, CsI:Tl, and BaF_2 are examples of scintillators with multiple decay times. In fact, there is a significant difference in the decay times and the maximum wavelengths λ_{max} for BaF_2 emissions.

Differences in decay time constants can be used to distinguish between particles, energies, and in some circumstances the particle mass. One example is the phoswich[10] detector, where two different scintillators with different time constants are laid one upon the other, and read out by a single light detection device. By distinguishing between the times constants, the operator can discern in which detector the interactions occurred. Designs and uses of this configuration are discussed in Chapter 20.

[10] Phosphor sandwich.

Energy Resolution

The energy resolution of a radiation spectrometer is defined as the full width of the spectroscopic energy peak (usually ΔE) at half the maximum intensity (*FWHM*). The energy resolution from scintillators is traditionally reported in terms of percent of the most probable energy (the mode) in the pulse height spectrum,

$$R_{\%} = 100\left(\frac{\text{FWHM}}{E_{max}}\right). \tag{13.28}$$

The minimum value of the FWHM can be modeled, to a first approximation, with Poisson statistics, i.e.

$$\text{FWHM} = 2\sqrt{2\ln(2)\text{var}(E)}, \tag{13.29}$$

where var(E) is the variance of the full energy peak in the pulse height spectrum. A FWHM is depicted in the example gamma-ray pulse height spectrum of Fig. 6.18, taken with a NaI:Tl detector. If the scintillator is coupled with a PMT light detector (Ch. 14), the light collected is converted to an electron signal. Hence, with the assumption that electronic noise from other electronic components is minimal, the variance in the number of electrons collected by the PMT is a measure of the variance of the pulse height spectrum, or $\sqrt{\text{var}(E)}/E_{max} \approx \sqrt{\text{var}(Q)}/Q_{max}$. The fractional variance in electrons collected by the PMT can be expressed as [Birks 1964]

$$v(Q) = \frac{var(Q)}{\bar{Q}^2} \approx \left[\frac{var(N)}{\bar{N}^2} - \frac{1}{\bar{N}}\right] + \frac{var(p)}{\bar{p}^2} + \frac{\bar{G}^2 + var(G)}{\bar{G}^2\bar{N}\bar{p}}, \tag{13.30}$$

where var(N) is the variance in the number of scintillation photons, $\bar{N}$ is the average number of scintillation photons, var(p) is the transfer variance, $\bar{p}$ is the average transfer efficiency, $\bar{G}$ is the PMT gain, and var(G) is the variance in the PMT gain (an intrinsic characteristic of the PMT). The transfer efficiency, and associated variance, are factors that affect the efficiency of how well photons produce photoelectrons, which may include scintillation wavelength matching to the PMT response, coupling efficiency between the scintillator and the PMT window, internal reflection, index of refraction mismatch between the scintillator and the PMT window, photocathode nonuniformities, and photoelectron collection efficiency [Dorenbos et al. 1995].[11] For the case of scintillation light yield based on Poisson statistics, the variance and the average value are equal, i.e.,

$$\text{var}(N) = \bar{N}, \tag{13.31}$$

and the bracketed expression in Eq. (13.30) reduces to zero. However, there are other intrinsic factors that can affect the energy resolution. The main two factors are (1) non-proportional light yield, discussed previously, and (2) non-uniformities in the luminescent center (activators) distribution. The overall energy resolution measured from the scintillator detectors becomes,

$$R^2 = R_i^2 + R_p^2 + R_G^2 \tag{13.32}$$

where R_i is the intrinsic light yield resolution of the scintillation crystal, R_p is the transfer resolution, and R_G is the PMT limiting resolution. Although there are methods to independently measure the effects of R_i and R_p, these contributions to the energy resolution are often combined and defined as the detector resolution $R_d^2 = R_i^2 + R_p^2$. For an ideal detector perfectly coupled to a PMT, $R_d = 0$ and $\bar{p} = 1$; hence Eq. (13.30) reduces to,

$$v(Q) \approx \frac{1 + \text{var}(G)/\bar{G}^2}{\bar{N}}. \tag{13.33}$$

[11] These factors affecting PMT performance are explained in Chapter 14.

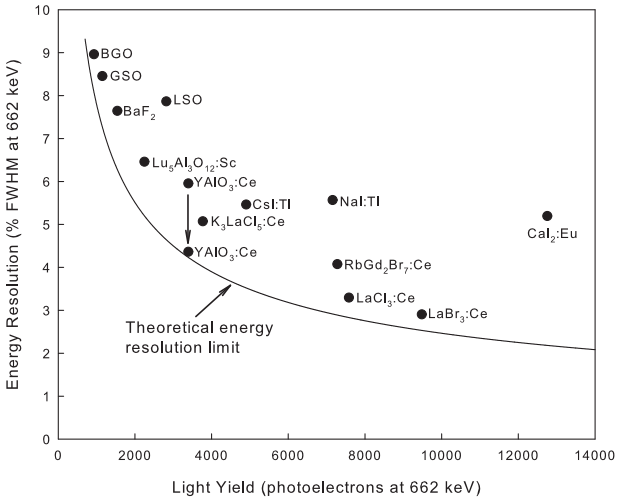

Figure 13.7. Measured energy resolution for several inorganic scintillating materials. Also shown is the theoretical limiting energy resolution. Data are from [Dorenbos 2002].

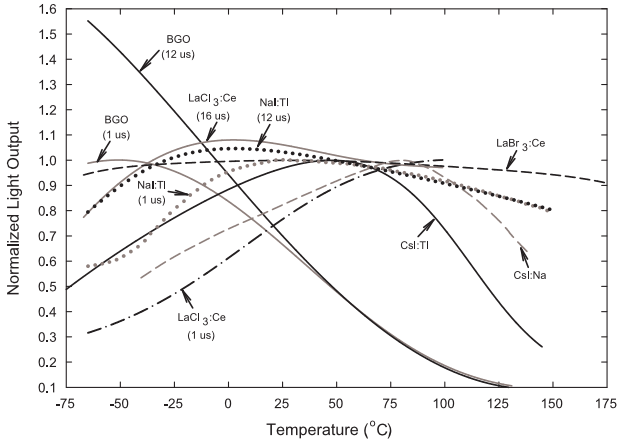

Figure 13.8. The light output, normalized at the maximum for $\tau = 1\mu$s, as a function of temperature for several common inorganic scintillators. The light output data for NaI:Tl, BGO, and $LaCl_3$ were normalized for data measured with a 1 μs shaping time, and comparison data is provided at longer shaping times. Data are from [Lindow et al. 1978, Saint-Gobain 2016].

Values for $\text{var}(G)/\bar{G}^2$ are usually between 0.1 to 0.2 [Dorenbos et al. 2002]. Hence, the ideal best energy resolution of a scintillator as a function of the number of photoelectrons produced becomes,

$$\%\ \text{FWHM} \approx 2\sqrt{2\ln(2)}\sqrt{\frac{1+0.1}{\bar{N}}} = 2.355\sqrt{\frac{1+0.1}{\bar{N}}}. \tag{13.34}$$

This ideal energy resolution is plotted as a solid line in Fig. 13.7, and is compared to measured values of many common inorganic scintillators. From Fig. 13.7, it is clear that almost all of the scintillators represented fall short of the predicted ideal energy resolution. Factors that broaden the energy resolution limit include non-proportional light yield, poor reflective properties of the crystal encapsulate, crystal transparency, crystal imperfections, and mismatch between the indices of refraction at the scintillator and light collection window interface. It is noteworthy that many of those scintillators shown to have large deviations from the predicted resolution also have significantly non-proportional light yield in the low energy region (< 200 keV), an indication of the importance of proportional light yield on scintillator performance. Energy resolution can sometimes be improved with better crystal synthesis and production methods. For instance, the energy resolution of the material $YAlO_3$:Ce (YAP) was reportedly reduced from 6% to 4.4% by improving the crystals (compare results of [Kapusta et al. 1999] to [Moszynski et al. 1998]).

Thermal Properties

From Fig. 13.2 and the explanation offered in the section on emission spectra, scintillation light yield at high temperatures ($> 100°$C) generally result in a reduction in relative light yield. One cause of the reduction is the increased numbers of excited electrons lost from direct transfer from the excited state to the ground state [Melcher 1989]. Another source of a decrease in light yield is the increase in $\sigma_e(T)$ with increasing temperature as can be seen from Eq. (13.14). This increase in $\sigma_e(T)$ spreads the light emission over more wavelengths and, consequently, reduces the maximum yield at λ_{max}. This reduction increases photon reabsorption from crystal defects as a result of increased wavelength mismatch between the light emissions and the light sensor (PMT, photodiode, etc.).

There is also a notable decrease in light yield for many scintillators at low temperatures, particularly at temperatures below room temperature. This decrease in relative light yield can be explained, at least in some circumstances, as a consequence of lengthening the primary decay constant. If the time constant of a light sensor is not lengthened to match the relative increase in τ, then an increased number of luminescent photons are not recorded. From Fig. 13.8, the light output of many common scintillators appears to decrease with lower temperature; however, changing the integration time of the light sensing system works to include previously lost photons, thereby increasing the relative light yield. Examples of such scintillators include BGO (1 μs $\rightarrow$ 12 μs), NaI:Tl (1 μs $\rightarrow$ 12 μs), and $LaCl_3$ (1 μs $\rightarrow$ 16 μs). Scintillators that have relatively flat thermal response to light yield over a broad range of energies include $LaBr_3$ and BaF_2 (220 nm emission only).

Material and Optical Properties

Important material properties for scintillators include fracture resistance, atomic number, mass density, radiation absorption length, and moisture resistance. The atomic number and material density affect the radiation absorption length. For gamma-ray detection, materials with at least one high Z component are best. Further, a high atomic density of the high Z constituent assists with photon absorption. For this fundamental reason, scintillators with high Z are sought for a variety of gamma-ray detection applications, including medical imaging, oil well logging, and gamma-ray spectroscopy. However, because of backscattering effects, low Z materials are best used for alpha-particle and beta-particle detection, and scintillators in which all constituents are low Z are best applied.

The fracture resistance is a measure of a scintillation crystal's ability to withstand shock. Many of the alkali-metal/halide and lanthanide/halide scintillators are soft and extremely fragile and crack under modest exposure to shock. For instance, NaI and CsI are both listed as '2' on the Moh hardness scale,[12] an indicator of resistance to fracture and plastic deformation. NaI is fragile and cracks easily, while CsI is pliable and can withstand more shock. Packaging improvements, which have internal shock resistant buffer regions, have allowed many of these delicate crystals to be used in rough environments such as oil well logging. Oxide based scintillators tend to be more resilient to shock than alkali halides, and they offer a solution for measurements conducted in rough environments. Some oxide based scintillators have high Moh hardness values, such as YAG (moh = 8.5) and YAP (moh = 8.6).

Many of the alkali-metal/halide and lanthanide/halide are chemically unstable in a humid environment, and require handling in special 'dry rooms' during the cutting and packaging process. Further, these *hygroscopic* crystals must be hermetically sealed in air tight containers to prevent decomposition. Otherwise they may absorb water moisture, which causes them to change color and/or decompose. The alkali-metal/halides NaI:Tl and LiI:Eu are very hygroscopic and are ruined if exposed to humidity. The same is true for the lanthanide/halides $LaBr_3$:Ce, $LaCl_3$:Ce, and $CeBr_3$. CsI:Na is also hygroscopic; however, pure CsI and CsI:Tl are only slightly hygroscopic. Oxide-based scintillators along with the alkali-earth/halides generally are not hygroscopic.

Two important optical properties are crystal clarity and the index of refraction, both at the scintillator peak luminescent wavelength. The scintillator materials should be transparent to the photons emitted by the luminescent centers; otherwise, they are reabsorbed and remain undetectable. The optical attenuation coefficient is defined as $\alpha = 1/d$, where d is the distance that a packet of photons with wavelength λ reaches an absorption loss of $1-e^{-1}$ (63.21%). A large Stokes shift assists with optical clarity, in that the luminescent photons are less likely to be absorbed in the crystal. The index of refraction is the ratio of light speed in vacuum to light speed in the medium ($n = c/v$). As presented in Chapter 14, this ratio changes with light

[12] This hardness scale, still used today, was initially developed in 1812 by Frederich Moh, who compared materials to ten commonly available minerals used as standards. The scale ranges from 1 to 10, with talc rated as '1' and diamond as '10'. It is neither linear nor logarithmic, but is ordinal and somewhat arbitrary in designation.

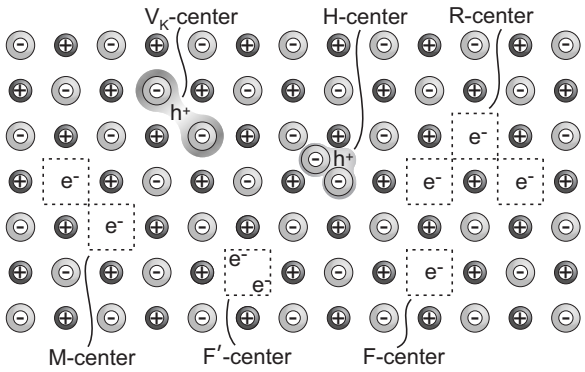

Figure 13.9. Depiction of several types of defects that can be formed in a crystal. F, F', M, and R centers involve vacancies, whereas V_K and H centers do not.

wavelength; hence the important value is the index of refraction at the most probable emission wavelength $\lambda_{\max}$. This index of refraction should be as close as possible to that of the light sensing instrument to obtain good coupling and light transmission. For typical glass windows on light sensing instruments, a scintillator index of refraction ≤ 1.5 is best.

Radiation Hardness

Radiation hardness is a relative measure of how well a substance resists changes in its important properties when exposed to large radiation doses. For scintillators, radiation hardness is usually used to describe the overall resistance to changes in its photon yield, pertaining either to luminescent intensity or emission spectra. Absorption of radiation causes changes in the crystalline structure, which can cause the introduction of defect centers called *color centers*. When a crystal takes on a visible hue, it has color centers in its makeup. These colors centers can absorb the scintillation light and re-emit light at a different wavelength.

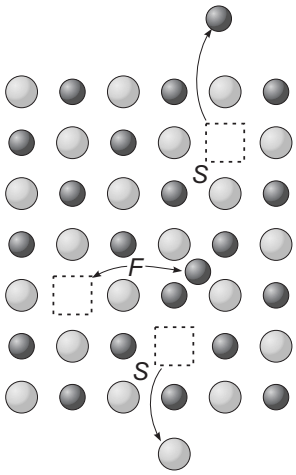

Figure 13.10. Depiction of a Frenkel pair and a Schottky defect pair (vacancies).

Although there are many types of color centers, perhaps one of the best understood is the *F-center*, so called from the German *Farbzentrum*, translated "color center". An F-center is formed by the displacement of a negative ion in the crystal structure, forming an anionic vacancy, which can trap an electron. The defect is formed by the coupling of a positive acting vacancy and the negative electron. This vacancy-electron combination produces energy levels in the band gap of the crystal, which can reabsorb luminescent photons, and through the Stokes shift, re-emit them at longer wavelengths, or lose the excited electron by phonon interactions. The net effect is to reduce the light yield. F-centers are native defects in alkali halide crystals, but can also be formed by x-ray, electron, or gamma-ray irradiation. In some cases, F-centers can be removed or reduced by annealing the crystal. There are many variants of these F-centers, all based on additional defects coupled to an F-center [Kittel 1956]. Included in the list of F-center variants are F'-centers, R-centers, and M-centers [Singh 2012], although the F-center is the most common. An F'-center is an anion vacancy with two trapped electrons [Kittel 1956], an M-center is a formation of two localized F-centers, and an R-center is a formation of three localized F-centers (see Fig. 13.9).

Trapped hole defects can also be formed, but do not involve a cation vacancy. Instead, a trapped hole is associated with either one or more negative ions [Ashcroft and Mermin 1976]. A V_k-center is formed when a hole is bound to two neighboring negative ions in the crystal, producing

characteristics of a singly charged negative diatomic ion (A_2^-). The H-center is formed when a hole is bound to both an interstitial anion and neighboring anion in the lattice, forming a singly charged negative diatomic ion at the ion lattice location.

With sufficient energy transfer, lattice atoms can be removed from their respective sites into interstitial locations. If the removed ion is a cation, creating a positive ion interstitial in the crystal and leaving behind a negatively charged vacancy, a *Frenkel* defect is formed, consisting of the vacancy-interstitial pair (see Fig. 13.10). If a negative ion vacancy is formed along with a positive ion vacancy, the defect pair is a *Schottky* defect. By definition, a Schottky defect is not paired with interstitial ions, the Schottky defect pair maintaining electrical neutrality and crystal stoichiometry. Hence, Schottky defects are more likely formed near surfaces where the displaced ions can leave the crystal bulk.

The energy required to displace atoms in most solids is on the order of 25 eV. Hence, energy transfer in excess of 25 eV by radiation interactions can lead to the formation of both Frenkel and Schottky defects. Gamma-ray irradiation can form Frenkel (and Schottky) defects by transferring energy to electrons, through photoelectric, Compton scattering, or pair production interactions, which in turn transfers kinetic energy to lattice atoms.

A single energetic neutron can transfer enough energy to a recoil atom that can subsequently cause a cascade of displacements, forming a *void* in the crystal. The maximum energy transfer from a radiation particle to a lattice atom is given by Eq. (4.58), repeated here for convenience,

$$T_{\max} = \frac{\beta^2}{1-\beta^2}\left[\frac{2Mm_i^2c^2}{m_i^2 + M^2 + [2m_iM/\sqrt{1-\beta^2}]}\right].$$

where M is the target atom mass, m_i is the radiation particle mass, $\beta = v_i/c$ is the velocity ratio of m_i, and c is the speed of light. The magnitude of T_{max} must be greater than the displacement energy in order to produce these radiation-induced defects. For non-relativistic particles, Eq. (4.58) reduces to

$$T_{max} \approx 4E\frac{m_iM}{(m_i+M)^2}. \tag{13.35}$$

These radiation-induced traps can form color centers, as well as shallow and deep electron and hole traps.

Irradiation with hadrons[13] can cause activation and autodoping. Activated crystals possess intrinsic background radiation that is present during radiation measurements. Autodoping is a process in which constituent atoms are transmuted into different elements, thereby producing new activator sites (energy levels). It is possible that these newly formed energy levels reduce light yield by quenching the light emissions from luminescent centers.

The main effect of radiation induced defects, the most common of which are color centers, is to reduce the light emission from the scintillator. However, many of these defects heal over a relatively short time, thereby allowing the scintillation crystal to recover. Alkali halide scintillators tend to be more susceptible to hadron damage than photon (or electron) induced damage, while oxide-based scintillators tend to suffer more damage by photons than do alkali halides [Rodnyi 1997]. However, the extent of damage from radiation exposure depends on the type of crystal and the type of radiation. A study by Zhu [1998] on several common scintillators indicated that oxygen contamination in the alkali halides was the main source of radiation damage in these scintillators. Apparently the incorporation of hydroxyl groups (OH^-) into a scintillator can be broken down by radiation interactions in the crystals, after which the constituents migrate to become interstitials or substitutional atoms in the crystalline lattice [Zhu 1994]. Work performed by Zhu

[13] Hadrons are categorized as either baryons or mesons. Baryons have three quarks and include neutrons and protons. Mesons have one quark and one antiquark and include pions and kaons.

[1996] provides evidence to support this theory who showed the radiation hardness of CsI:Tl was improved by reducing the oxygen contamination. Zhu [1998] also concluded that radiation damage to oxide-based scintillators was due mainly to the formation of oxygen vacancies.

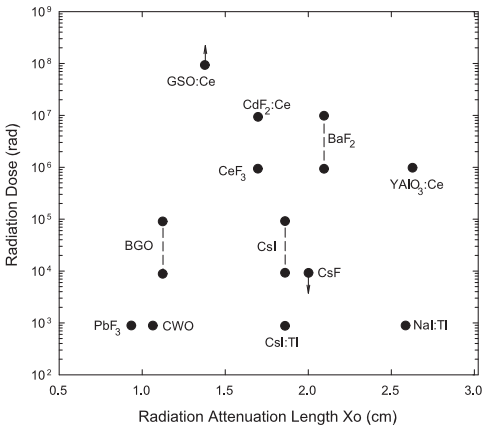

Figure 13.11. The radiation hardness of several scintillators versus unit radiation absorption length. Data are from Ishii and Kobayashi [1991].

Ishii and Kobayashi [1991] studied the effects of gamma radiation on scintillator performance. The study, conducted for applications in high energy physics, defined radiation hardness as that dose at which the light transmittance decreased by 2% per unit gamma-ray attenuation length (see Fig. 13.11). Although this measure may not apply to all scintillator applications, it does provide a relative measure of the radiation hardness between various common scintillator materials. From Fig. 13.11, of those scintillators studied, NaI:Tl, CsI:Tl, cadmium tungstate ($CdWO_4$), and PbF_2 had the lowest radiation resistance while gadolinium orthosilicate (GSO) had the highest tolerance. Zhu [1998] found that, depending on the dose rate, BGO and $PbWO_4$ can quickly (hours to weeks) recover from radiation damage at room temperature. Some of the more interesting properties regarding radiation hardness are described for a few specific scintillators in the following sections.

13.2.3 Properties of Several Common Inorganic Scintillators

Scintillators have been used for various radiation detection applications for over a century. Fluorescent screens and coatings were used in Crookes tubes, and $PtBa(CN)_4$ was the scintillating material that led to Röntgen's discovery of the x ray. ZnS:Ag was used for alpha particle counting by Rutherford, Geiger, and Crookes. In the early 1940s, organic scintillators were matched with efficient light collection devices to produce better scintillation detectors. However, it was the discovery of the bright inorganic scintillator NaI:Tl in 1948 by Hofstadter that allowed the practical application of scintillators to gamma-ray spectroscopy. Since then, the search has continued for better and brighter scintillators for higher energy resolution gamma-ray spectroscopy.

There have been some limited successes, which include those scintillators listed in Table 13.1. For instance, CsI:Na is similar in performance to NaI:Tl, but has a longer decay time. CsI:Tl has much higher light output than NaI:Tl, but the emission spectrum has a maximum at 560 nm, a wavelength that does not couple well to PMTs. However, CsI:Tl has been coupled to Si photodiode sensors quite successfully. Bismuth germanate (BGO) has lower light output, but is much denser and a better absorber of gamma rays. As a result, BGO has been used for medical imaging systems to reduce the overall radiation dose that a patient receives during the imaging procedure. In recent years, LSO:Ce has become an effective and useful alternative to BGO. LSO:Ce has higher light yield than BGO while also having comparable gamma-ray sensitivity. LiI:Eu is a scintillator that is primarily used for neutron detection because of the ^{6}Li content in the crystal. In recent years, $LaBr_3$:Ce, a relatively new scintillator with exceptional properties for gamma-ray spectroscopy, has become available. $LaBr_3$:Ce has a much higher light yield and a much shorter decay time constant than NaI:Tl. Further, it is composed of higher Z elements and, hence, is a better gamma-ray absorber than NaI:Tl. However, it is extremely hygroscopic and fragile and, thus, it is difficult to produce and handle. Although it has become commercially available, it is presently much more expensive than NaI:Tl because of production and fabrication problems.

Overall, there are numerous inorganic scintillators available for special radiation detection purposes. In fact, after more than 120 years of exploration for different scintillators, several hundreds have been identified. For example, tables of scintillators numbering in the hundreds, still incomplete, can be found in the literature

[Derenzo et al. 1991, 2016]. It is beyond the scope of the present text to be all inclusive of this extensive list of scintillators, and the authors limit the following descriptions to those scintillators that either have proven applications, historical significance, or show potential as scintillators for new applications.

Alkali-Metal Halide Scintillators

This family of scintillating salts composed of alkali metals and halogens is perhaps the most successful class of bright scintillators. Outlined here are some properties of a few notable scintillators in popular use, which are also listed in Table 13.1. A convenient and more extensive list of scintillator properties is provided by Derenzo et al. [2016].

Sodium Iodide (NaI, NaI:Tl) The most widely used inorganic scintillator is NaI:Tl. The notation ':Tl' indicates that the NaI crystal has been doped with the activator Tl. It is one of the brightest scintillators available, has acceptably good light yield proportionality, and can be grown in large sections. NaI:Tl was first reported by Hofstadter [1948] who prepared, initially, a powder sample of material with thallium added to the mixture that produced scintillation light when exposed to alpha particles. The sample was found to be hygroscopic, turning yellow within a few hours when exposed to room air. He then produced tiny NaI:Tl crystals (about 1 to 2 mm in size) in an evacuated ampoule. These crystals proved to be brighter than other scintillating materials known at the time.

NaI:Tl yields approximately 43,000 photons per MeV of energy absorbed in the crystal. Light emitted from NaI:Tl has a continuous wavelength spectrum, with a most probable emission at $\lambda_{max} = 415$ nm. The emission spectrum from NaI:Tl matches well to common K-bialkali and S-11 commercial photomultiplier tubes. NaI:Tl shows non-proportional light yield in the low energy region, below 200 keV, which consequently compromises spectroscopic performance. Regardless, NaI:Tl performs adequately well for a general use gamma-ray spectrometer. The decay time for NaI:Tl is 230 ns, which is relatively long compared to almost all organic scintillators and some inorganic scintillators. Although the decay time is manageable, it generally precludes NaI:Tl as a candidate for fast timing measurements.

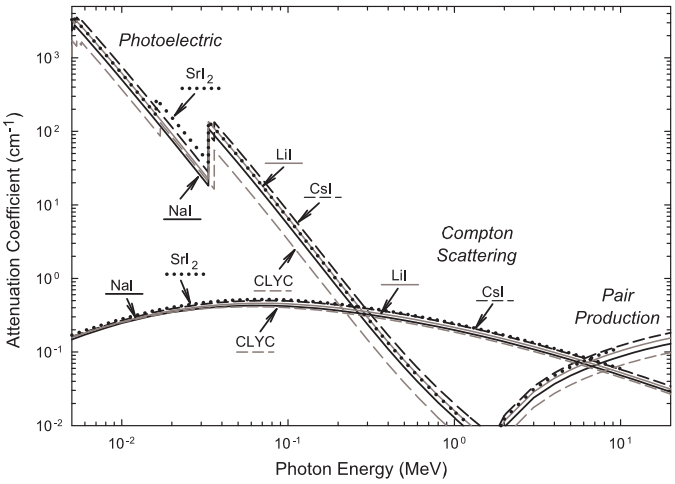

Figure 13.12. Gamma-ray linear attenuation coefficients for several common alkali-metal halide scintillators. Data are from [NIST XCOM].

For the most probable wavelength of 415 nm ($E = 2.99$ eV), a photon yield of 43,000/MeV represents only 12.8% of the energy absorbed. Other mechanisms for energy relaxation include phonons (heat) and phosphorescence. NaI:Tl has a slow 150 ms phosphorescent component, contributing about 9% of the photoelectron yield [Koički et al. 1973]. The emission rate is relatively low but usually does not interfere with low activity measurements, mainly because the low emission rate of phosphorescence produces low pulse height events easily rejected by a discriminator. This phosphorescent yield becomes important for high gamma-ray interaction rates during which it can become a steady source of background noise for radiation measurements and is often called *afterglow*.

Yet, it is the availability of large sizes and the relative linear response to gamma rays that makes NaI:Tl so important. Many different sizes are available, ranging in size from cylinders that are only 0.5 inches in diameter to almost a meter in diameter. Yet, the most preferred detector geometry remains the 3 × 3 inch

right circular cylinder. It is the most characterized NaI:Tl detector size with extensive efficiency data in the literature. Further, it is the standard by which all other inorganic scintillators are measured.

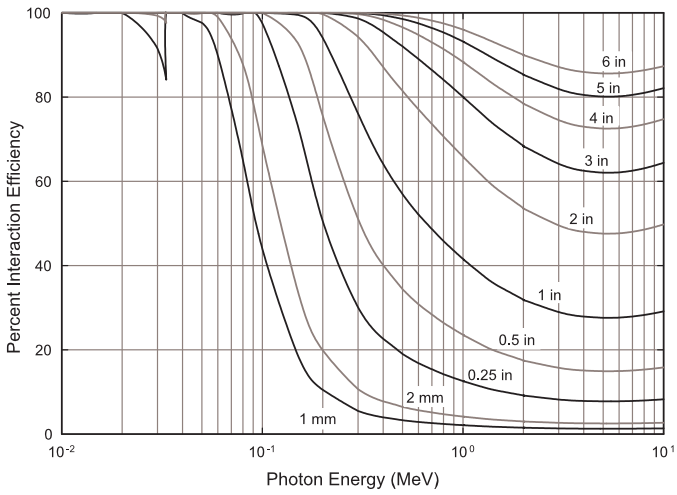

Figure 13.13. The calculated interaction efficiency for photons in NaI as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

NaI:Tl is widely used to measure x rays and gamma rays because of its high efficiency for electromagnetic radiation, mainly due to the high interaction efficiency of iodine (see Fig. 13.12). The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.13.[14] X-ray detectors with a thin entrance window containing a very thin NaI:Tl detector are often used to measure the intensity and/or spectrum of low energy electromagnetic radiation. NaI:Tl detectors do not require cooling during operation and can be used in a great variety of applications. The bare NaI:Tl crystal is hygroscopic and fragile. However, when properly packaged in ruggedized containers, field applications are made possible and NaI:Tl detectors can operate over a long time period in warm and humid environments, resist a reasonable level of mechanical shock, and are resistant to radiation damage. For any application requiring a detector with a high gamma-ray efficiency and modest energy resolution, the NaI:Tl detector is clearly a good choice.

Pure NaI also produces scintillation light without the assistance of activator dopants. At room temperature, the light yield of pure NaI is low, having less than 2% energy conversion efficiency with a most probably emission wavelength of λ_{max} around 310 nm [Van Sciver 1956; Van Sciver and Bogart 1958]. Relatively recent measurements by Moszinzki et al. [2003b] with room temperature pure NaI indicated the release of 1,000 photoelectrons/MeV for a bialkali type PMT [Moszynski et al. 2003a]. The decay constant is substantially smaller for pure NaI than for NaI:Tl, being less than 20 ns at room temperature. At cryogenic temperatures, the light yield increases tremendously up to 25% energy conversion efficiency [Van Sciver and Bogart 1958], a yield of about 63,000 photons per MeV with a maximum light emission at approximately 77 K. Recent measurements put this yield for pure NaI closer to 44,000 ± 4,000 photons/MeV at 77 K [Moszynski et al. 2002]. Note that this trend of increased light yield with reducing temperature is observed for the entire family of pure alkali-metal/iodine scintillators [Boananami and Rossel, 1952]. The decay constant τ for pure NaI increases as the temperature is lowered, increasing from about 16 ns at room temperature up to about 95 ns at 4 K and about 63 ns at 77 K [Van Sciver and Bogart 1958].

The performance of pure NaI at low temperature (125 K), when coupled to a PMT, was reported as 18% FWHM for 122 keV gamma rays [Persyk et al. 1980]. As pointed out by Van Sciver and Bogart [1958], there are problems with operating scintillators coupled to PMTs at low temperature, which include efficient cooling of the PMT that is coupled to the scintillator, difficulties with coupling compounds that retain

[14] Figures such as Fig. 13.13 have been used for decades in textbooks and commercial literature and have been labeled as "absorption efficiency". However, this designation is misleading, because these dependencies are generated from only the total gamma-ray interaction coefficient μ by taking % "efficiency" as $100(1 - \exp[-\mu_t x])$. The calculation does not take into account Compton scatter losses or 511 keV losses from pair production, but instead represents only the probability of a primary interaction occurring. High energy gamma rays are predominantly forward scattered, leading to reduced energy attenuation and higher losses.

needed characteristics at cryogenic temperatures, and the fact the scintillators must be relatively small (< 12.5 mm thick) to reduce photon self-absorption losses. At least one of these problems can be addressed by coupling pure NaI to a photodiode instead of a PMT, as reported by Moszynski et al. [2002; 2003a; 2003b]. This use of a photodiode gave $3.8 \pm 0.1\%$ FWHM for 662 keV gamma-rays when cooled to 100 K.

Cesium Iodide (CsI, CsI:Tl, CsI:Na) The absolute light yield of thallium doped CsI (CsI:Tl) has been measured to have a range between 54,000 photons/MeV to 61,000 photons/MeV by various sources [Saint Gobain 2016; de Haas et al. 2005; Mozynski et al. 1997b]. The refractive index is 1.79 and has a critical angle of 56.9° with a glass interface. The material is only slightly hygroscopic and is much more resilient than NaI:Tl. In fact, CsI:Tl can be machined (to some extent) and it has significantly fewer problems with shock and fracturing. Thin sheets of CsI:Tl are slightly malleable and can be formed over curved surfaces. With constituent elements Cs ($Z = 55$) and I ($Z = 53$), the gamma-ray attenuation coefficient is higher than that of NaI:Tl, as shown in Fig. 13.12. Hence, the gamma-ray intrinsic detection efficiency per unit volume is better for CsI:Tl than NaI:Tl. The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.14.

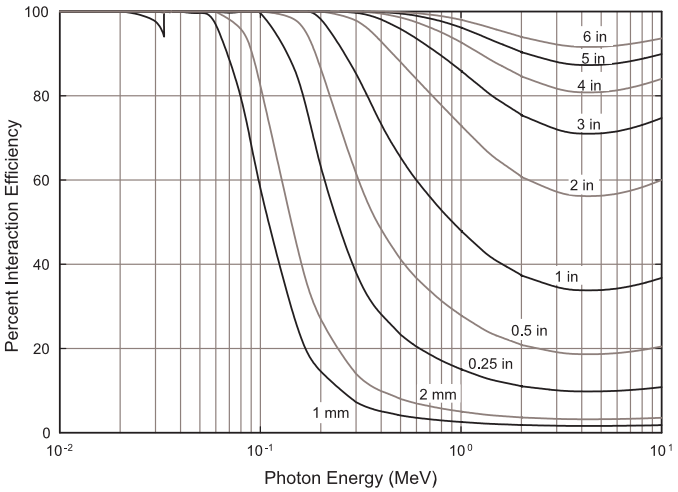

Figure 13.14. The calculated interaction efficiency for photons in CsI as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

CsI:Tl has two decay components, 600 ns and 3.5 μs, with λ_{max} of 550 nm [Saint Gobain 2016]. Although CsI:Tl has a considerably higher light yield compared to most inorganic scintillators, the large mismatch of the luminescent spectrum with the response functions of common S-11 and K-bialkali PMTs, as can be seen from Fig. 13.3, compromises the spectroscopic performance. The spectroscopic performance can be improved by using long shaping times, thereby collecting more of the light from the luminescence. However, a longer collection time increases dead time problems and integrates more electronic noise. The maximum emission wavelength fortuitously matches well to the response function of Si photodiodes. Hence, reasonable spectroscopic performance can be achieved by coupling CsI:Tl crystals to either Si photodiodes or Si photomultipliers (or SiPMs; see Chapter 14). The maximum light output of CsI:Tl is observed at approximately 50°C, and reduces with lower or higher temperatures (see Fig. 13.8). Temperatures deviating only ±50°C from the optimum can cause a light yield reduction greater than 15%. Light loss to gamma radiation damage can become significant at doses approaching 10 Gray, with a measured light reduction of 15% [Saint Gobain 2016].

CsI:Tl can be grown by physical vapor deposition to form narrow vertical columns of the crystal [Jing et al. 1992]. Methods have been developed that create layer thicknesses up to 2 mm with column diameters as small as 5 μm [Nagarkar et al. 1998]. These columns perform as miniature optical fibers that propagate light, directionally, through the scintillator to the readout device. The CsI:Tl thin film can be patterned through optical lithography methods to place the scintillator on select locations [Jing et al. 1992]. When coupled to a Si diode or SiPM, the structure can be used to image a collimated beam of x rays. X-ray spatial resolution on the order of 75 microns was reported when the device was exposed to a collimated 25 μm wide $\leq$ 30 keV x-ray beam [Jing et al. 1992].

A variant of CsI has Na as the activation dopant. The absolute light yield of CsI:Na has been measured to range between 41,000 photons/MeV and 49,000 photons/MeV [Saint Gobain 2016; de Haas et al. 2005]. The refractive index is 1.84 with a critical angle of 54.6° to a glass interface. CsI:Na is much more hygroscopic than CsI:Tl, and care must be taken to prevent exposure to moisture. The primary decay time is also long, but less than CsI:Tl at 630 ns, with a λ_{max} of 420 nm. This luminescent spectrum from CsI:Na is a much better match to common K-bialkali and S-11 PMTs (see Fig. 13.3), with a reported photoelectron production about 85% of that observed with NaI:Tl [Saint Gobain 2016]. However, with the long decay time and the lower resolution performance, CsI:Na offers little advantage over NaI:Tl, except, perhaps, for its superior mechanical robustness. The maximum light output of CsI:Na is observed at approximately 80°C, and reduces with temperatures either lower or higher (see Fig. 13.8). The thermal dependence is greater than observed with CsI:Tl, and temperature deviation of ±50°C from the optimum can cause a light yield reduction greater than 20%.

Undoped CsI (or CsI(pure)) also produces scintillation light, but has very different properties than activated CsI:Tl or CsI:Na scintillators. At room temperature, it produces approximately 2,000 photons per MeV, with λ_{max} at 315 nm [Saint Gobain 2016]. The index of refraction for pure CsI is 1.95, which produces a critical angle of 50.3° at a glass interface. The primary decay time is much shorter than its doped counterparts, namely about 16 ns. Amsler et al. [2002] conducted experiments to measure the light yield and time response, and report the existence of three decay constants, all significantly shorter than doped CsI, namely 28 ± 2 ns, 6 ± 1 ns, and a third fast component reported to be 2 ns. Notably, the light yield of pure CsI increases significantly at low temperature, with a documented light yield of 50000 ± 5000 photons per MeV at 77 K [Amsler et al. 2002] and yielded an energy resolution of 8.3% FWHM for 511 keV photons when coupled to a PMT. Only a single decay constant was observed at low temperatures, which increased significantly up to about 1 μs at 85 K.

Both pure CsI and CsI:Tl recovered from radiation damage at room temperature, but at a slow rate of less than 0.5% per day. Thermal annealing of CsI or CsI:Tl does not assist with recovery, and appears to make matters worse if conducted at temperatures exceeding 300°C.

Lithium Iodide (LiI:Tl, LiI:Eu) Lithium iodide is an alkali-metal halide scintillator that is used as both a gamma-ray and neutron detector. LiI is hygroscopic and must not be exposed to humidity. Thus, LiI requires all handling to be performed in a dry environment. LiI has been used as a scintillator for several decades after being developed around the same time that NaI:Tl was introduced [Hofstadter 1948; Hofstadter at al. 1951]. These initial LiI crystals were doped with Tl as the activator [Hofstadter 1950]. Many of these crystals were yellowish in color, most likely a side effect from impurity contamination. It was also discovered that the activator dopant distribution in LiI:Tl was non-uniform, a side effect from crystal growth problems. The dopant source (LiTl) introduced into the crystal melt was not uniformly incorporated into the crystal lattice, a result which consequently compromised the spectroscopic performance [Bernstein and Schardt 1952]. Within a few years, alternative activator dopants were studied including In, Ag, Sn, Sm, Eu. Of these alternative activator dopants, Eu gave the best light output [Nicholson et al. 1955], and LiI:Eu remains the most studied and used of the LiI variants. With a mass of 4.08 g cm^{-3}, LiI:Eu has nearly the same gamma-ray interaction efficiency as NaI:Tl. LiI:Eu is a relatively slow scintillator with a decay time of 1.4 μs. The measured λ_{max} value is 475 nm with an absolute photon yield of approximately 1,500 per MeV, and has yielded 7.5% FWHM energy resolution for 662 keV gamma rays [Syntfeld et al. 2005]. LiI:Eu has a refraction index of 1.96, which gives a critical angle of 49.93° at an interface with common glass.

It is notable that in recent work LiI crystals doped with 0.5% Tl yielded $14,000 \pm 1,400$ photons per MeV [Khan et al. 2015]. Two decay constants were observed, one at 185 ns yielding 88% of the photons and a slower decay time at 1.089 μs yielding the remaining 12% of photons. The wavelength at the emission

maxima ($\lambda_{\max}$) was measured to be 470 nm. Energy resolution of LiI:Tl was reported to be 8.5% FWHM for 662 keV gamma rays.

The lithium constituent of LiI:Eu enables thermal-neutron detection through the ^{6}Li(n,^{3}H)^{4}He reaction. The natural abundance of ^{6}Li is 7.59%, yielding an atomic density of ^{6}Li in natural LiI:Eu of 1.39×10^{21} cm^{-3}. The resulting thermal macroscopic cross section for the ^{6}Li(n,^{3}H)^{4}He reaction is 1.31 cm^{-1} with an absorption length of 0.76 cm. If the Li is replaced with enriched ^{6}Li, the thermal-neutron absorption macroscopic cross section can be increased to 17.27 cm^{-1}, and the absorption length is reduced to 0.58 mm. Further discussion on LiI as a neutron detector is reserved for Chapter 17 on neutron detectors.

Some Other Alkali-Metal Halide Scintillators Once a scintillator has been developed from an alkali-metal/halogen salt, the obvious question to ask is, what else is there? Indeed, practically all binary combinations of alkali metals and halogens have been studied to determine if they have practical use as radiation detecting scintillators (except for those compounds based on francium or astatine). Some of these other combinations did show promise, but simply did not outperform those materials already described in this section. Combinations in which both constituent atoms are of low Z are less interesting for gamma-ray detectors and spectrometers, hence can be excluded based on their low interaction efficiency. Described here are a few of those other possibilities that have relatively high Z elements.

Potassium iodide (KI) was actually investigated by Hofstadter before NaI was, and led to the investigation of NaI:Tl powders as a scintillator [Hofstadter 1948]. Although relatively bright compared to other known scintillators at the time, KI:Tl does not have the high light yield produced by NaI:Tl and has a light yield of approximately only 9,700 photons/MeV [Holl et al. 1988]. It has two main decay branches at 240 ns and 2.5 μs [Robertson and Lynch 1961]. There also appears to be a change in decay constants when irradiated with alpha particles instead of gamma rays with decay times of 210 ns and 1.76 μs. Milton and Hofstadter [1949] report $\lambda_{\max} = 400$ nm with a slightly narrower spread in the emission spectrum than observed with NaI:Tl. Similarly, Cook and Mahmoud [1954] report $\lambda_{\max} = 425$ nm; hence, KI:Tl has a similar emission output as NaI:Tl.[15] The index of refraction for KI is 1.68 and has a critical angle of about 63° with a common glass interface. KI has a density of 3.12 g cm^{-3}, which is lower than that of NaI. Although K is a higher Z element than Na, it does little to improve the interaction efficiency of KI over NaI because iodine is the main photon absorber in both materials; hence, the gamma-ray interaction efficiencies are nearly the same. Along with the problems listed above, natural potassium has a radioactive isotope ^{40}K, which produces an intrinsic radiation background with K-based scintillators.

Cesium fluoride (CsF) is a fast inorganic scintillator initially studied by Van Sciver and Hofstadter [1952]. It has a mass density of 4.12 g cm^3, higher than that of NaI. As with many alkali-metal/halides, CsF is hygroscopic. CsF scintillates without the assistance of an activator dopant and has $\lambda_{max} = 390$ nm [Moszynski et al. 1983]. The absolute photon yield is approximately 1950/MeV at room temperature [Moszynski et al. 1983; Van Eijk et al. 1993]. CsF has an index of refraction of 1.48, below that of common glass, so that the critical angle of internal reflection is 90°. The measured decay time is 5 ± 1 ns, making it one of the fastest inorganic scintillators available. These studies revealed that the luminescent efficiency was much higher for gamma-ray interactions than for alpha particle interactions by approximately a factor of 4 $\pm$ 10%. It was also observed that the alpha particle pulses were produced by a much slower decay constant of about 200 ns. These multiple interesting properties make CsF an attractive scintillator for fast timing applications.

[15] KI:Tl has also been reported to have a broad emission spectrum at room temperature with a $\lambda_{\max}$ of about 301 nm [Edgarton and Teegarden 1963]. Other measurements indicated $\lambda_{\max}$ of about 410 nm [Smol'skaya et al. 1969] and is similar to that found by Milton and Hofstadter [1949]. It is quite possible that the samples studied by Edgarton and Teegarden [1963] were contaminated with additional impurities, yet this possibility is hard to ascertain from the references.

Cesium Bromide (CsBr) is a heavy element alkali-metal/halide with some interesting properties. It has a density of 4.44 g cm^{-3} with an refractive index of 1.7. It is also hygroscopic like many alkali-metal/halides. CsBr activated with Tl has been reported to have several decay times [Robertson and Lynch 1961; Robertson et al. 1961]. It was found that CsBr:Tl had two main decay times, which differ with the type of radiation particle. Notably, alpha particles (5.3 MeV) were observed to produce shorter decay times at 2.3±0.15 μs and 14.5 ± 1.34 μs than electrons (from 662 keV gamma rays) at 2.57 ± 0.13 μs and 24.23 ± 1.5 μs [Robertson and Lynch 1961]. Pure CsBr also scintillates, although the luminescent yield is poor, reportedly 20 photons/MeV [Van Eijk et al. 1993]. The decay constant of pure CsBr is unusually short for an alkali-metal/halide at 0.07 ns with $\lambda_{max} = 250$ nm.

Rubidium iodide (RbI) has a density of 3.11 g cm^{-3} with a refractive index of 1.64. It has been reported to have two decay constants at 1 μs and 200 μs [Birks 1964]. RbI:Tl has a reported emission wavelength of 4.43 nm (at 80 K) [Babin et al. 1999; Zazubovich 2001], with the interesting property that light emission increases, and the appearance of a luminescent recombination peak of similar intensity appears at 318 nm when the crystal is placed under stress. Ultimately, the light yield is much lower than that observed for NaI:Tl. Pure RbI has a third decay constant reported to be 100 μs at low temperature (about 175 K) [Birks 1964]. Natural rubidium has a radioactive isotope ^{87}Rb, which produces an intrinsic radiation background with Rb-based scintillators.

Alkali-Earth Halide Scintillators

Alkali-earth halides generally consist of those scintillators possessing the form AB_2, where A is an alkali earth and B is a halide. These scintillators are usually hygroscopic and are often relatively soft. Many possess good properties for scintillator detectors, some with good properties for special applications.

Barium Fluoride (BaF_2) Barium fluoride is a commercially available scintillator that is slightly hygroscopic. It is relatively soft with a ranking of 3 on the Moh hardness scale. The mass density of BaF_2 is 4.88 g cm^{-3}, and the atomic numbers of the elemental constituents are 56 and 9. The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.15. It has two important luminescent emissions at 310 nm and 220 nm, both intrinsic emissions. The 310 nm luminescent emission has a decay constant τ of 630 ns, while the 220 luminescent emission has a much faster decay constant ranging between 600 to 800 ps. The refractive index of BaF_2 at 220 nm is 1.54 and at 310 nm it is 1.50, both practically the same as common glass windows on PMTs. Pure BaF_2 was initially studied by Faruhki and Swinehart in 1971, although there was no report of the short wavelength component at the time. The absorption of light in common soda-lime glass is much too high to allow the transmission of either of the two luminescent wavelengths. Although some borosilicate glasses can be used for the 310 nm emissions, they are inadequate for transmittance of the 220 nm emissions. Perhaps it is for this reason that the fast luminescent component remained unreported until 1983 [Laval et al. 1983]. Instead, a PMT with a fused quartz window is preferred if the 220 nm wavelength is to be used (see Chapter 14 on PMTs). Light yield for

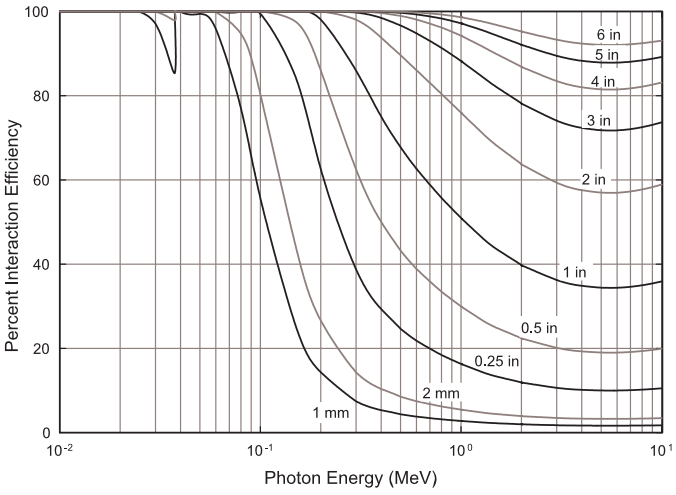

Figure 13.15. The calculated interaction efficiency for photons in BaF_2 as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

the slow component (310 nm) is about 10,000 photons/MeV and for the fast component (220 nm) is about 1,800 photons/MeV.

As pointed out by Ishii and Kobayashi [1991], BaF_2 is mainly important for its fast decay time at the 220 nm emission, and radiation damage that reduces this transmission is of primary concern. Studies by Messner and Smakula [1960] and also Heath and Sacher [1966] predicted high radiation hardness for BaF_2. Measurements by Majewski and Anderson [1985] apparently confirm this prediction as fact. They irradiated BaF_2 with energetic protons, with exposures up to 1.3×10^7 rad, and found a loss of only 1%/cm light transmission. BaF_2 crystals have shown good resistance to gamma-ray irradiation up to 10^6 rad [Woody et al. 1989]. Another study showed that Pb contaminants in BaF_2 significantly reduced radiation hardness [Murashita et al. 1986]. Is was concluded by Ishii and Kobayashi [1991] that highly purified BaF_2 should yield excellent radiation hardened scintillators. BaF_2 did not recover from radiation damage at room temperature in the study performed by Zhu [1994], although there was indication of partial recovery at room temperature in the study performed by [Caffrey et al. 1986], or some damage recovery when exposed to sunlight [Murakami et al. 1991].

An interesting physical aspect to the light emissions from BaF_2 is that the 310 nm emission is greatly affected by temperature changes while the 220 nm emission is not. Studies performed by Schotanus et al. [1985] revealed that the 310 emission spectrum increases in intensity to approximately 3 times that of its room temperature output when the temperature is reduced to about 175 K, and practically disappears when the temperature is increased up to 358 K. However, the 220 nm emission is unaffected by these temperature changes.

Calcium Fluoride (CaF_2:Eu) Europium doped calcium fluoride, initially reported by Menefee et al. in 1966, is a commercially available scintillator that is not hygroscopic and is practically insoluble in water. It has a ranking of 4 on the Moh hardness scale. Because it is not hygroscopic and relatively robust, it can be used under rough circumstances which would be inappropriate for delicate hygroscopic scintillation crystals. The mass density of CaF_2:Eu is 3.18 g cm^{-3}, and the atomic numbers of the elemental constituents are 20 and 9, both relatively low for gamma-ray detection. With a photoelectric/Compton crossover near 70 keV, CaF_2:Eu is best applied for detection of only low energy gamma rays as can be seen from Fig. 13.16. However, CaF_2;Eu can be used as a beta particle detector because backscattering is reduced by the low Z constituents [Colmenares et al. 1974]. Its primary emission wavelength λ_{max} is 435 nm with a relatively long primary decay constant τ of 940 ns. The absolute light yield is reported to be 19,000 photons/MeV [Saint Gobain 2016], approximately 50% of the light yield of NaI:Tl. The refractive index at λ_{max} is 1.47, lower than common glass, indicating that internal reflection when coupled to the glass window of a PMT can be minimized to small values.

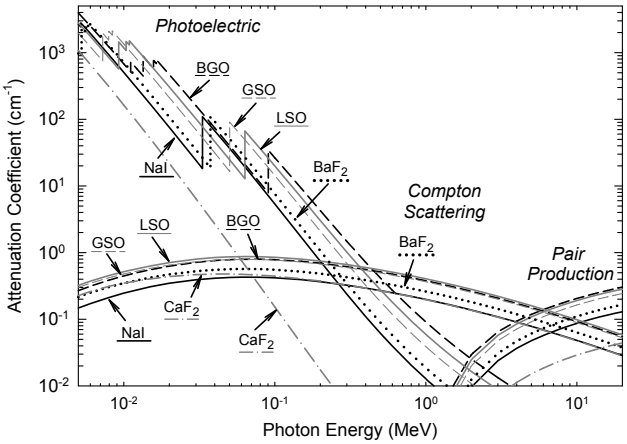

Figure 13.16. Gamma-ray linear attenuation coefficients for a few common scintillators as compared to NaI. Data are from [NIST XCOM].

Calcium Iodide (CaI_2, CaI_2:Tl, CaI_2:Eu) Calcium iodide (doped) is a hygroscopic rare-earth/halogen scintillator initially studied by Van Sciver and Hofstadter [1951] and Hofstadter et al. [1964a; 1964b; 1967]. Having a similar performance to that of NaI:Tl, this scintillator showed great promise. The pure form of

CaI_2, along with CaI_2 activated with either Tl or Eu, were reported as bright scintillators [Hofstadter et al. 1964b]. The mass density of CaI_2 is 3.96 g cm^{-3}. The initial work on CaI_2 was conducted with Tl as the activator [Van Sciver and Hofstadter 1951]. It was found that CaI_2:Tl had a measured decay constant of 1.1 μs and a light yield approximately the same as that for NaI:Tl. The most probable emission wavelength (λ_{max}) was 420 nm. Years later, pure and Eu-activated CaI_2 were studied by Hofstadter et al. [1964a; 1964b] and yielded better results than CaI_2:Tl. It was reported that both pure CaI_2 and CaI_2:Eu yielded up to 200% light yield as that for typical NaI:Tl crystals. The most probable emission wavelength for pure CaI_2 was 410 nm with a decay constant of 550 ns, and the most probable emission wavelength for CaI_2:Eu was 470 nm with a decay constant of 790 ns [Hofstadter et al. 1964b]. Energy conversion efficiency was calculated to be approximately 25%. In that same study, energy resolution of 5.19% FWHM was reported for 662 keV gamma-rays for a CaI_2:Eu sample. Recent work on CaI_2 indicates that the theoretically achievable light yield for CaI_2:Eu is 114,000 photons/MeV, while the measured value was 110,000 photons/MeV [Cherepy et al. 2009]. Hofstadter et al. [1964b] describe multiple problems with the production of CaI_2 crystals, mainly, the material is more hygroscopic than NaI:Tl and it is also quite easily fractured. CaI_2 has a rhombohedral crystalline lattice formed in a layered structure with weak bonds between the basal planes. Unfortunately, the crystal is prone to cracking and plastic deformation during both crystal growth and detector fabrication, and is most likely the reason why CaI_2 has not been extensively explored. Methods to improve crystal growth and material quality have been implemented [Boatner et al. 2015], although the scintillation performance of these newer high-quality crystals was significantly below that of the earlier results reported by Hofstadter.

Strontium Iodide (SrI_2, SrI_2:Eu) Strontium iodide doped with Eu is a hygroscopic rare-earth/halogen scintillator, initially studied by Hofstadter [1968], but it received little attention at the time. Recently this important scintillator has regained attention as a potential high-resolution scintillator. The measured light yield of 115,000 photons/MeV [Cherepy et al. 2009] is much higher than that of commercially available NaI:Tl and $LaBr_3$:Ce scintillators. The most probable emission λ_{max} for Eu-doped SrI_2 is 435 nm [Cherepy et al. 2009], and there is a reported broad emission peak that appears between 550 and 600 nm, depending on the scintillator temperature [Alekhin et al. 2011]. The density of SrI_2 (4.55 g cm^{-3}) combined with the relatively high Z constituent atoms (38/53) makes it an efficient gamma-ray absorber. Strontium iodide has a relatively long decay time of 1.2 μs, a common consequence associated with Eu activators. Unfortunately, the long decay constant makes SrI_2:Eu less attractive than NaI:Tl and $LaBr_3$:Ce for many radiation measurement applications, especially for those with high count rates. The relative light yield is good with a nominally proportional response down to 15 keV (see Fig. 13.5). It has a refractive index of 2.05 at λ_{max} and a critical angle with common glass of 47°. Energy resolution on the order of 2.7% has been reported for SrI_2:Eu crystals irradiated with 662 keV gamma rays [Cherepy et al. 2009; Cherepy et al. 2013]. The relative light yield increases at low temperature (80 K) and decreases significantly at temperatures above 300 K [Alekhin et al. 2011]. Alekhin et al. [2011] report spectral broadening of the emission spectrum from SrI_2:Eu as the temperature is increased from 100 K to 600 K. Also reported is an increase in decay constant τ with temperature going from 400 ns below 100 K to 7 μs at 600 K [Alekhin et al. 2011]. This unusual increase in τ with temperature is hypothesized to be a consequence of photon self-absorption of emissions from Eu luminescent centers. Pure SrI_2 also scintillates (λ_{max} is about 600 nm), but apparently lacks the property of an increasing decay constant with increasing temperature; rather there is a decrease in τ at higher temperatures, ranging from 1.5 μs at 78 K down to 450 ns at 300 K. Recent studies indicate that scintillations from pure SrI_2 are defect (or impurity) related, in that defect-free high purity crystals of undoped SrI_2 and SrI_2:Eu crystals lack this emission altogether [Kawai at al. 2016].

Transition Metal Scintillators

Yttrium Aluminum Perovskite ($YAlO_3$:Ce or YAP) Yttrium Aluminum Oxide (or YAP) is a transition element rare earth (Y) having the general chemical formula of ABO_3, making a mineral of the perovskite[16] family. Perhaps the most interesting property of $YAlO_3$:Ce (YAP:Ce) is its unusually good linearity in the low energy range, leading to energy resolution approaching the theoretical maximum. With an average light yield of about 18,000 photons/MeV, is has about 42% of the NaI:Tl light yield, yet the light yield linearity property of YAP:Ce also produces much better energy resolution. For example, a FWHM energy resolution of less than 4.4% has been reported for ^{137}Cs 662 keV gamma rays [Kapusta et al. 1999, Moszynski 2003]. Other advantages of YAP:Ce include a fast decay time of 27 ns, a relatively high mechanical strength and chemical stability, and thermal stability [Leroq et al. 2006]. The fast decay time enables fast timing applications, while the mechanical and chemical robustness reduces problems with detector fabrication (slicing and polishing). The thermal stability produces a minimal change in performance with temperature variations and allows its use at higher temperatures than other scintillators. However, disadvantages include relatively low Z numbers for the constituent elements (39,13,8), a high index of refraction (1.95), and a relatively low value for λ_{max} of 370 nm. Although the density of YAP is 5.35 g cm^{-3} (higher than that of NaI:Tl), the low Z elements yield a relatively low attenuation coefficient at moderate and high gamma-ray energies. The high index of refraction causes the critical angle for internal reflection at a glass interface to be high, approximately 50°. The low value of λ_{max} causes inefficient coupling to standard bialkali and multialkali PMTs.

Lutetium Aluminum Perovskite ($LuAlO_3$:Ce or LuAP) Lutetium Aluminum Oxide (LuAP), also a rare earth perovskite, has many similar properties to YAP. Perhaps the most important differences are LuAP's higher density of 8.34 g cm^{-3} and its higher Z constituent element Lu ($Z = 71$), both of which significantly increase its gamma-ray absorption coefficient. It certainly has one of the highest average gamma-ray attenuation coefficients of the known scintillators. It is also a fast decay scintillator, with two decay constants of 16.5 ns and 74 ns. However, the light yield of LuAP is only 11,400 photons/MeV with $\lambda_{max} = 365$ nm. Its index of refraction is 1.94; hence, the critical angle is also approximately 50° with most common glasses used for PMT windows. Consequently, these multiple disadvantages produce a measured energy resolution usually inferior to that observed with YAP:Ce, although there is at least one report indicating that relatively good energy resolution can be achieved, namely 6.8% FWHM at 662 keV for small crystals [Balcerzyk et al. 2005]. Although the light yield is only 26.5% of that of NaI:Tl, its energy resolution can be comparable, most likely a beneficial consequence of LuAP:Ce having a proportional relative light yield in the low energy region similar to that observed with YAP [Balcerzyk et al. 2005].

Yttrium Aluminum Garnet ($Y_3Al_5O_{12}$:Ce or YAG:Ce) Yttrium aluminum garnet[17] YAG:Ce is a nonhygroscopic relatively fast inorganic scintillator that has found use with scanning electron microscope (SEM) systems [Autrata et al. 1978; Bok and Schauer, 2014]. It has relatively high resistance to radiation damage, making it suitable for use under the expected high electron bombardment in a SEM. YAG has a density of 4.55 g cm^{-3}, and its highest Z component is yttrium (39) so that it has only modest gamma-ray absorption coefficients. YAG has a cubic crystal structure and rates 8.5 on the Moh hardness scale.

It is yellow in appearance, with a most probable wavelength of emission λ_{max} at 550 nm. Manufacturers recommend the use of an extended red PMT response, such as the S-20 PMT. However, the use of a silicon photodiode (Si PD) is a good alternative, mainly because the quantum efficiency is well matched between a Si PD and the emission spectrum from YAG:Ce. It has an index of refraction of 1.82 that produces a critical angle of 55.5° at a glass interface. Depending on the doping concentration and type of radiation,

[16] Discovered in the Ural Mountains in 1839 by Gustov Rose, this mineral is named after the Russian mineralogist Lev Perovski.
[17] The word "garnet" is derived from the Middle English word 'gernet', which means 'dark red'.

YAG:Ce has multiple decay times [Moszynski et al. 1994]. Moszynski et al. [1994] report decay times of 88 ns and 302 ns when irradiated with gamma rays, and decay times of 68 ns and 247 ns when irradiated with alpha particles. These differences in decay times for heavy charged particles and gamma rays have been used to discriminate radiation types through pulse shape discrimination [Ludziejewski et al. 1997]. The absolute light yield is approximately 15,000 photons/MeV if measured with a Si PD, but somewhat less at 1,270 photons/MeV when measured with a PMT [Ludziejewski et al. 1997]. Energy resolution of 11.1% was reported for 662 keV gamma rays when coupled to a PMT [Moszynski et al. 1994].

Lutetium Aluminum Garnet ($Lu_3Al_5O_{12}$:Ce or LuAG:Ce) Closely associated with YAG is LuAG, which is interesting for gamma-ray detection because of the higher Z component lutetium (71). A comprehensive review by Nikl et al. [2013] provides general information on its development. LuAG has a crystalline cubic structure, a density of 6.76 g cm^{-3}, and rates 8.5 on the Moh hardness scale. LuAG has been discovered to yield good performance with Ce [Chewpraditkul et al. 2009] and Pr activator dopants [Yanagida et al. 2011]. LuAG:Ce, also yellow in color, has a peak emission wavelength λ_{max} between 510 and 535 nm and a decay constant between 55 and 70 ns. The absolute light yield ranges between 18,000 and 26,000 photons/MeV and is relatively proportional above 100 keV [Nikl et al. 2013]. Gamma-ray performance is good, with a reported FWHM energy resolution between 5.5 and 7% at 662 keV [Nikl et al. 2013 and references therein]. LuAG:Pr has a reported peak emission wavelength λ_{max} of 310 nm [Świderski et al. 2009a] and a decay constant of 20 ns [Furukawa 2016]. A reported absolute light yield is 22,000 photons/MeV for commercial material [Furukawa 2016]. The light yield proportionality is quite excellent for energies above 100 keV [Świderski et al. 2009a], and most likely assists with the good energy resolution observed, with a best resolution reported as 4.2% at 662 keV for commercial LuAG:Pr [Furukawa 2016].

Zinc Sulfide (ZnS:Ag) Zinc sulfide is a relatively old scintillator, having been discovered by Théodore Sidot in 1866. It is a non-hygroscopic material with a density of 4.09 g cm^{-3}. Because of its low Z constituents, it is not an efficient gamma-ray detector, but is a relatively bright scintillator for heavy charged particles. ZnS was used as the scintillator for alpha particle counting by Rutherford and Geiger and is also the scintillating component in common spinthariscopes. There are two main crystalline forms of ZnS that can exist at room temperature, a cubic (zinc blend) form and a hexagonal (wurtzite) form, which unfortunately makes single crystal growth difficult and leads to polymorphism. Because of the difficulty in producing single crystals, ZnS is available either as a polycrystalline powder or as thin optical crystals. ZnS is also a wide band-gap semiconductor material with the hexagonal and cubic forms having band gaps of 3.91 eV and 3.54 eV, respectively.

When doped with Ag as an activator, ZnS:Ag has a most probable emission wavelength $\lambda_{max} = 450$ nm. Its refractive index is high at 2.36 that produces a critical angle of 39.5° when coupled with glass or acrylic.[18] ZnS:Ag has poor light response to gamma rays, but is relatively bright for heavy ion interactions. The light yield is about 54,000 per MeV for alpha particles, or approximately 126% of the light output of NaI:Tl and has a reported decay constant of 110 ns [Saint Gobain 2016]. ZnS:Ag in the form of polycrystalline powder is opaque to its own light emissions for mass thicknesses greater than 25 mg cm^{-2} (or 61 microns). Hence, most detectors utilizing ZnS:Ag are limited to thin films. ZnS:Ag is generally used for heavy ion detection. Two interesting configurations are the Lucas cell and the Hornyak detector.

A Lucas cell is a cylindrical cup configured as a gas-flow chamber, usually with dimensions on the order of 5 cm in diameter and 5 cm long. The gas-flow chamber has inlet and outlet ports, and the inside of the chamber is coated with a scintillator, usually ZnS:Ag [Lucas, 1957]. A Lucas cell is designed to accept a gas sample, filter out the radioactive particulates, and subsequently count radioactive decay products as they produce scintillation light when they strike the chamber walls. A PMT attached to the open top of

[18] Poly(methyl methacrylate) or PMMA, also known as plexiglass or lucite.

the chamber registers light pulses, thereby producing a count rate from the chamber. A Lucas cell is often used to measure radon gas concentrations [Abbady et al., 2004]. Radon, a radioactive gas, decays by α particle emission, which produces a chain of radiative daughter products. Inhalation of radon can result in radioactive daughter products becoming lodged on the surfaces of the respiratory system, and presents a health risk in regions of high radon accumulation. The standard for measuring radon gas can be found in the ANSI/AARST MS-PC 2015 report.

A Hornyak detector [Hornyak 1952], often called a Hornyak button, is a detector configuration used for fast-neutron detection while suppressing signals from slow neutrons and gamma rays. The original devices were composed of ZnS:Ag particles interspersed within an acrylic medium. Modern Hornyak buttons have interspersed concentric cylinders, similar to a "bull's eye" target, alternating between non-scintillating acrylic light waveguides and layers of ZnS:Ag. Fast neutrons interact in the plastic and eject protons into the ZnS:Ag. The energetic protons fluoresce the ZnS:Ag, and a fraction of the light propagates through the plastic to a light detection device, such as a PMT. Hornyak buttons are used for fast neutron detection in high gamma-ray environments in order to reduce the background emissions. More detail on this type of detector can be found in Chapter 18.

Post-Transition Metal Scintillators

Bismuth Germanate ($Bi_4Ge_3O_{12}$ or BGO) Bismuth germanate, commonly referred to as BGO, is a relatively rugged fracture resistant non-hygroscopic material, and it is rated as 5 on the Moh hardness scale. BGO has one high Z constituent (Bi = 83, Ge = 32, O = 8), along with a relatively high density of 7.13 g cm^{-3}, making it a good gamma-ray absorber. The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.17. Ishii and Kobayashi [1991] report that it is a relatively radiation hard material, capable of withstanding gamma-ray dose between 10^4 and 10^5 rad before showing significant light absorbance. Because of its high gamma-ray absorption efficiency, thereby reducing patient dose, it has found practical use in the medical imaging industry [Cho and Farukhi 1977]. The most probable emission wavelength λ_{max} is 480 nm with a decay time of 300 ns. The absolute light yield at room temperature is approximately 8,200 photons/MeV, with a PMT response of only 13% relative to NaI:Tl; hence the gamma-ray energy resolution is poor by comparison to NaI:Tl. BGO also has a lower luminosity fast emission, yielding about 700 photons/MeV with $\tau = 60$ ns. With a relatively large refractive index of 2.15, it has a narrow critical angle of 44.2° at the glass interface of a PMT window, making light collection more difficult than with other inorganic compounds with lower indices of refraction. Overall, energy resolution of 15% FWHM is typical for 662 keV gamma rays [Nestor and Huang, 1975].

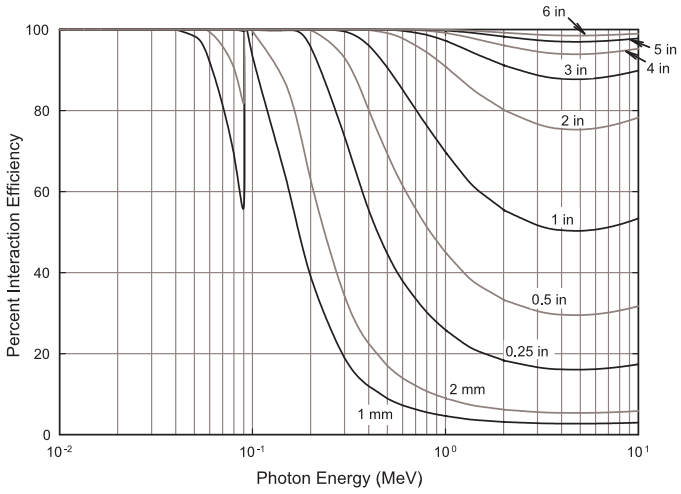

Figure 13.17. The calculated interaction efficiency for photons in BGO as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

BGO scintillates without an activator, the luminescence caused by intrinsic $^3p_1 \rightarrow {}^1s_0$ transitions of the Bi^{3+} ions in the crystals [Weber and Monchamp 1973]. The Bi^{3+} ion actually has a small band gap (about 2 meV) between the excited states $^3p_1$ and $^3p_0$ and, thus, has two different transitions, namely the $^3p_1 \rightarrow {}^1s_0$ and the $^3p_0 \rightarrow {}^1s_0$ [Rodnyi 1997]. These two possible transitions help explain the appearance of two

emission wavelengths and decay times. The Stokes shift is large enough such that BGO is transparent to its luminescent photons. BGO light yield is significantly dependent upon temperature and shows high thermal quenching above room temperature. Provided that an adequately long electronic shaping time is applied, the absolute light yield of BGO at 77 K can be double its room temperature yield (see Fig. 13.8). Ivanov et al. [1987] report an increase of relative quantum efficiency, compared to NaI:Tl, of 0.13 at room temperature, increasing to 0.44 at 80 K.

Lanthanide Scintillators

Lanthanide halides are those scintillators with the chemical makeup of AB_3, where A is an element in the lanthanide series and B is a halide. These scintillators are generally very hygroscopic and fragile, but many possess outstanding absolute light yield, good relative light yield proportionality, fast decay times, good gamma-ray absorption efficiency (Fig. 13.18), and ultimately superior energy resolution compared to NaI:Tl. Several are now commercially available, although mainly in sizes of 3 × 3 in right cylinders or smaller. For scintillators with the element La as a main constituent, a deficiency is the presence of ^{138}La, which is radioactive with a natural abundance of 0.09%. It emits low energy beta particles along with 1435.8 keV (BR = 0.7) and 788.7 keV (BR = 0.3) gamma rays. Although the gamma-ray emissions can be used as intrinsic calibration energies, they unfortunately also produce an intrinsic radiation background.

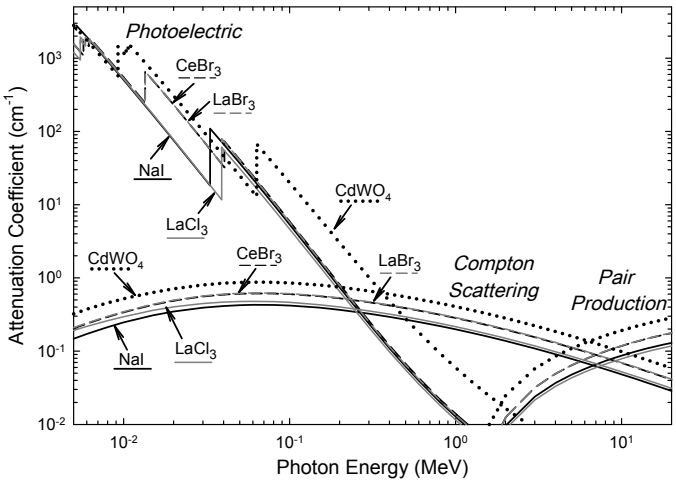

Figure 13.18. Gamma-ray linear attenuation coefficients for a few lanthanide scintillators as compared to NaI. Data are from [NIST XCOM].

Cerium Bromide ($CeBr_3$) Cerium bromide is a lanthanide halide scintillator that has received much attention in recent years. Although it was synthesized as early as 1899 [Muthman and Stüzel 1899], only recently was it recognized as a bright luminescent radiation detection material [Shah et al. 2005]. $CeBr_3$ has a density of 5.1 g cm^{-3}, and with constituent elements Ce ($Z = 58$) and Br ($Z = 35$) it has good gamma-ray absorption efficiency. $CeBr_3$ has a hexagonal crystal structure, is hygroscopic and fragile, easily cleaving along the slip planes [Doty et al. 2007]. The most probable light emission is at 390 nm with a decay constant of 19 ns. The reported light yield is approximately 68,000 photons per MeV [Shah et al. 2005], and the relative light yield is reasonably proportional above 100 keV, although less so than $LaBr_3$:Ce for energies below 100 keV [Khodyuk and Derenbos 2012, Quarati et al. 2013]. Luminescence from $CeBr_3$ arises from an excited state of the Ce^{3+}, and it does not require an activator dopant. It has a refractive index of 2.09 at λ_{max} with a critical angle of 45.9° at a common glass interface and with such a high refractive index, significant amounts of light can be lost from internal reflections. Regardless, energy resolution of 3.2% FWHM at 662 keV was reported for $CeBr_3$ doped with Ca^{2+} [Guss et al. 2014]. Methods have been implemented to address the fragility of $CeBr_3$, and other lanthanide halides, using aliovalent doping to inhibit cracking and had some promising success [Harrison et al. 2009]. Tests with gamma-ray irradiation indicate that $CeBr_3$ can withstand dose exceeding 100 kGy with only a minor decrease is energy resolution performance [Drozdowski et al. 2008b].

Lanthanum Chloride ($LaCl_3$:Ce) Cerium activated lanthanum chloride ($LaCl_3$:Ce) was reported by van Loef et al. in 2001 as a new bright scintillator that can perform in a fashion similar to that of NaI:Tl. The combination of a low mass density of 3.84 g cm^{-3} and only one substantial Z number atomic constituent La (57) yields $LaCl_3$:Ce gamma-ray detection efficiency similar to that of NaI:Tl. The material is very hygroscopic and brittle, and has a hexagonal crystal structure that cleaves easily along the {100} planes.[19] The most probable emission wavelength for $LaCl_3$:Ce λ_{max} is 350 nm, which unfortunately is not well matched to common PMTs and results in a loss in sensitivity to the light emissions. The refractive index is 1.9, which produces a critical angle of 52.1° with a glass interface. The absolute light yield is 49,000 photons/MeV, which is higher than NaI:Tl, but because of the spectral mismatch, its photoelectron response with a bi-alkali PMT ranges between 70% to 90% of that measured with NaI:Tl. Commonly reported energy resolution is near 4.0% FWHM at 662 keV for various crystal sizes. The good energy resolution observed from $LaCl_3$:Ce is most likely due to the relatively good proportionality of the crystal for energies above 30 keV. It is also a fast scintillator with a decay constant of $\tau = 28$ ns. The light yield from $LaCl_3$:Ce decreases with decreasing temperature with an integration time constant of 1 μs; however, if the integration time constant is increased to 16 μs, the light output response is fairly constant over a wide range of temperatures (see Fig. 13.8).

Lanthanum Bromide ($LaBr_3$:Ce) Cerium activated Lanthanum bromide ($LaBr_3$:Ce) was reported in 2002 by van Loef et al. as a new scintillator that can perform with better energy resolution than that of NaI:Tl. After a lull in the discovery of bright scintillators capable of competing with NaI:Tl performance, the discovery of Ce activated $LaBr_3$ helped reenvigorate the search for bright scintillators. $LaBr_3$:Ce has a mass density of 5.06 g cm^{-3}, and with relatively large atomic constituents of 57 (La) and 35 (Br), it has good gamma-ray absorption efficiency. The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.19. The material is very hygroscopic and brittle, and has a hexagonal crystal structure that cleaves easily along the {100} planes.[18] The probable emission wavelength for $LaBr_3$:Ce λ_{max} is 380 nm, which matches well-enough with common PMTs. The refractive index is 1.9 that produces a critical angle of 52.1° with a glass interface. The absolute light yield is 63,000 photons/MeV, and its photoelectron response with a bi-alkali PMT ranges between 130% to 165% of that measured for NaI:Tl. The energy resolution achieved is quite excellent for a scintillation, with reported values below 2.9% FWHM at 662 keV for various crystal sizes. The excellent energy resolution is a combined effect of the absolute light yield and the good relative light yield proportionality. It is also a fast scintillator with a decay constant of $\tau = 16$ ns, a time which requires that the light detection device be capable of following such a fast and bright light output without causing space charge buildup.[20]

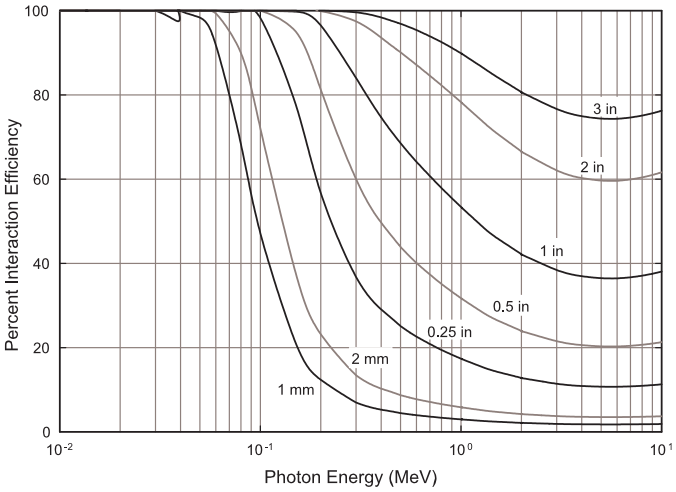

Figure 13.19. The calculated interaction efficiency for photons in $LaBr_3$ as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

[19] or, more traditionally, the $\{10\bar{1}0\}$ planes.

[20] Charge buildup from dense electron packages in a PMT can alter the internal voltage and produce non-linear output spectra.

Alternative activator co-dopants have been explored with $LaBr_3$:Ce scintillators, including Li, Na, Mg, Ca, Sr, and Ba as co-dopants to Ce [Alekhin et al. 2013a]. Of these, usage of Sr as a co-dopant with Ce shows excellent improvement, reported as approaching 2% FWHM for 662 keV gamma rays from ^{137}Cs [Alekhin et al. 2013b]. This improvement in energy resolution is attributed to a reduction in scintillation light losses from competing radiationless recombination processes and also an observed increase in light yield. Consequently, the light response linearity is improved, even in the low energy region between 10 to 100 keV [Alekhin et al. 2013b]. A drawback to co-doping with Sr is typically longer, and multiple, decay times, including some phosphoresence with decay times in microseconds.

Rare Earth Orthosilicates

Gadolinium Oxyorthosilicate (Gd_2SiO_5:Ce or GSO:Ce) Gadolinium oxyorthosilicate is a lanthanide silicate scintillator discovered in 1982 by Takagi and Fukazawa. It has one element with a high Z constituent (Gd $Z = 64$, Si $Z = 14$, O $Z = 8$) and also a density of 6.71 g cm^{-3} and, thus, makes it a relatively efficient absorber of gamma rays. GSO has a monoclinic crystal structure and is not hygroscopic. Doped with the activator Ce, it has a fast decay component of 60 ns and a slow decay component of 600 ns. The light yield of the fast component is about 8,000 photons/MeV with about 20% light response to a common bi-alkali PMT compared to that of NaI:Tl, and the light yield of the slow component is about 1,000 photons/MeV [Rodnyi 1997]. The most probable decay component is centered at $\lambda_{\max} = 430$ nm. This emission mechanism is believed to be mainly from self-trapped holes. GSO has an index of refraction of 1.85 which yields a critical angle of 54.2° at a glass interface and thus indicates that a large percentage of photons can be internally reflected. Energy resolution of less than 7.0% FWHM at 662 keV has been reported [Melcher et al. 1996, Kamae et al. 2002]. GSO has a natural radioactive background component from ^{152}Gd, which has a natural abundance of 0.2% and emits 2.14 MeV alpha particles.

The migration coefficient of Ce in GSO is near unity, meaning that the dopant is uniform throughout the crystal [Takagi and Fukazawa 1983]. A uniformity study performed by Ishibashi et al. [1998] indicated that the GSO doped with 0.5% mol Ce had less than 7% light variation over an ingot 280 mm long and 80 mm in diameter. With growth improvement, excellent results were achieved by Kurashige et al. [2004] with larger 100-mm diameter and 290 mm long crystals and produced only 0.42% standard deviation in light yield across the diameter and only 0.4% standard deviation along the length. Further, the decay constant was shown to be unaffected by small changes in Ce distribution and were found to have less than standard deviations of 1.7% longitudinally and 1.0% standard deviation radially.

Studies show that GSO is somewhat non-proportional over a wide energy range [Balcerzyk et al. 2000], but has better proportionality than either LSO or YSO. GSO is also a thermally stable scintillator, and had been used for oil well logging [Roscoe et al. 1992]. Due to its good gamma-ray detection efficiency and its superior energy resolution to that of BGO, it has also found some use in medical imaging PET instruments [Ficke et al. 1994].

The removal of impurities from the crystal improved light yield by a significant amount and increased the light yield by about 30% [Kamae et al. 2002]. Energy resolution for some of these samples was 6.7% FWHM at 662 keV. It was also found that co-doping with Zr improved light yield as well and increased the yield by 20% [Shimura et al. 2006], with best results having a Zr concentration of 200 ppm.

With the enormous thermal-neutron absorption cross section of natural Gd (49,000 b), GSO has been studied as a possible neutron detector by reliance upon either the prompt reactions ^{157}Gd(n,γ)^{158}Gd or ^{155}Gd(n,γ)^{156}Gd as the detection mechanism [Reeder 1994]. Conversion electrons and gamma-ray emissions can be detected after a neutron absorption, and the important characteristic emissions can be absorbed in only 75 μm of GSO. Unfortunately, GSO is also an efficient gamma-ray detector; hence, it is sensitive to background radiations that can be falsely interpreted as neutron induced events.

Lutetium Oxyorthosilicate (Lu_2SiO_5:Ce or LSO:Ce) Cerium activated lutetium oxyorthosilicate (LSO:Ce) is a relatively new scintillator discovered and developed by Melcher in 1990 [see Melcher 1990; Melcher 1991; Melcher and Schweitzer 1992; Daghighian et al. 1993]. The scintillator was originally developed for oil well logging measurements, but was found to have severely degraded energy resolution at the elevated temperatures typically encountered during oil well logging measurements. Further, the energy resolution was poor compared to common NaI:Tl detectors. However, it was measured to have 75% of the absolute light yield of NaI:Tl (about 31,000 photons/ MeV), which at the time was a tremendous breakthrough for inorganic scintillators [Daghighian et al. 1993]. LSO:Ce has a mass density of 7.4 g cm^{-3}, and with its large Z number constituent Lu (71), it has excellent gamma-ray absorption efficiency, comparable to that of BGO. The primary interaction efficiency as a function of gamma-ray energy and detector thickness is shown in Fig. 13.20. Daghighian et al. [1993] report two decay constants of 12 ns (30%) and 42 ns (70%), with a most probable emission wavelength λ_{max} of 420 nm. However, from various sources, the reported decay constant ranges between 37 ns to 47 ns [Rexon 2015; Ludziejewski et al. 1995]. It has relatively proportional light yield for gamma-ray energies greater than 200 keV, but not below 100 keV. The index of refraction is 1.82 which produces a critical angle of 55.5° at a glass interface. The crystal is robust, is not hygroscopic, and rates 5.8 on the Moh hardness scale. LSO:Ce has found good use as a replacement for BGO in PET scan systems [Daghighian et al. 1993]. It has 190% of the absolute light yield measured for common BGO crystals while having almost the same gamma-ray interaction efficiency. Energy resolution for 662 keV gamma rays as low as 10.3% FWHM have been measured, much better than that for BGO. Further, it is radiation hard, with a reported radiation limit of greater than 10^6 rads. A significant problem with LSO:Ce is that it is naturally radioactive because of ^{176}Lu (2.59% isotopic abundance) which emits beta particles and gamma rays. This problem is further exacerbated by unintentional doping with other radioactive impurities from the crystal growth source materials. However, for specific applications such as PET measurements, which uses coincidence counting, this natural background is of less concern. Another problem is that LSO:Ce has long phosphorescence, which has been measured to last several seconds [Szupryczynski et al. 2004]. Nassalski et al. [2007] generally concluded the long phosphorescence precludes LSO:Ce from application in CT systems because of the detector requirements.

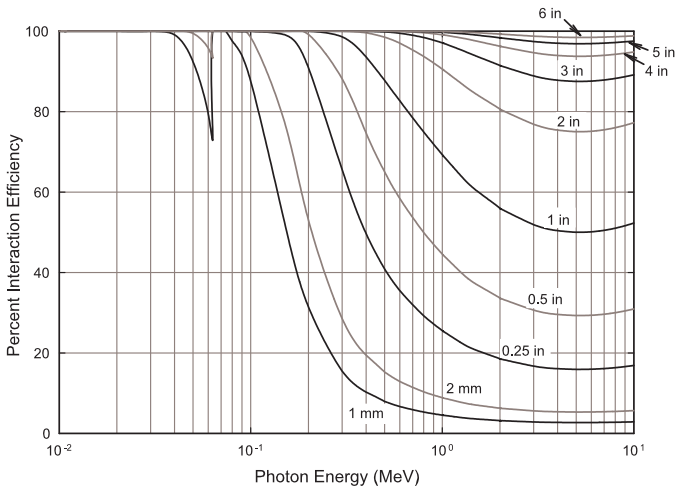

Figure 13.20. The calculated interaction efficiency for photons in LSO as a function of energy and detector depth. The probability of an initial interaction is shown and not the probability of subsequent or multiple interactions.

Yttrium Oxyorthosilicate (Y_2SiO_5 or YSO:Ce) Ce-doped yttrium orthosilicate (YSO:Ce) is a non-hygroscopic rare-earth oxyorthosilicate. The material has a density of 4.45 g cm^{-3}. YSO is disadvantaged as a gamma-ray spectrometer because of its relatively low Z number constituents (the largest is $Z = 39$ for Y) and moderate mass density. YSO:Ce has a most probable wavelength λ_{max} of 420 nm and relatively good energy proportionality above 100 keV [Cutler et al. 2009]. The decay constant τ is about 50 ns. Commercial YSO:Ce usually has an absolute light yield around 10,000 photons/MeV [Melcher 1996], although a higher light yield of about 24,000 photons/MeV has been reported for optimized crystals [Balcerzyk 2000, Cutler 2009]. Co-doping with Ce/Ca has been studied with reportedly small effect and produced an absolute light

yield of 21,200 photons/MeV. The index of refraction is 1.8 to produce a critical angle of 56.4° at a glass interface. The reported energy resolution often is 9.0% to 9.4% FWHM for 662 keV gamma rays, although energy resolution as low as 7.4% FWHM has been reported [Dahlbom et al. 1997].

Lutetium Yttrium Oxyorthosilicate ($Lu_{1.8}Y_{0.2}SiO_5$:Ce or LYSO:Ce) Lutetium yttrium oxyorthosilicate (LYSO:Ce) has been grown in an attempt to include the main advantages of both LSO and YSO crystals [Cooke et al. 2000; Pepin et al. 2004; Chen et al. 2007]. LYSO:Ce is a commercially available scintillator with similar properties as LSO:Ce [Rexon 2015, Omega 2016]. In summary, the density of LYSO is 7.4 g cm^{-1} with a refractive index of 1.82. The decay constant has been measured to be between 40 and 44 ns with a most probable emission wavelength between 420 and 428 nm. It has similar radiation hardness (greater than 10^6 rad) as LSO, but it produces increased afterglow phosphorescence with increased radiation damage. The light yield is also the same as LSO, at approximately 31,000 photons/MeV. It is robust, non-hygroscopic with a Moh hardness of 5.8. Energy resolution is similar to that of LSO, near 10% FWHM for 662 keV [Chen et al. 2007]. Because of the natural abundance of ^{176}Lu, it also has an intrinsic radioactive background. Cooke et al. [2000] report lower temperature dependence on light yield than observed with LSO. Further, Cooke et al. [2000] note that the main advantages to LYSO over LSO are lower production costs, fewer inclusion defects in the crystals, and easier incorporation of the Ce activator dopant in the crystal lattice.

Elpasolites

Elpasolites[21] are a new class of scintillators of the form A_2BRX_6, where A and B are alkali metals, R is a rare earth, and X is a halogen. They have essentially a double perovskite structure, and many maintain a cubic structure over a broad range of formations [see Doty et al. 2012]. The possible combinations number in the thousands, and several have been identified as potentially good scintillators for gamma-ray spectroscopy and neutron detection [Gundiah et al. 2014; Wei et al. 2014; Doty et al. 2012]. Listed here are only a few combinations that show promise.

Cesium Lithium Yttrium Chloride (Cs_2LiYCl_6:Ce or CLYC:Ce) The relatively new cesium-based elpasolite scintillator Cs_2LiYCl_6:Ce, or CLYC:Ce, is a dual-use inorganic scintillator that can detect both gamma rays and neutrons. It has a density of 3.31 g cm^{-3}, with its highest Z component being Cs ($Z = 55$). However, the actual density of Cs atoms comes to 6.94×10^{21} cm^{-3}, approximately 66% of the atomic fraction for CsI, with an effective atomic number Z_{eff} of 44.5 [Lecoq et al. 2006]. CLYC:Ce is hygroscopic and, thus, must be encapsulated. The refractive index of CLYC is 1.81, which produces a critical angle at a common glass interface of 56°. CLYC:Ce has decay constants at 600 ns and 6 μs both of which are relatively long for most scintillator applications [Combes et al. 1999]. The luminescent emissions for Ce doped CLYC are centered at 372 nm and 400 nm, while undoped CLYC has a single emission centered at 305 nm [Combes et al. 1999]. With a 1 μs shaping time, between 7,000 photons/MeV (no Ce doping) to 10,200 photons/MeV (3% Ce doping) are observed. With a longer shaping time of 10 μs, between 22,000 photons/MeV (no Ce doping) to 10,800 photons/MeV (3% Ce doping) are measured. Despite the relatively low light yield and long decay constants, good energy resolution has been reported for CLYC:Ce, as low as 4.2% FWHM for 662 keV gamma rays [RMD 2016].

The lithium constituent of CLYC:Ce allows neutron detection through the ^{6}Li(n,^{3}H)^{4}He reaction. For natural Li as a constituent, the atomic density of ^{6}Li in CLYC is 2.6×10^{20} cm^{-3} to produce a macroscopic cross section for the ^{6}Li(n,^{3}H)^{4}He reaction of 0.248 cm^{-1}, or an absorption length of about 4 cm. If the Li is replaced with enriched ^{6}Li, the thermal-neutron absorption macroscopic cross section can be increased to 3.27 cm^{-1}, and the absorption length is reduced to 3 mm. Unfortunately, CLYC also has competing neutron absorbers, mainly Cl ($\sigma_{Cl} = 33.5$ b) and Cs ($\sigma_{Cs} = 28$ and 2.6 b), that ultimately limit its neutron detection

[21] The etymology comes from the location where these minerals were first found in El Paso County, Colorado, USA.

efficiency. With six halogen atoms per molecule, the neutrons lost to parasitic absorptions can be significant, limiting the maximum thermal neutron detection efficiency to approximately 22% for CLYC:Ce loaded with natural Li and approximately 78% neutron detection efficiency for CLYC:Ce loaded with enriched ^{6}Li.

There is also a core valence emission, with a decay constant of 2 ns with a yield of 660 photons/MeV (no Ce doping) to zero photons/MeV (3% Ce doping), produced by the radiative recombination of a valence electron with a core hole [Bessiere et al. 2005]. This core valence emission appears under gamma-ray irradiation, but not under alpha particle irradiation. Hence, detection of this emission can be used to distinguish between gamma-ray and heavy charged particle emissions such as those produced from neutron interactions.

Cesium Lithium Lanthanum Bromide ($Cs_2LiLaBr_6$:Ce or CLLB:Ce) Also new is the cesium-based elpasolite scintillator $Cs_2LiLaBr_6$:Ce, or CLLB:Ce, which also has dual use as a gamma-ray and neutron detector. It has a density of 4.2 g cm^{-3} and its highest Z components are Cs ($Z = 55$) and La ($Z = 57$). The density of Cs and La atoms comes to 8.51×10^{21} cm^{-3}, approximately 81% of the atomic density of Cs in CsI.

CLLB:Ce has multiple decay constants at 55 ns and at about 270 ns, and there is no reported core valence emission for CLLB. The luminescent emissions for Ce doped CLLB:Ce are centered at 390 nm and 420 nm [Shirwadkar et al. 2011]. With Ce doping, the luminescent yield is between 50,000 photons/MeV and 60,000 photons/MeV [Glodo et al. 2011; Shirwadkar et al. 2011]. This high light output, along with the fact that the luminescent yield is more proportional than that found with CLYC:Ce, indicates that CLLB:Ce is a promising new scintillator. Indeed, energy resolution of 3.0% to 2.9% FWHM for 662 keV gamma rays has been reported [Glodo et al. 2011; Shirwadkar et al. 2011].

As with CLYC:Ce, the lithium constituent of CLLB:Ce enables neutron detection through the ^{6}Li(n,^{3}H)^{4}He reaction. For natural Li as a constituent, the atomic density of ^{6}Li in CLLB is 2.16×10^{20} cm^{-3} to produce a macroscopic cross section for the ^{4}He(n,^{3}H)^{4}He reaction of 0.2027 cm^{-1}, or an absorption length of 4.93 cm. If the Li is replaced with enriched ^{6}Li, the thermal neutron absorption macroscopic cross section can be increased to 2.67 cm^{-1} and the absorption length is reduced to 3.75 mm.

Other Notable Elpasolites Other bright elpasolite scintillators that show promise include cerium activated Cs_2NaLaI_6:Ce, $Cs_2LiLaCl_6$:Ce, $Cs_2NaLaBr_6$:Ce, and Cs_2LiLaI_6:Ce. These scintillators are relatively proportional, provide good light yield, and have short decay constants on the order of 50 ns [Doty et al. 2012]. Kerisit et al. [2014] report that elpasolites with Br as the halogen rather than Cl should theoretically have higher light yields and quote theoretical light yields above 100,000 photons/MeV for $Cs_2LiLaBr_6$:Ce and Cs_2LiYBr_6:Ce. Gundiah et al. [2014] report a good light yield of about 46,000 photons/MeV for $Cs_2NaLaBr_6$:Ce with an energy resolution of 3.9% FWHM at 662 keV. Two emission maxima were observed at 387 nm and 415 nm, both adequately matched to a bi-alkali PMT. A recent introduction to the elpasolite family that shows great promise is $Cs_2LiLa(Br_{6-x}Cl_x)$ or CLLBC:Ce, which has good gamma-ray energy resolution ($\sim$ 3% FWHM at 662 keV) and retains the neutron detection characteristic of CLYC:Ce [Shirwadkar et al. 2012]. The substitution of Br for Cl works to reduce parasitic neutron losses, while the substitution of La for Y works to slightly increase parasitic neutron losses.

Rb_2LiYBr_6:Ce, and many others, show bright light output for neutron absorption [Birowosuto et al. 2008]. Rb_2LiYBr_6:Ce produces prompt reaction products from the ^{6}Li(n,^{3}H)^{4}He reaction, producing between 59,000 $\pm$ 5,400 to 83,000 $\pm$ 8,300 photons per neutron capture, depending on the Ce^{3+} doping concentration (between 0.1 and 0.5 %). The light yield for gamma rays varies between 16,500 $\pm$ 1,600 to 23,000 $\pm$ 2,300 photons/MeV for Ce^{3+} for concentrations between 0.1$ and 0.5%, respectively. It has at least three main decay components, reported as 71 ns (31%), 400 ns (53%), and 1400 ns (16%). Energy resolution for 662 keV gamma rays was reported as low as 4.6% FWHM [van Eijk et al. 2005]. The difference in light output

between gamma-ray interactions, along with good energy resolution, allows pulse height discrimination between neutron and gamma-ray events.[22]

Ceramic and Glass Scintillators

Methods of producing fully transparent ceramic scintillators were initially developed by GE Corporation [Cusano et al. 1980; Dibianca et al. 1985] and ceramic casting offers an alternative method of scintillator production to that of growing a single crystal. Although each type of scintillator may have unique manufacturing processes particular to the material, there are several steps generally applicable to the manufacture of ceramic scintillators. The materials should be very pure (greater than 99.99%), near 100% phase purity, a total high specific surface area greater than 5 m^2g^{-1}, and a median particle size of 3 microns or less [Greskovich and Duclos 1997]. The general process involves the production and subsequent introduction of nanoparticles of scintillator material into a vessel for compaction. This unfired material is usually termed a "green" ceramic. The green ceramic is then mixed with the requisite scintillator host and fluorescent activator dopants. This mixing is one of the main advantages of the ceramic process because the desired activator concentration can be maintained in the ceramic far more easily than with the traditional crystal growth method. The compacted material is heat treated to temperatures of approximately 1,200°C in air, followed by vacuum sintering (at about 10^{-6} torr) at temperatures up to 2,000°C. Finally, hot pressing at pressures up to 29,000 psi in argon and at a temperature of 2,000°C is used to achieve a maximum density. The final product is a ceramic billet with grain sizes on the order of 10 microns.

There are multiple advantages to ceramic scintillators, namely they have a high radiation hardness compared to halide single crystals, they have relatively low production costs, they are hard and non-hygroscopic, they are machinable, they are environmentally robust, and they can be manufactured in large sizes that might be difficult to produce as single crystals. Among the earliest materials investigated as ceramic scintillators were BaFCl:Eu, LaOBr:Tb, CsI:Tl, $CaWO_4$, and $CdWO_4$ [Cusano et al. 1980]. Cubic crystal structure has been identified as a condition for successful production of high light yield ceramic scintillators [Debianca et al. 1985]. Non-cubic crystals have increased refraction at the grain boundaries that increases light self-absorption and ultimately decreases light yield. Unfortunately, the crystal grains for the materials listed in the patent by Cusano et al. [1980] are non-cubic, except for that of CsI:Tl which is hygroscopic. Bixbyite ceramic scintillator structures[23] were investigated by Debianca et al. [1985], and include Gd_2O_3, Y_2O_3, La_2O_3, Lu_2O_3. Neither Gd_2O_3 nor La_2O_3 are cubic in form, but are made cubic by incorporating about 50 mole percent of Y_2O_3 into the ceramic. Both Y_2O_3 and Lu_2O_3 are cubic structured. Lu_2O_3:Eu has been developed for x-ray imaging [Lempicki et al. 2002] and has reported properties of 9.4 g cm^{-3} mass density, a λ_{max} of 610 nm, a light yield of about 60% of that of CsI:Tl, and a long decay time constant τ of 1.3 ms. The production of $(Y,Gd)_2O_3$:Eu ceramic scintillators led to their incorporation in CT scanners [Duclos et al. 2003]. The reported properties of $(Y,Gd)_2O_3$:Eu are a λ_{max} of 611 nm, a decay constant τ of 960 μs, and an optical attenuation coefficient of 1 cm^{-1}.

Numerous ceramic scintillators have been investigated and much significant progress has been achieved in recent years. These ceramics include various garnets, perovskites, bixbyites, and pyrochlores[24] [Cherepy et al. 2008]. Two interesting ceramic scintillators recently developed are $Gd_{1.5}Y_{1.5}Ga_2Al_3O_{12}$ (GYGAG) and $Gd_{0.3}Lu_{1.6}Eu_{0.1}O_3$ (GLO) [Cherepy et al. 2014, 2015]. Cerium doped gadolinium yttrium gallium aluminum garnet (GYGAG), $(Gd,Y)_3(Ga,Al)_5O_{12}$ or GYGAG:Ce, have been under development for many years. The

[22] Note that the Q-value for the ^{6}Li(n,^{3}H)^{4}He reaction is 4.7 MeV, giving an upper light yield of about 17,300 photons/MeV as is similar to that for gamma-ray events. However, it is unlikely that gamma rays with energies approaching 4.78 MeV are fully absorbed, so discrimination is still possible.

[23] Named after Maynard Bixby, who discovered the ore in 1897.

[24] The etymology comes from the Greek $\pi\tilde{\upsilon}\rho$ (pyr = fire) and $\chi\lambda\omega\rho\acute{o}\varsigma$ (chloros = green) because pyrochlores often turn green with a common flame blowpipe analysis.

material is a robust transparent ceramic with mass density of 5.8 g cm^{-3} and an absolute light yield of approximately 50,000 photons/MeV. GYGAG:Ce has at least two decay times, a fast component at 250 ns and a slow component at 1.7 μs. This unfortunate slower component is thought to be a consequence of the energy transfer process in the scintillator [Cherepy et al. 2011]. Regardless, energy resolution of 4.5% FWHM at 662 keV has been reported for a GYGAG:Ce sample coupled to a PMT when operated with a 4 μs shaping time. Better energy resolution is achieved when coupled to a Si photodiode with reported values of 3% to 3.5% FWHM at 662 keV [Cherepy et al. 2015]. Cerium doped gadolinium lutetium europium oxide (GLO:Eu) is used for MeV-photon radiography. The material has a high mass density of 9.1 g cm^{-3} and an absolute light yield of approximately 55,000 photons/MeV [Cherepy et al. 2015].

Ce-activated glass scintillators were originally developed by Corning Glass Company, as evidenced from the patents listed in the literature [see Ginther and Schulman 1958]. Of these original scintillation glasses, it was Ce activated high silica glass that performed best [Ginther and Schulman 1958]. Shortly thereafter, Voitovetskii et al. [1960a, 1960b] reported different compositions of $Li_2O{\cdot}Si_2O$:Ce glass as neutron detecting scintillators. Ginther [1960] determined that a bright variation of a Li glass scintillator was a mixture of 26% MgO, 13% $LiO_{0.5}$, 10% $AlO_{1.5}$, 50% SiO_2, and 1% $CeO_{1.5}$, which yielded a light yield of 14% of that of NaI:Tl (nominally 5,000 to 6,000 photons/MeV) and has a most probable emission wavelength of about 390 nm. The Ginther and Schulman study revealed that contaminants in the glass can adversely affect brightness, especially for alkali earths Ca and Ba contaminants.

Glass scintillators can be machined or formed into various shapes that may not be achievable with common crystalline solids. Further, glass scintillators are relatively robust and shock resistant, and glass scintillators have a relatively constant light yield over a wide range of temperatures. These scintillators are used for a variety of applications, including neutron detection, oil well logging, and charged-particle detection in extreme environments. Modern commercial Ce-activated Li glass scintillators can be acquired with different Li activator concentrations and enrichments such as natural Li, 96% enriched ^{6}Li, and fully depleted of ^{6}Li. Glass scintillators with ^{6}Li can be used for combined neutron and gamma-ray detection, whereas glass scintillators depleted of ^{6}Li can be used in mixed radiation fields when neutron induced counts are undesirable. The resulting neutron attenuation efficiencies for various commercial Li glasses are shown in Fig. 13.21. The decay times generally range between 20 to 105 ns, and depend on the Li concentration and the type of radiation particles interacting in the scintillator. These scintillators have higher light yields for irradiation by electrons than by alpha particles, with an α/β ratio of about 0.23. Glass density is also a function of Li concentration, ranging from 2.42 g cm^{-3} for 24% Li up to 2.64 g cm^{-3} 7.5% concentration [Scintacor 2016]. The light yield of these glass scintillators is reported to be between 20% and 30% of that of anthracene (or 8.7% to 13% of NaI:Tl), depending on the type of glass and Li concentration. The index of refraction varies between 1.55 to 1.58 at the peak emission wavelength [see Table 13.2, also Applied Scintillation 2016].

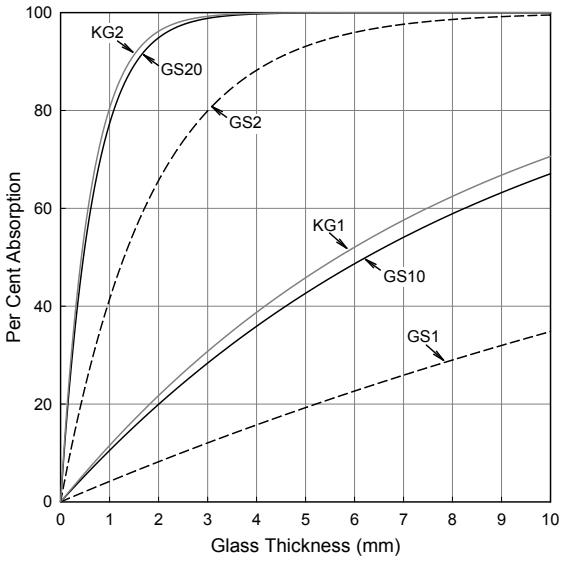

Figure 13.21. Thermal (2200 m s^{-1}) neutron absorption efficiency for various commercial Li glasses. Properties are listed in Table 13.2.

Other scintillating glasses have been explored and include boron-based scintillating glass and Li glasses that have been activated with either Tb or Eu. Boron-based glass scintillators have lower light yields than Li

Table 13.2. Properties of some commercial Ce activated ^{6}Li-glass (natural Li/ 95% enriched ^{6}Li) .

Glass Designation	GS1/GS2	GS10/GS20	KG1/KG2

glasses, and consequently have less practical application [Bollinger et al. 1962]. Glasses with Tb activators have higher light yields than Ce activated glasses, up to 50,000 photons/MeV [Pavan et al. 1991], and are reported to be 2 to 3 times more radiation hard than Ce activated glasses. However, the most probable wavelength of emission is around 550 nm with long decay times of about 3 to 5 ms. Glasses with Eu as the dopant were found to have a slightly higher light yield than that of Ce activated glass [Fujimoto et al. 2015], namely about 110% of that of a common GS20 Li glass scintillator. The most probable wavelength of emission is near 450 nm with a relatively long decay time of 1230 ns [Fujimoto et al. 2015].

13.3 Organic Scintillators

Because the energy bands and corresponding energy levels in inorganic solids appear as a consequence of a periodic potential, dissociation of the solid either through melting, decomposition, or solvation usually eliminates the luminescence. Organic scintillator luminescence originates from molecular π bonds and, thus, is fundamentally different from inorganic solids that emit light from luminescent centers such as defects and impurity dopants in a crystalline lattice. Organic scintillators depend primarily on the molecular structure of the material for the scintillation mechanism, and as a result, organic scintillators can emit photons as either solids, liquids, or gases.

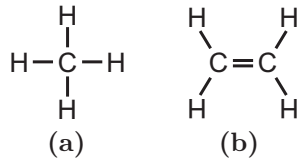

Figure 13.22. Common depiction of σ and π bonds. In (a), methane is formed by four σ bonds between carbon and four hydrogen atoms. In (b), ethylene is formed with a σ bond and a π bond between the two carbon atoms, with the remaining four hydrogen atoms forming σ bonds with the carbon atoms.

Overlapping s and p orbitals can form a strong σ bond, for instance, as is the case of methane in which the four electrons in the carbon p orbitals combine with the s orbital electrons of four hydrogen atoms to produce CH_4. As described with fundamental organic chemistry, π states appear from the formation of π bonds, which occur when two p orbitals overlap in a side-by-side configuration. For instance, the simple molecule of ethylene (C_2H_4) is formed with the two carbon atoms sharing electrons in two p orbitals, the first producing a σ bond and the second forming a parallel π bond, while the remaining electrons form σ bonds with hydrogen atoms (Fig. 13.22).[25] Although a π bond is weaker than a σ bond, together they

[25]The graphic depiction in Fig. 13.22b is usually used in organic chemistry to depict a π bond. However, the bond should be more correctly thought of as a single strong electron bond between the carbon atoms with a weaker associated bonded electron traveling in the vicinity of the bond.

produce a stronger bond than either individually. The π bond is a common building block for many organic scintillation materials, such as found in benzene rings (Fig. 13.23).

In Fig. 13.24 an energy diagram is shown that is typical of an organic scintillator. An independent molecule of organic scintillation material can have an electron excited through the π states up from the ground state into an excited singlet state, of which there are many levels. Hence, electrons in the molecule can be excited through molecular states rather than atomic states.

There are many vibrational states associated with the ground states, typically denoted by S_{0x} in which x refers to one of the vibrational sub-states. There are also numerous excited singlet states as well as excited triplet states associated with the carbon π bonds. Electrons that gain energy rise to one of the excited vibrational states and generally fall rapidly to the lowest S_{10} state, which then de-excite through two possible channels. If the electrons de-excite directly from the S_{10} state to one of the S_{0x} states, the light emission is rapid and is referred to as scintillation fluorescence. Decay times for fluorescence are typically only a few nanoseconds, and fluorescent emission can be easily linked to individual radiation events. However, if the electrons de-excite by crossing to the triplet states T_{1x} and then fall to one of the S_{0x} states, the light emission is slow and is referred to as scintillation phosphorescence. This second light producing mechanism is undesirable because phosphorescent emission is slow and continues to produce afterglow for extended periods of time and, hence, cannot be directly linked to individual radiation events, especially in high-radiation fields. Regardless, the main point to notice is that organic scintillators depend on the organic structure, often a benzene ring structure, and do not need activator dopants for the scintillation mechanism. Hence, they also do not need to be crystalline or polycrystalline in structure. As a result, organic scintillators can be formed as solids, liquids, gases, and plastics. Some common organic scintillators are listed in Table 13.3.

Organic scintillators are composed mostly of hydrogen and carbon, both of which are poor absorbers of gamma rays. They are also notoriously non-linear in light output for heavy ion radiation. However, they are much more linear in response to electrons and beta particles, and the low atomic numbers for the constituents tend to make light ion backscattering almost negligible. Hence, organic scintillators are usually used for beta particle and electron detection.

Another use for hydrogen rich detector materials is fast neutron detection. As discussed in Chapter 4, and later Chapter 18, energetic neutrons lose more energy by scattering from low A materials than high A materials. Fast neutrons scatter off of the hydrogen and carbon in the organic scintillator, producing recoil hydrogen and carbon atoms that then slow down by causing ionization and excitation of other molecules in the organic scintillator. Because organic scintillators depend on molecular structure for light emission, other materials can be mixed in the scintillator without destroying the scintillation process. For instance ^{10}B, ^{6}LiF, or Gd can be mixed into an organic solution or a plastic to make them more sensitive to neutrons. Likewise, heavy metal particles, such as Pb, can be mixed into the organic or plastic to make them more sensitive to gamma rays. There is of course a limit to the amount of absorber material that can be added because the scintillator transparency reduces with increases in foreign material.

Overall, organic scintillators provide an excellent option when a larger less expensive detector is needed. Although not well suited for use in gamma-ray spectroscopy, they are quite useful as beta particle and fast neutron detectors. Moreover, because these detectors are composed of hydrogen, carbon, and oxygen with an average density of 1.032 g cm^{-3}, they make near "tissue equivalent" detectors, which is desired for dosimetry measurements.

13.3.1 Theory of Scintillation for Organic Scintillators

Radiation absorption within an organic scintillator produces energetic electrons, or recoil nuclei, that can continue to travel through the scintillator and excite more electrons. There are many possible vibrational and rotational energy levels and, consequently, the ground state (S_0) and the singlet and triplet states (S_1

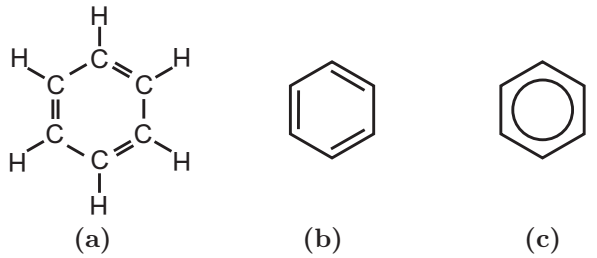

Figure 13.23. Three representations of a benzene ring. The shorthand version of (b) or the modern shorthand version (c) are now in more common usage. It is assumed that the "corner" carbon atoms of the benzene ring are attached to hydrogen atoms unless otherwise indicated.

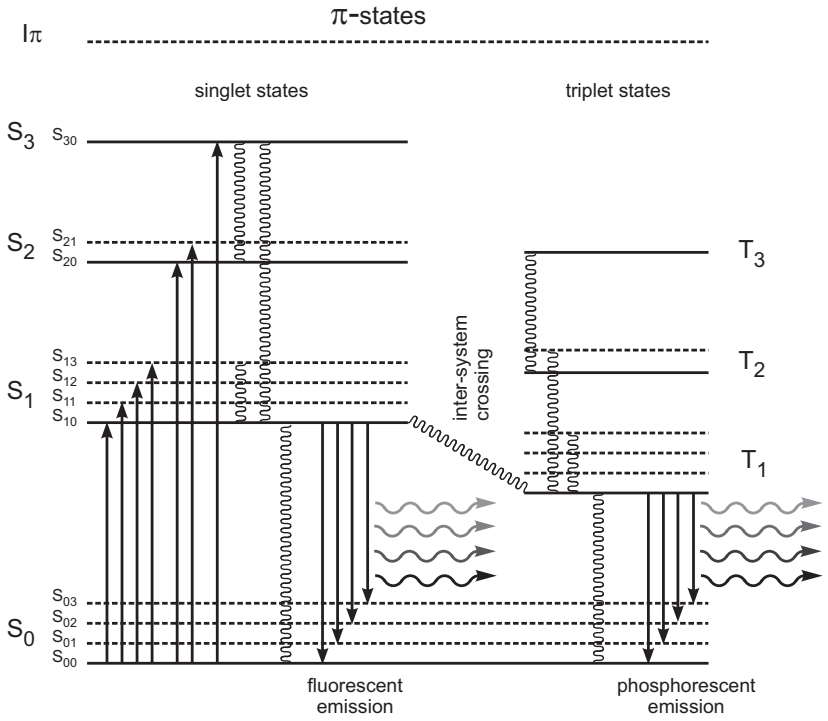

Figure 13.24. Jablonski diagram of the two basic methods by which an organic scintillator produces light. π electrons in the organic molecule are excited into upper vibrational states from a radiation event and rapidly de-excite to the lowest S_{10} state. Electrons that then de-excite directly to the S_{0x} states contribute to scintillation fluorescence. Those electrons that transfer to the triplet states fall to the T_{10} state, and gradually de-excite to the S_{0x} states, a process known as phosphorescence. Straight arrows are radiative transitions, while "squiggly" lines indicate non-radiative transitions. After Birks [1964].

Table 13.3. Common organic scintillator materials and their properties. The light yield is units of % that of anthracene, which, for comparison, is about 40% that of NaI:Tl.

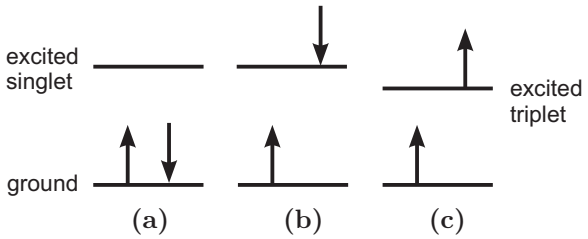

Figure 13.25. Shown are (a) an organic molecule singlet ground state, showing up and down spin of the electrons, (b) the singlet excited state, and (c) the triplet excited state. Note that the electron spins are alike in the triplet state, thereby through the Pauli exclusion principle, preventing the excited electron from dropping to the ground state.

and T_1) have many vibrational states. The energetic electrons are excited from the ground state into many of these possible vibrational states.

Electron spins are paired in singlet states, and the spin of an excited electron in a singlet state (S_{10} for instance) is still paired with the ground state electron. However, electrons in triplet states are no longer paired to electrons in the ground state, meaning they have identical spin and, therefore, cannot make the transition because of the Pauli exclusion principle (Fig. 13.25). Note that direct excitation to a triplet state from the ground state involves a forbidden spin transition and is, thus, improbable.

Electrons can be excited to upper singlet vibrational levels, which include the various S_1, S_2 and S_3 levels. The electrons in the higher S_1 levels quickly drop to the S_{10} state within about 10^{-12} seconds, while electrons in the higher S_2 and S_3 states rapidly relax to the S_1 through non-radiative processes. Electrons can also transfer to triplet states by $S_1 \rightarrow T_1$, a process referred to as non-radiative intersystem crossing, by which the spin of electron is reversed. The probability of intersystem crossing increases when the vibrational levels of the two excited states overlap, mainly because little or no energy must be gained or lost in the transition. Further, intersystem crossing apparently increases with molecules with high-Z atoms [Kearvell and Wilkinson 1968].

The relaxation process for $S_1 \rightarrow S_0$ is a spin-allowed transition and generally occurs on a times scale of a few nanoseconds. However, because $T_1 \rightarrow S_0$ is spin-forbidden, the transition takes significantly longer, on the order of μs to ms. This slow process of luminescence, thus, gives rise to phosphorescence.

As with luminescent centers in inorganic scintillators, there is also a Stokes shift with organic scintillators and can be understood by reviewing Fig. 13.2. However, now the vibrational states are molecular for organic scintillators. Shown in Fig. 13.26 is a depiction of the origins of the absorption and emission spectra from an organic scintillator. Electrons excited from the ground state (S_0) up to an excited vibrational state (S_1 states) quickly deexcite to the S_{10} state through non-radiative processes. Because there are many possible excited vibrational states, the absorption efficiency is a function of the allowed transitions (see

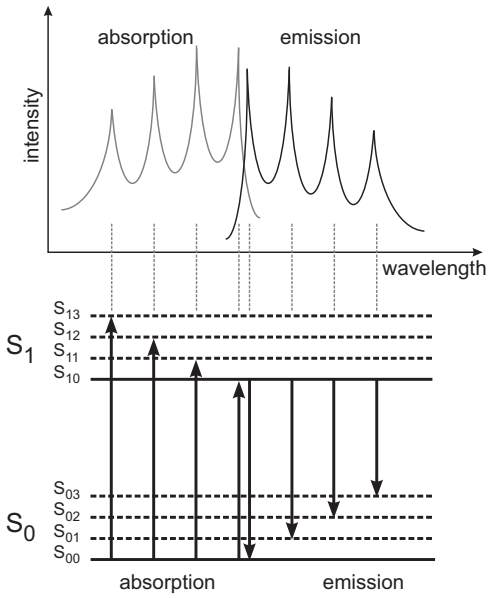

Figure 13.26. Depiction of absorption and emission spectra from an organic scintillator. Adapted from Adachi and Tsutsui [2007].

Fig. 13.26). These excited electrons can radiatively deexcite to the many possible ground states, which release photons at wavelengths corresponding to the energy loss between the different states. The luminescent transition from $S_{10} \rightarrow S_{00}$ appears identical to the absorption transition $S_{00} \rightarrow S_{10}$, but is in fact of lower energy because of the Stokes shift.

Light Yield

Solid organic scintillators generally produce higher light yields than organic liquids or gases primarily because of the efficient transfer of energy between luminescent centers. Although organic scintillators should produce the same luminescent spectrum in either a solid or as independent molecules, significant changes can be observed because intermolecular complexes that can form between molecules in a solid and because of the differences in the energy transfer mechanism between molecules [Adachi and Tsutsui 2007]. Impurities in the organic crystal can also change the luminescent spectrum because efficient energy transfer allows trace impurities to become the primary luminescent center rather than the host molecule.

Studies performed by Bowen et al. [1949] with mixtures of organic crystals lead to the hypothesis that energy transfer between organic molecules was substantially due to exciton transfer. This transfer sequence would progress until the exciton was ultimately captured. Birks and Black [1951] showed that light output decreased in anthracene when electron irradiation was replaced by alpha particle irradiation. The explanation for this light reduction is that the damage caused by heavy ions created competing trapping centers, which could also capture excitons, and as a result caused luminescent quenching. From these observations, a semi-empirical dependence of light yield as a function of energy deposition was proposed by Birks [1951]. The number of excitons produced in the scintillator per unit path length of travel by the radiation particle can be described by $A(dE/dx)$ where A is a proportionality constant and dE/dx is the ion energy loss (or energy deposition) per unit pathlength of travel. Further, the local concentration of ionized molecules, excited molecules, and damaged molecules along the ion path, can be described by $B(dE/dx)$, where B is also a proportionality constant. If one defines k as the probability that an exciton is lost to a non-radiative transition, the specific fluorescence is[26]

$$\frac{dL}{dx} = \frac{A\ dE/dx}{1 + kB\ dE/dx}, \tag{13.36}$$

where the product kB is the quenching parameter. If the energy loss is small, or the corresponding damage is small, as observed with fast electrons and beta particles, then Eq. (13.36) reduces to

$$\frac{dL}{dx} \approx A\frac{dE}{dx}, \tag{13.37}$$

which shows a linear relationship with light yield and energy deposition. However, if the energy loss is large, and the corresponding damage is significant, such as that produced by protons, alpha particles and fission fragments,

$$\frac{dL}{dx} \approx \frac{A}{kB}, \tag{13.38}$$

which implies constant light output regardless of energy deposition. For most organic scintillators, fast electrons and beta particles with energies above 125 keV do in fact have a relatively linear light yield response. For slow electrons and beta particles with energies below 125 keV, dE/dx increases and produces

[26] Equation (13.36) is often referred to as "Birks' Equation" or "Birks' Law", although John Birks did not promote the name. Also, B is sometimes referred to as Birks' constant, although it appears in Eq. (13.36) mainly because the letter 'B' conveniently follows 'A' in the English alphabet, and not because it is the first letter in the name 'Birks'. Birks named the product kB the 'quenching parameter' [Birks 1964].

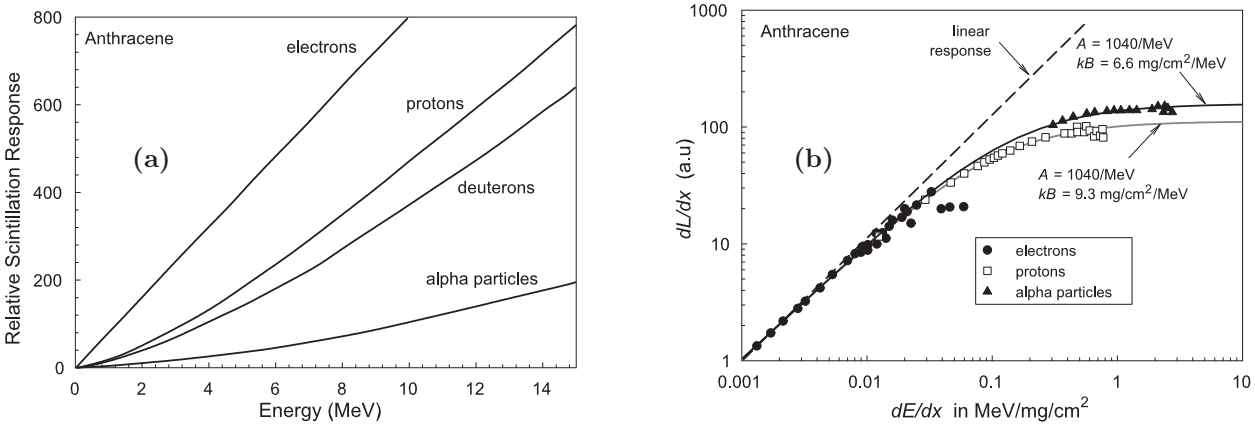

Figure 13.27. (a) Relative scintillation response for different energies of electrons, protons, deuterons, and alpha particles in anthracene. Data are from Birks [1951]. (b) Variation of specific fluorescence $\mathrm{d}L/\mathrm{d}x$ with specific energy loss $\mathrm{d}E/\mathrm{d}x$ for electrons, protons, and alpha particles in anthracene. Also shown are results from a linear dependence (Eq. (13.38)) and the dependence expressed by Eq. (13.36) with $kB = 6.6$ mg cm^{-2} MeV^{-1} and $kB = 9.3$ mg cm^{-2} MeV^{-1}. Data are from Brooks [1956].

a non-linear output in dL/dx. This effect is also apparent for protons, alpha particles and heavy ions. The severity of the effect in anthracene is shown in Fig. 13.27. In Fig. 13.27(a) there is shown a clear difference in total light yield as a function of particle type and energy. Shown in Fig. 13.27(b) the dramatic effect of Eq. (13.37) is apparent where it is seen that as dE/dx becomes large the value of dL/dx becomes constant. Note that specific energy loss described by the Bragg distribution is highest near the end of the particle range for protons, deuterons, and alpha particles. Hence, dL/dx tends towards a constant value as these heavy particles slow down.

A parameter sometimes quoted for organic scintillators is the α/β ratio, which is defined as the ratio of light produced by ^{210}Po (5.3 MeV) alpha particles to light produced by ^{137}Cs conversion/Auger electrons (624 keV),[27]

$$\frac{\alpha}{\beta} = \frac{(L/E)|_\alpha}{(L/E)|_{e^-}} \simeq \frac{(dL/dE)|_\alpha}{(dL/dE)|_{e^-}} = \frac{\dfrac{A}{kB}(dE/dx)|_\alpha}{A} = \frac{(dE/dx)|_\alpha}{kB}. \tag{13.39}$$

The quenching parameter can be approximated for a scintillator by measuring the α/β (or α/e^-) light ratio,

$$kB = \frac{(dL/dE)|_{e^-}}{(dL/dx)|_\alpha} = \frac{(dE/dx)|_\alpha}{(\alpha/e^-)}. \tag{13.40}$$

Quenching factors have been measured [Czirr 1964] and calculated for a few common organic and inorganic scintillators by Tretyak [2010] and Nyibule et al. [2014]. There has been work published aimed at refining the accuracy of Eq. (13.36) by adding more terms to the equation to mainly address the non-linear light output from heavy ions in organic scintillators [Blanc et al. 1964; Smith et al. 1968; Craun and Smith 1970]. Craun and Smith [1970] propose the addition of a third term,

$$\frac{dL}{dx} = \frac{A\ dE/dx}{1 + kB\ dE/dx + C\ (dE/dx)^2}. \tag{13.41}$$

[27] In reality, the 624-keV conversion electron is emitted by $^{137m}_{56}$Ba the daughter produced in the beta decay of ^{137}Cs. The same is true for the 662-keV gamma ray commonly attributed to ^{137}Cs. But the usage here is almost universally used.

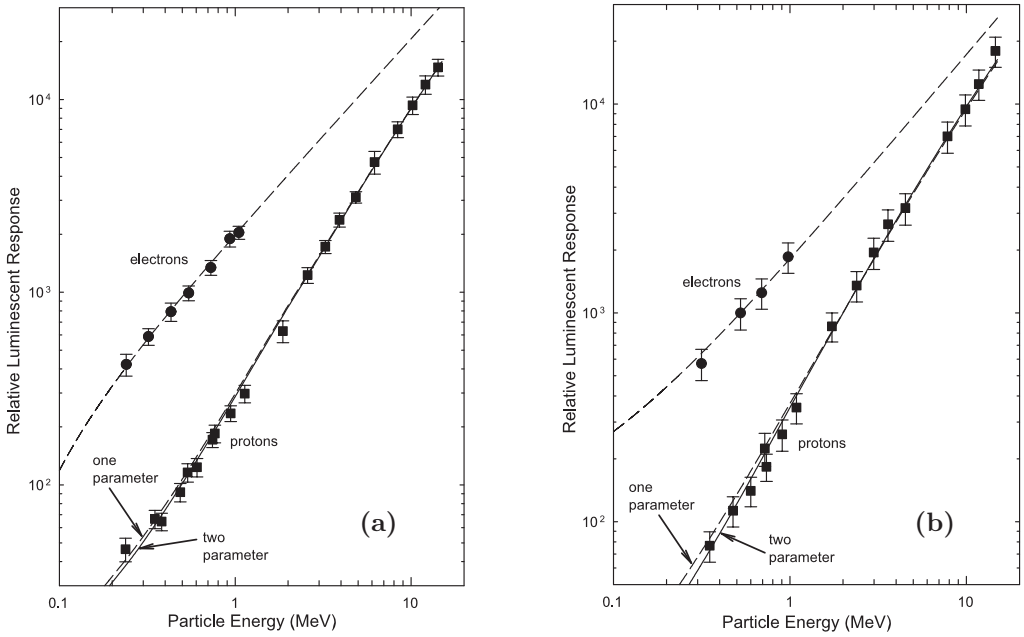

Figure 13.28. Semiempirical curve fits to luminescent yields from electrons and protons in (a) anthracene and (b) (*E*)-stilbene scintillators. Data are from Smith et al. (1968); curve fitting parameters are from Craun and Smith (1970).

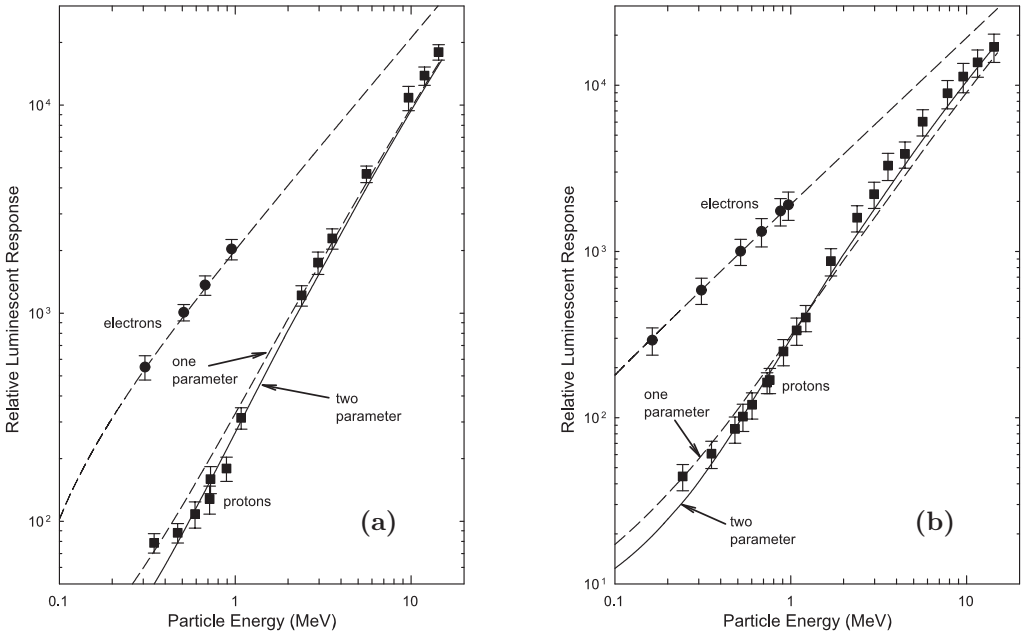

Figure 13.29. Semiempirical curve fits to luminescent yields from electrons and protons in (a) NE-102 (plastic) and (b) NE-213 (liquid) scintillators. Data are from Smith et al. (1968); curve fitting parameters are from Craun and Smith (1970).

Shown in Fig. 13.28 and Fig. 13.29 are comparisons of empirical results from Eq. (13.36) and Eq. (13.41) for organic crystals of anthracene and *trans*-stilbene, organic plastic NE-102, and organic liquid NE-213 luminescent light yields. Equation (13.41) with the additional parameter appears to fit the low energy data better than Eq. (13.36). Quenching parameters kB and C for a few organic scintillators are available in the literature [Craun and Smith 1970].

Decay Time

A generally accepted description of light emission uses the same theory of Eq. (13.26) (repeated here for convenience), in which there is a given rise time τ_r to populate the S_{10} π states and a given decay time τ_d to decay through the $S_{10} \rightarrow S_{00}$ process. The light emission as a function of time is thus given by

$$L(t) = \frac{N_c(t)}{\tau_d} = \frac{N}{\tau_r - \tau_d}\left(e^{-t/\tau_r} - e^{-t/\tau_d}\right).$$

The population rise time τ_r is usually only a fraction of a nanosecond, while τ_d is usually only a few nanoseconds. However, most organic scintillators have complex decay schemes that are difficult to model with a simple exponential equation. This difficulty is largely due to changes in decay time with the type of radiation particle and the fact that there often are multiple decay times involved.

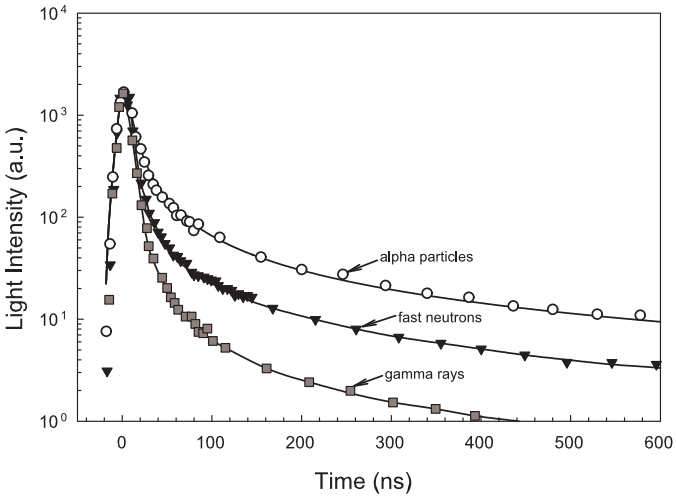

Figure 13.30. Luminescent decay from (E)-stilbene for alpha particles, neutrons, and gamma rays. Data are from Bollinger and Thomas [1961].

By inspection, the two decay modes seem to appear, typically labeled *fast* and *slow* decay components. An example is seen from the emissions from *trans*-stilbene which are shown in Fig. 13.30. Owen simplified the luminescent decay by assigning only two decay constants to the light yield of organic scintillators, one fast decay time τ_f and one slow decay time τ_s [Owen 1959]. It is the fast component of an organic scintillator that is most often quoted in the literature. The short decay times were quite different for the organic crystals studied and listed in Table 13.3. Owen found that the long decay times were similar for anthracene, *trans*-stilbene, and quaterphenyl, ranging between 350 ns and 370 ns. These long decay times differed with the type of radiation absorbed, showing marked differences between neutron (n, p) events and gamma-ray events.

Another modification was suggested by Bengsten and Moszynski [1974], who proposed that the rise time of the pulse be represented by a Gaussian distribution $f(t)$ with $\acute{\sigma}_{\mathrm{ET}}$ as the standard deviation. This additional modification takes into account energy transfer and wavelength shifting in the scintillator along with time spread in the PMT. Bengsten and Moszynski [1974] successfully apply this modification to specific plastic scintillators.

Pulse Shape Discrimination

Inspection of Fig. 13.30 reveals major differences among the light emission pulse shapes from alpha particles, neutrons, and gamma rays. This known phenomenon can thus be used to distinguish among different particle events in a mixed radiation field [Wright 1956; Owen 1958; Bollinger and Thomas 1961; Brooks and Jones 1974; Yanagida et al. 2015]. Pulse shape discrimination (PSD) can be used to match the decay time of the

short component to the most probable interacting particle, mainly because the short decay time is strongly dependent on the type of incident particle. This comparison can be accomplished by plotting the ratio of light released by the slow component and the fast component (ordinate) against the light released by the fast component (abscissa), and thus produces a two-dimensional map that separates neutron induced events from gamma-ray events [Zaitseva et al. 2009; Yanagida et al. 2015].

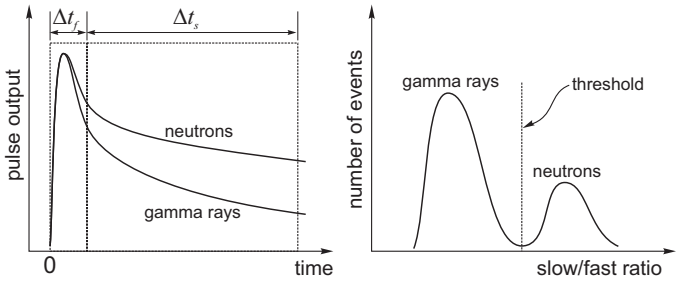

Figure 13.31. (left) Depiction of scintillation pulse output for gamma rays and neutrons. (right) Depiction of a histogram of events versus the slow/fast integrated signal ratio, which shows a clear difference between gamma-ray and neutron related events.

Another discrimination method is to find the ratio of integrated signals (the charge integration method) produced during separate time periods, Δt_f and Δt_s, that span the decay periods of the fast and slow components. A histogram of events (ordinate) is then plotted against this ratio as in Fig. 13.31(right). The method to produce a useful ratio of fast to slow signal components may vary, but ultimately the concept is the same. Several other methods have been explored to produce improved results for PSD [Back et al. 2008; Griffiths et al. 2018].

Often a clear spectral separation appears, especially between heavy ions and gamma rays so that events below a designated slow/fast threshold are attributed to gamma rays and events above the slow/fast ratio threshold are designated as neutron events. Once this cutoff threshold is determined, modern electronics can quickly process information in real time to discriminate between neutron and gamma-ray events. Because organic scintillators can be used as fast neutron detectors from (n, p) reactions, either method provides a means to discriminate between neutron induced events and gamma-ray induced events [Yanagida et al. 2015].

13.3.2 Organic Crystalline Scintillators

Although the first scintillators used for radiation detectors were inorganic (ZnS:Ag and $PtBa(CN)_4$), it was naphthalene, an aromatic hydrocarbon crystalline solid, coupled to a photomultiplier tube that was first used as a practical scintillation detector [Broser and Kallman 1947b; Hofstadter 1975]. Shortly thereafter, anthracene, an organic compound similar to naphthalene, was shown to be a relatively bright scintillator [Bell 1948]. Birks [1964] lists numerous organic crystalline solids as scintillators, a few of which are described here (see also Table 13.4).

Anthracene

Anthracene is one of the brightest organic scintillators available, and has a light yield of about 17,000 photons/MeV, or approximately 43.5% of the light yield of NaI:Tl (see Table 13.3). Anthracene is classified as an aromatic hydrocarbon. Just as inorganic compound scintillators are traditionally compared to NaI:Tl for relative performance, the relative brightness of most organic compounds is compared to that of anthracene whose brightness is taken as 100%. This relative benchmark comparison arises because anthracene is one of the first bright organic scintillators discovered. However, the relative light yield from anthracene is not only a function of particle type, but also the particle trajectory within the crystalline lattice [Tsukada and Kikuchi 1962; Tsukada et al. 1965; Oliver and Knoll 1968], a common trait for crystalline organic scintillators [Brooks and Jones 1974]. Birks [1964] considered this anisotropic light emission characteristic a fundamental drawback to having anthracene as the light yield scintillation standard for organic scintillators. The most probable wavelength of emission is approximately 447 nm, as depicted in the spectrum of Fig. 13.33. The decay time is approximately 30 ns and is fast compared to most inorganic scintillators. Anthracene can

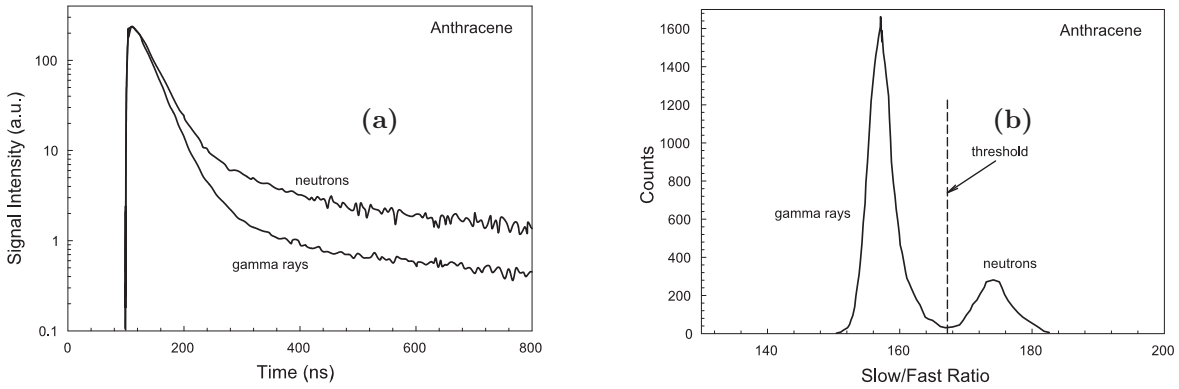

Figure 13.32. (a) Scintillation decay response in anthracene from gamma rays and neutrons. (b) Histogram of gamma-ray and neutron events versus the fast/slow integrated signal ratio for $\Delta t_f = 20$ to 40 ns and $\Delta t_s = 40$ to 150 ns. Data are from Yanagida et al. [2015].

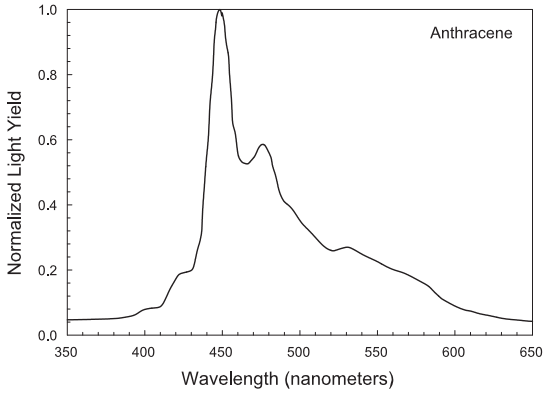

Figure 13.33. Emission spectrum from crystalline anthracene. Data are from Sangster and Irvine [1956].

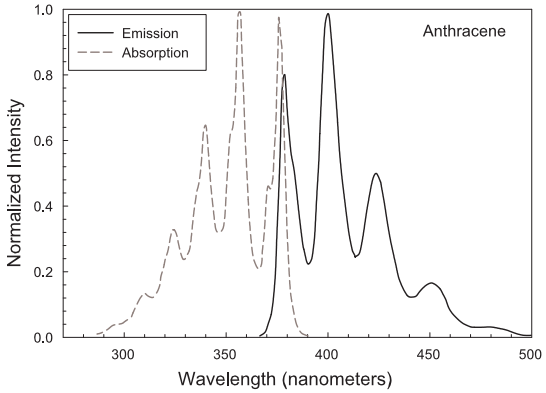

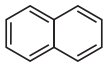

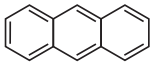

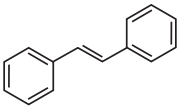

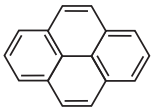

Figure 13.34. Absorption and emission spectra from anthracene dissolved in cyclohexane and fluoresced with 235.7 nm light. Data are from Berlman [1971].

be used for pulse shape discrimination between heavy ions, neutrons, and beta particles. Anthracene was shown in a recent study to be superior for neutron/gamma-ray pulse shape discrimination (PSD) over that for *trans*-stilbene and *p*-terphenyl and showed a clear distinction between neutron and gamma-ray events Fig. 13.32 [Yanagida et al. 2015].

The mass density of anthracene is 1.25 g cm^{-3} with a molecular weight of 178.23 g mol^{-1}. The refractive index of anthracene is 1.595, closely matching that of common borosilicate glass used for PMT windows. Anthracene crystals have a monoclinic lattice, and the chemical structure of anthracene ($C_{14}H_{10}$) is shown in Table 13.4. The melting point of anthracene is 215.76°C.

Anthracene can be used in crystalline form, but must be encapsulated to prevent the formation of an oxidation layer on the outer surface. This surface layer behaves as a quenching region, thereby reducing the absolute light yield and prolonging decay times. The decomposition of the surface through photo-oxidation is also promoted by exposure to light if not encapsulated. Anthracene is also fragile and can be easily fractured.

Table 13.4. Chemical formulas and structures of a few crystalline organic scintillators.

Fluor	Chemical Formula	Chemical Structure
Naphthalene	$C_{10}H_8$	
Anthracene	$C_{14}H_{10}$	
Diphenylacetylene	$C_{14}H_{10}$	
(*E*)-Stilbene	$C_{14}H_{12}$	
Pyrene	$C_{16}H_{10}$	
p-Terphenyl	$C_{18}H_{14}$	
p-Quaterphenyl	$C_{24}H_{18}$	

Anthracene can be dissolved in a solvent and used as a liquid scintillator, although the emission spectrum appears to shift (see Fig. 13.34). When dissolved in cyclohexane, the emission peak shifted to 401.6 nm with a decay time of 4.9 ns [Berlman 1971].

Pyrene

Pyrene is an aromatic hydrocarbon composed of four benzene rings with chemical formula $C_{16}H_{10}$ and monoclinic crystal structure (Table 13.4) [Camerman and Trotter 1965]. The relative light yield of pyrene is 60% that of anthracene and has a most probable emission wavelength of 477 nm [Birks 1964]. The emission spectrum is shown in Fig. 13.35. The decay time of pyrene is relatively long for an organic scintillator at 90 ns. The mass density of pyrene is 1.27 g cm^{-3} with a molecular weight of 202.25 g mol^{-1}. The refractive index of pyrene is 1.85, which produces a critical angle of 54° at a glass interface. The hydrogen to carbon (H/C) ratio is 0.625. Pyrene begins to soften at 146°C.

p-Quaterphenyl

One of the many *p*-oligophenylenes studied as scintillator solutes is *p*-quaterphenyl which has a molecular formula $C_{24}H_{18}$ (see Table 13.4). The *p*-oligophenylenes are aromatic hydrocarbon compounds composed of rings united in the para position by single σ bonds and their general formula is $C_{6n}H_{4n+2}$, where n is the number of rings and $n \geq 3$. It has a relatively high light yield of about 85% of that of anthracene [Birks 1964]. The maximum emission wavelength λ_{max} is 438 nm with a decay constant between 7 and 8 ns. The emission spectrum is shown in Fig. 13.36. The melting point is near 150°C. Pure crystals of *p*-quaterphenyl are difficult to produce and the material is usually available only in powder form and, thus, may have contributed to its limited use.

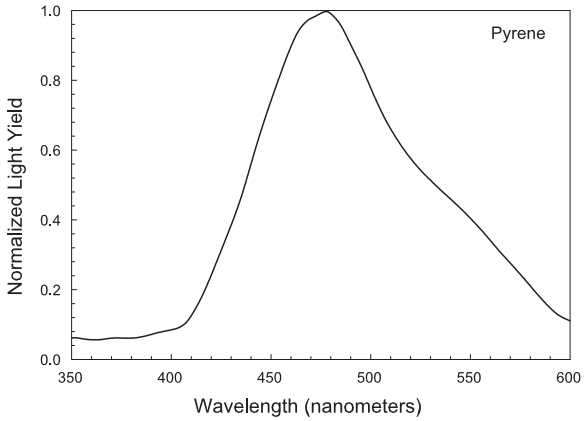

Figure 13.35. Emission spectrum from crystalline pyrene. Data are from Sangster and Irvine [1956].

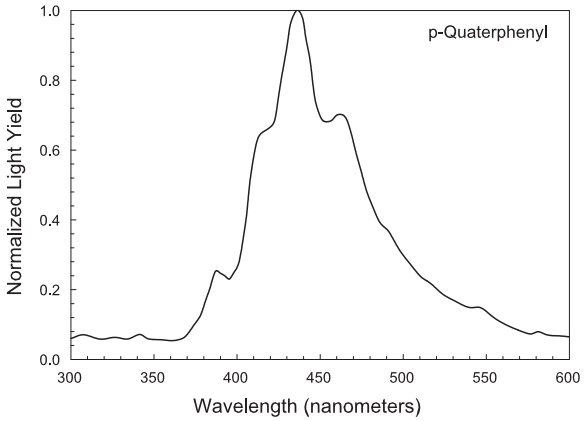

Figure 13.36. Emission spectrum from crystalline p-quaterphenyl. Data are from Sangster and Irvine [1956].

Trans-Stilbene

The organic *trans*-stilbene (or (*E*)-stilbene or diphenyl-ethylene) is a diphenylpolyene and is historically one of the more important crystalline scintillators. It has a mass density of 0.97 g cm^{-3}, a molecular density of 180.25 g mol^{-1}, and a chemical formula $C_{14}H_{12}$. The light yield is approximately 70% that of anthracene, which makes it a relatively bright organic crystal. The wavelength at maximum (λ_{max}) is near 400 nm with a fast decay time of 3.5 ns. The emission spectrum is shown in Fig. 13.37. The refractive index of *trans*-stilbene is 1.62 that produces a critical angle of 67.6° at a glass interface. As observed with many other organic crystalline scintillators, the light yield in *trans*-stilbene is directionally dependent upon the interacting particle trajectory [Hansen and Richter 2002; Cvachovec et al. 2002]. Stilbene is non-hygroscopic and relatively non-flammable (NFPA 704 rating of '1'), thus making it relatively easy to process.

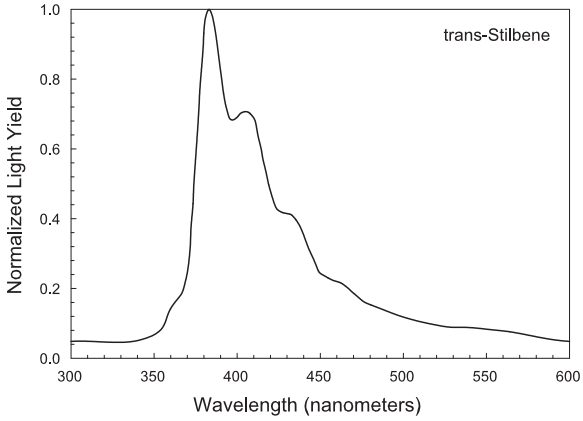

Figure 13.37. Emission spectrum from crystalline *trans*-stilbene. Data are from Sangster and Irvine [1956].

It has a melting point of 125°C and transparent crystals can be grown with the Bridgman technique. However, these melt-grown crystals are generally limited to small sizes. Recently, large faceted transparent crystals of *trans*-stilbene with 10-cm dimensions have been grown through solution methods [Zaitseva et al. 2011a; Carman et al. 2013; Zaitseva et al. 2015] and are now commercially available [Inrad 2016]. As a result there has been renewed interest in *trans*-stilbene as a fast neutron detector. These solution-grown crystals can be machined into varying shapes, and reportedly have similar performance as traditional Bridgman-grown crystals [Zaitseva et al. 2015]. Stilbene can be used for pulse shape discrimination between heavy ions, neutrons, and beta particles [Bollinger et al. 1961; Konobeevski et al. 2012; Yanagida et al. 2015]. The work of Harihar et al. [1977] indicates that the short decay time of *trans*-stilbene is mostly unaffected by the magnitude

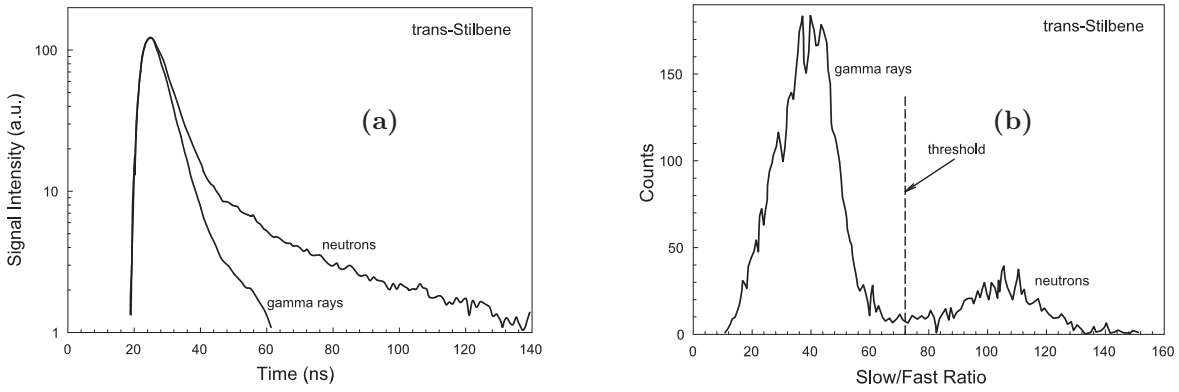

Figure 13.38. (a) Scintillation decay response in *trans*-stilbene from gamma rays and neutrons. (b) Histogram of gamma-ray and neutron events versus the fast/slow integrated signal ratio for $\Delta t_f = 20$ to 40 ns and $\Delta t_s = 40$ to 150 ns. Data are from Yanagida et al. [2015].

of the specific energy loss dE/dx while the long decay time increases with dE/dx. Zaitseva et al. [2011b] report on the use of *trans*-stilbene and mixed organic crystals of *trans*-stilbene for fast neutron detection using PSD methods. According to the results of Yanagida et al. [2015], shown in Fig. 13.38, *trans*-stilbene is a good scintillator for fast neutron PSD, yet not quite as good as anthracene and *p*-terphenyl. Overall, *trans*-stilbene is a good choice for fast neutron detection because it is relatively bright, can now be acquired in large sizes, is optically clear, fast, and couples well to common PMTs.

p-Terphenyl

Another *p*-oligophenylene studied as a scintillator solute is *p*-terphenyl, having molecular formula $C_{16}H_{14}$ (see Table 13.4). Pure crystals of *p*-terphenyl have a light yield of about 40% compared to that of anthracene [Birks 1964]. However, commercially produced large crystals of doped *p*-terphenyl are available with reported light yields that is 135% that of anthracene [Proteus 2016; Cryos-beta 2016]. The density of *p*-terphenyl is 1.23 g cm^{-3} with molecular weight of 230. The H/C ratio is 0.778 and the melting point is 213°C. This organic scintillator is relatively fast with decay times between 3.0 and 3.7 ns. The maximum emission wavelength λ_{max} is 420 nm, which matches well to common bi-alkali PMTs. The emission spectrum is shown in Fig. 13.39. The refractive index is 1.65 with a critical angle of about 65°C at the interface of common borosilicate glass. *p*-terphenyl can be used for pulse shape discrimination between heavy ions, neutrons, and beta particles [Yanagida et al. 2015]. The response of *p*-terphenyl to neutrons and gamma rays is shown in Fig. 13.40. A study with *p*-terphenyl in a composite scintillator in which the organic crystal was mixed into a polymer matrix, outperformed composite *trans*-stilbene

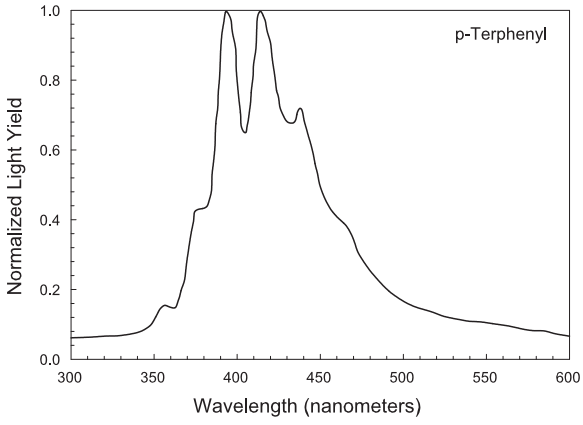

Figure 13.39. Emission spectrum from crystalline p-terphenyl. Data are from Sangster and Irvine [1956].

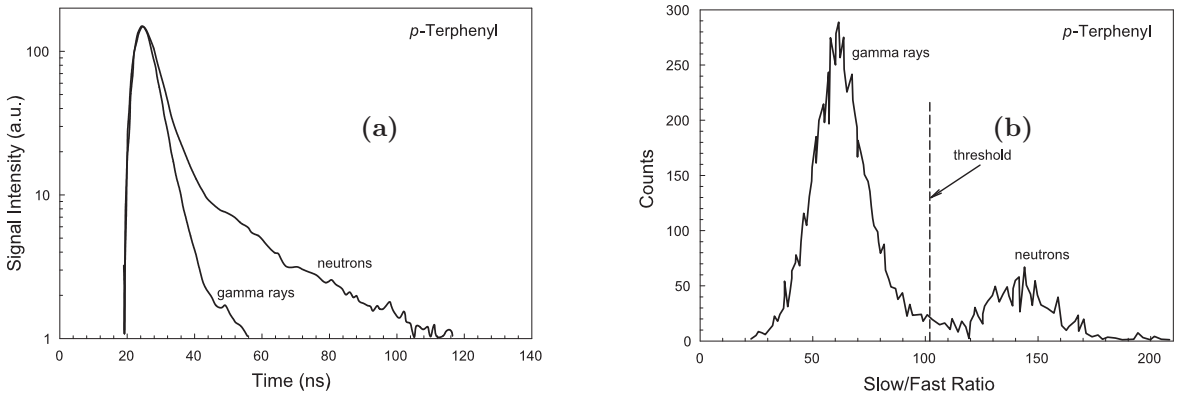

Figure 13.40. (a) Scintillation decay response in *p*-terphenyl from gamma rays and neutrons. (b) Histogram of gamma ray and neutron events versus the fast/slow integrated signal ratio for Δt_f = 20 to 30 ns and Δt_s = 30 to 150 ns. Data are from Yanagida et al. [2015].

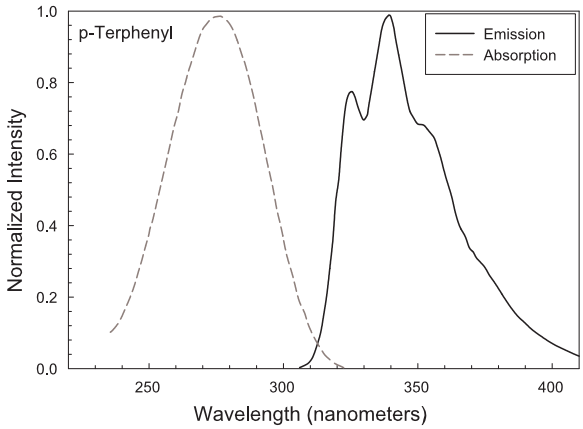
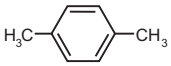
mixtures for neutron/gamma-ray PSD [Iwanowska et al. 2011]. Further, *p*-terphenyl can be used as the solute in a liquid scintillation cocktail [Brooks 1956]. The absorption and emission spectrum of such a cocktail is shown in Fig. 13.41.

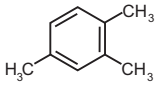
13.3.3 Liquid Scintillators

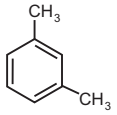
For many radiations the energies of the particles are too small to be measured by conventional means discussed up until this point. For instance, β-particle emissions from tritium (^{3}H) have a maximum energy of 18.59 keV, and the maximum energy of β-particles from ^{14}C is 156.47 keV. The energies emitted from these β-particle emitting sources are generally insufficient to penetrate the enclosure of most radiation detectors, including gas-filled detectors with thin BoPET windows. Sample preparation can also inhibit detection from energy self-absorption of the radiation particles within the sample. Although some of these radiations can be detected in a 2π or 4π gas-filled proportional counter, the detection method of choice is presently a technique referred to as liquid scintillation counting (LSC), can be used to measure α- and β-particle emissions, positrons, Auger electrons, internal conversion electrons, and Compton electrons.

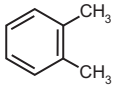
The measurement method involves mixing a radioactive (typically aqueous) sample with the organic scintillation solution. The organic scintillation solution is commonly referred to as a "cocktail", and is composed of a solvent, a surfactant emulsifier and one or more fluors. The primary fluor is added to convert absorbed energy into fluorescent light. At times it is beneficial to mix a wavelength shifting scintillator, or secondary scintillator, into the solution to improve the scintillation response. Common fluors and solvents are listed in Tables 13.5 and 13.6, respectively.

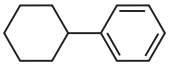


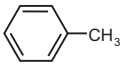


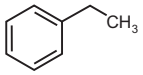


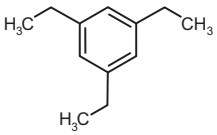


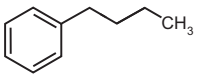


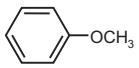


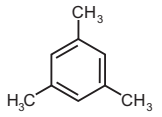


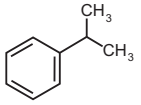












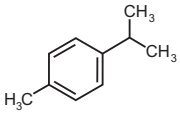


Figure 13.41. Absorption and emission spectra from p-terphenyl dissolved in cyclohexane and fluoresced with 303 nm light. Data are from Berlman [1971].

Table 13.5. Chemical Formulas and Structures of a Few Organic Liquid Scintillation Fluors (solutes).

Fluor	Type	Formula	Structure
p-Terphenyl	primary	$C_{18}H_{14}$	
PPO	primary	$C_{15}H_{11}NO$	
POPOP	wavelength shifter	$C_{24}H_{16}N_2O_2$

*As compared to toluene.

Liquid Scintillation Counting

The solvent serves as a suspension for the primary scintillator fluor; hence, the fluor must be soluble in the chosen solvent. The excitation energy of the solvent should be relatively low, thereby allowing efficient transfer of energy to the solvent from the radiation particles. Further, there must be efficient energy transfer from the solvent to the fluor in order to maintain efficient light output. Historically there are several solvents, termed "classical" solvents that have been used to great success and consist mostly of the aromatic organic benzene derivatives (see the list in Table 13.6). Aromatic organic molecules, such as toluene, *p*-xylene and *m*-xylene, have high densities of electrons, thereby producing efficient interaction between β-particles and molecular electrons so as to generate a relatively large light yield when mixed with a scintillation fluor. However, these same aromatic hydrocarbons have multiple health risks. Typically they are flammable with a low flash point (<50°C), pose an inhalation problem and can cause skin irritation with direct contact. Further, there is evidence that benzene and some associated aromatic hydrocarbons cause bone marrow failure and can lead to forms of cancer involving blood cells (such as leukemia), consequences which have led to stricter regulations regarding their use.

Until only a few decades ago, scintillation cocktails were usually mixed by the radiation practitioner. However, in modern times, premixed proprietary cocktail solutions are commercially available from vendors such as Beckman Coulter, Perkin-Elmer, Fisher Scientific, MP Biomedicals, National Diagnostics, and Research Products International. In recent times, most of these aromatic hydrocarbons, except, perhaps, pseudocumene (1,2,4-trimethylbenzene), have been replaced with safer solvents. However, pseudocumene continues to be used in a variety of commercially available "classical" cocktails. An alternative branch of solvents, named "safer" solvents, are in common use for LSC, considered safer because the safety aspects to these alternative solvents are safer than traditional classical aromatic hydrocarbons. For instance, a few alternative safer chemical solvents for LSC are benzyltoluene (BT), 1,2-diphenylethane (bibenzyl or DPE), 2,6-diisopropylnaphthalene (2,6-DIPN or DIN), phenyl xylylethane (PXE), and dodecylbenzene, a linear alkylbenzene (LAB) [Nemchenok et al., 2011], all of which have low vapor pressures with flash points above 140°C and are classified as safe for transport and storage.

There are many benefits to adding a wavelength shifting fluor to the cocktail [Schram 1963]. First, the emission wavelengths of many primary fluors have sufficient energy to be significantly reabsorbed in the cocktail solution. The wavelength shifter converts light to lower energies, thereby reducing the probability of reabsorption. Second, a wavelength shifter can be selected that emits photons that match well to the light collection device such as a PMT. For instance, a solution with *p*-terphenyl as the primary scintillator with λ_{max} near 340 nm may have a wavelength shifter added, such as POPOP with λ_{max} near 410 nm and this improves transparency with a better match to a common bi-alkali PMT. Third, the longer wavelength photons are less likely to be absorbed by the container structure, such as the vial walls that contain the cocktail. Fourth, the longer wavelength photons ($\lambda > 400$ nm) are more effectively reflected by TiO_2, a Lambertian reflector often used in scintillation counting. Typically, wavelength shifting fluors have lower solubility in the solvent than the primary fluor, hence the reason for their exclusion as a primary fluor. However, the energy transfer process between fluors requires only a small fraction of wavelength shifter, on the order of 1% concentration of the primary fluor. Energy lost during the energy transfer process between primary and wavelength shifting fluors is more than made up for by the improved luminescent transparency in the cocktail and efficient light coupling to the PMT (or other light sensitive device).

Details on liquid scintillation solutions and measurement methods can be found in several excellent books on the topic such as those by Ross, Noakes, and Spaulding [1991] and L'Annunziata [2012]. Here, only a brief overview of the art is presented.

Scintillator Vials LSC systems have conveyer systems that may consist of a belt with vial slots or racks capable of holding approximately 10 vials. Systems are designed for several vial sizes ranging from 4 ml to

25 ml capacity, although the most popular size seems to be 20 ml vials. The 20 ml size became the standard size limit mainly because of conventional photomultiplier tube diameters. A study conducted with 7 ml and 20 ml indicates that there is little difference in performance using either size of vial [Moore et al. 1977], although efficiency was better for low energy beta particles (^{3}H) for the 20 ml vials. It was determined that use of either should be filled more than halfway to reduce problems with quenching. Overall, the lower cost of operating with 7 ml vials seemed to be the main consideration. These vials have caps that include either a white Lambertian or a specular internal reflector.

These LSC vials are available fabricated from several different materials, including quartz, soda lime glass, borosilicate glass, polyethylene, polypropylene, nylon, and Teflon [Peng 1977]. Quartz has low background concentrations and is optically clear for UV light emissions, making it a preferred choice for vials. However, quartz vials are also relatively expensive, and are seldom used for routine samples. Borosilicate glass has a lower background, mainly from ^{40}K, than soda-lime glass and is optically clear, thereby making it a good choice. Further, glass is chemically inert to the organic compounds usually used in LSC. However, glass does adsorb a variety of other chemicals, including lipids, cations, anions, amino acids, polyethylene glycol, and many other compounds with hetero-atoms [Peng 1977]. Various additives and surface treatments can be used to reduce chemical adsorption in glass vials. Polyethylene vials do not appear to suffer from these adsorption effects. Glass can break, which has the risk of contaminating the workspace and counting system. Further, it is possible for radioactive particles to fluoresce the glass, which ultimately adds to the background light output. Finally, glass vials can be costly; therefore, many labs choose to clean used vials rather than dispose of them.

Polyethylene vials are more economical, but some of the solvents used in LSC can cause plastic vials to swell (mainly toluene and xylene) which can cause vials to become lodged in a system. Further, the continuous change in the cocktail solution because of diffusion of the solution through the vials causes a drift in the measured light output over time. To reduce risk of solvent loss and vial swelling, cocktails with volatile solvents contained in plastic vials are best measured within a day of preparation. Swelling is less of a problem with high density polyethylene (HDPE). Polypropylene vials suffer similar problems as polyethylene vials. Also, there are polypropylene vials available with internal anti-diffusion coatings that effectively reduce this problem. Polyethylene vials can have higher light transmission efficiency than glass for wavelengths between 360 and 400 nm, and they do not have the risk of breaking. Antistatic plastic vials are available if static electricity is a concern.

Nylon vials can soften with water-based or alcohol solutions, but are relatively resistant to toluene. Teflon vials are also inert to chemicals used for LSC, but are more expensive than nylon or polyethylene. Teflon vials also have a lower radiation background than glass, quartz, and polyethylene vials.

Radiation Measurement Laboratory LSC systems are configured in coincidence mode, such that a cocktail sample is inserted between two photomultiplier tubes (PMTs) gated to allow a 'count' only when both PMTs produce a signal above a discriminator setting within a defined time window Δt. The intensity of light, or electrical signal, is a relative measure of the energy deposited within the scintillator. Operating in coincidence mode reduces sporadic background counts from cosmic rays or other background radiations that may interact directly with either of the PMTs. To further reduce background, laboratory LSC systems have an abundance of lead shielding[28] surrounding the PMTs and internal source (if there is one). Laboratory units are designed to handle numerous samples in sequence. An operator can load hundreds of vials into racks or a conveyor, and each sample is systematically inserted between the PMTs, and the system automatically records data from each of the samples.

[28] One of the authors nearly crushed a perfectly good hand-cranked lift by raising a small Beckman laboratory LSC from the bottom floor of his lab to a second floor loft area.

The pulse height spectrum energy from a LSC is usually projected onto a logarithmic scale along the abscissa (channel number). This arrangement becomes necessary when comparing low and higher energy beta particle emissions that are significantly different such as those from ^{3}H and ^{14}C. In Fig. 13.42, pulse height spectra from three common beta particles sources are shown (^{3}H, ^{14}C, ^{32}P) with maximum energies of 18.3 keV, 156 keV, and 1.71 MeV, respectively. Each spectrum ranges from zero up to the end point energy, a consequence of the beta particle always sharing energy with an anti-neutrino decay product. Because the anti-neutrino does not produce scintillation light, only the energies from beta particles are recoded in the spectrum.

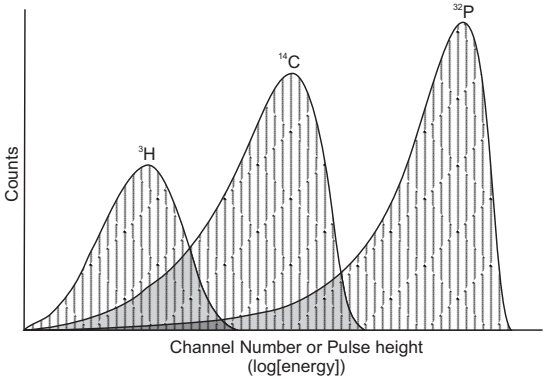

Figure 13.42. Depiction of output spectra from three beta particle sources. After [Beckman 1985].

Quench Correction Foreign matter and diluting fluids can cause light loss in a scintillation cocktail. If the amount of light produced in the scintillator falls below the discriminator setting, then the event is not recorded by the system. This light attenuation effect is usually categorized as "color" or "chemical" quenching. Color quenching is a result of chemicals in the solution that change its color and absorb scintillation light. For instance, yellow coloration produces strong color quenching, whereas blue coloration usually quenches very little. Chemical quenching occurs when chemicals added to the cocktail interfere with the energy transfer process and causes inefficient energy transfer to the scintillation phosphor. In either case, the result is a loss of light, which consequently changes the pulse height spectrum. For example, counts falling within ch2 in Fig. 13.43 may have 75% efficiency for a low quenched sample, but only 5% efficiency for a highly quenched sample of the same activity. All LSC samples are quenched and require some amount of quench correction to determine the actual sample activity. There are many quench correction techniques developed by LSC manufacturers, and are generally categorized as internal or external standard methods. Some of these methods are briefly described here.

Internal Standard Quench Correction The internal standard method typically requires that a known amount of radioactive sample be added to a scintillation cocktail. The sample is initially measured in the LSC system and afterwards a known amount of radionuclide, generally with high specific activity, is added to the cocktail followed by another measurement. The efficiency of the standard is determined by,

$$\epsilon_s = \frac{\mathrm{Cps}(s+x) - \mathrm{Cps}(x)}{\mathrm{Dps}(s)}, \tag{13.42}$$

where $\mathrm{Cps}(s+x)$ refers to the count rate from the mixed calibrated standard and sample, $\mathrm{Cps}(x)$ refers to the count rate from the sample, and $\mathrm{Dps}(s)$ refers to the known activity of the calibrated standard. The activity of the sample can then be found from,

$$\mathrm{Dps}(x) = \frac{\mathrm{Cps}(x)}{\epsilon_s}. \tag{13.43}$$

The internal standard method is best used for manual scintillation systems, such as field units, rather than automated systems. Although the internal standard method is considered accurate, it is time consuming and impractical for large numbers of samples. Note the method presumes that adding the known standard to the vial does not affect the overall quench. However, the addition of the standard to the vial changes

the total liquid volume and can change the sample quenching, and, consequently, reduce the accuracy of the measurement. A disadvantage of the method is that the sample cannot be recounted, mainly because the activity is altered by the addition of the internal standard. Further, opening the vial, especially in a cool environment, my cause water condensation in the vial, and water is a strong quencher. Also, contamination from the transfer method (pipette, for instance) can add unintended quench matter into the cocktail. Addition of these quenches into the sample cocktail lead to exaggerated corrections to the calculated activity.

Internal standards for ^{3}H and ^{14}C are commercially available. Typically it is advised to use cocktail solutions for the radioassay with the composition as the quenched standards. Unquenched standards are best acquired from commercial vendors, mainly because they are usually flushed with argon to remove dissolved oxygen. Removal of the dissolved oxygen works to increase the scintillation efficiency. A variation of the internal standard method includes a unique cap on the vial that systematically pumps a known amount of calibrated quench fluid into the vial.

Channels Ratio Method LSC is most often used for beta emitting radionuclides; hence the pulse height spectrum extends from zero up to the maximum energy of the beta particles and the spectrum is very similar to the beta-particle energy distribution. If the pulse height spectrum is divided into two channels, then the ratio of counts in the channels can be used to determine the amount of quenching. An advantage of the method is that no additional standard need be added to the samples, and these samples can be recounted many times.

The LSC system usually has two independent channels, as shown in Fig. 13.43. Many ratio variations can be used, and do yield different results [Horrocks 1974]. For instance, the numerator may be ch 1, while the denominator is ch 2, or the numerator may be ch 2 while the denominator is the sum of ch1 and ch 2, and so on. The ratio choice should be selected so that the experimentally determined ratio does not produce a value close to zero.

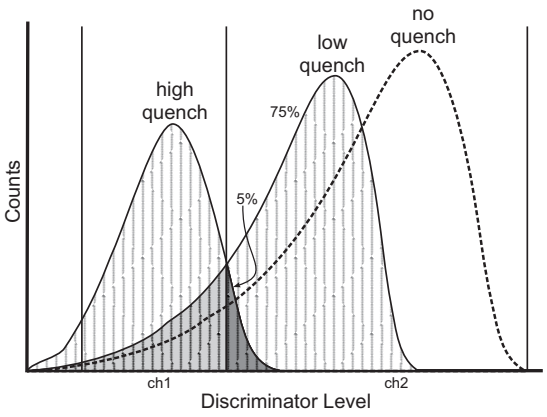

Figure 13.43. Depiction of output spectra from unquenched and quenched standards used for the channels ratio calibration. The number of counts in channel 1 increase with quenching, while the number of counts in channel 2 decrease with quenching.

The channels ratio quench correction method is performed by initially measuring a set of quench correction standards. These standards have a specific radionuclide of interest in the cocktails, ^{3}H or ^{14}C for instance, and each standard has a different level of quench agent added. At least one of the standards remains unquenched. With the unquenched standard, a measurement is conducted and the channels set at specific locations to split the spectrum into two portions. These channels remain unchanged for both the calibration and sample measurements. The remaining standards are measured, and the number of counts registered in both channels are recorded for each measurement.

The known activity of the unquenched standard is compared to the total counts summed from channels 1 and 2. This same exercise is repeated for all standards in the set. The channels ratio (for example, ch 1 divided by ch 2) is plotted against the counting efficiency for each measurement, thereby providing a characterization curve for the radionuclide samples. For each unknown sample, the ratio of ch1/ch2 is determined and compared to the calibration graph, which yields the efficiency. The corrected activity is then determined with Eq. (13.43).

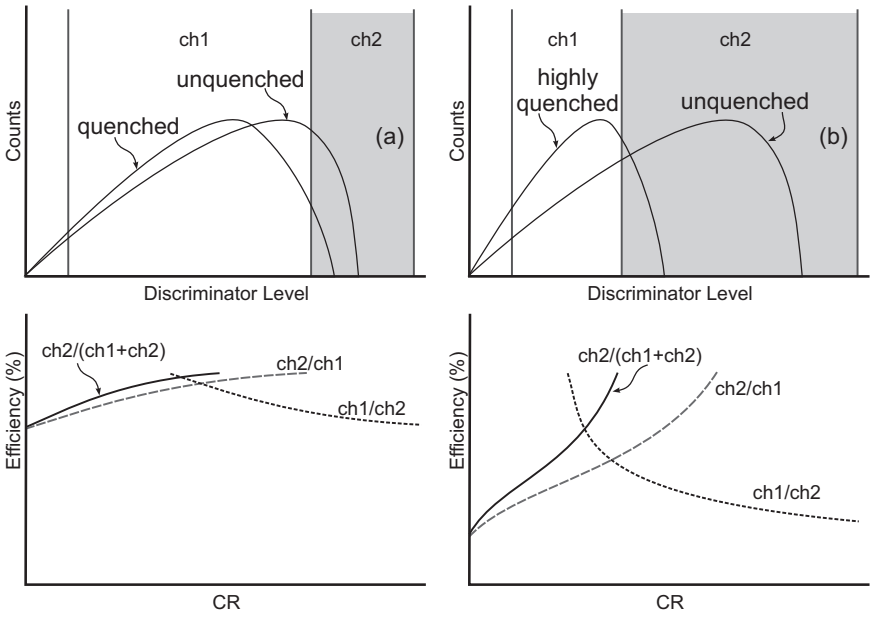

Figure 13.44. Counting efficiency as a function of the channels ratio for two different discriminator settings. In example (a) both channels are set relatively high, while a greater separation is between channel settings in example (b).

Proper selection of the channels is critical to this quench correction method. Consider the two examples shown in Fig. 13.44. The channel selection of Fig. 13.44(a) causes the counts in channel 2 to approach zero at relatively low quench. In other words, selection of the channel ratio method causes the ratio to either approach zero or infinity at a low amount of quench. Although it provides detail in the quench curve for low quenched samples, it has no information for highly quenched samples. For the channel selections of Fig. 13.44(b), the spectrum is more evenly distributed, thereby allowing the calibration of quench curves over a broader range of quenched solutions.

External Standard Method The basic external standard has a gamma-ray source of known activity, usually a ^{137}Cs source, as a component in the LSC system. This gamma-ray source (sometimes called a "pea") is withdrawn into a shielded region inside the LSC system to prevent unwanted background in a scintillation cocktail sample. With a sample in the system, the gamma-ray source is withdrawn from the shield and produces a Compton scattering continuum of energetic electrons in the scintillation cocktail, which adequately mimics the fluorescent yield of beta particles. The original method proposed by Higashimura et al. [1962] used the observed count rates and efficiencies from a set of known beta particle standards. For each quench standard, the counting efficiency is determined by,

$$\epsilon_{\mathrm{i}} = \frac{\mathrm{Cps}(S_i)}{\mathrm{Dps}(S_i)}, \tag{13.44}$$

where $\mathrm{Cps}(S_i)$ is the count rate for standard i and $\mathrm{Dps}(S_i)$ is the known activity of standard i. Each of these standards, immediately after (or before) the measurement, is exposed to the external standard gamma-ray source and the new count rate is recorded. This gamma ray source is placed in the same location with respect to the vial for each measurement. An efficiency calibration curve is developed using the net count

rate response from the gamma-ray source,

$$\text{NCps}(\epsilon_i) = \text{NCps}(\gamma) = \text{Cps}(S_i + \gamma) - \text{Cps}(S_i), \tag{13.45}$$

where $\text{Cps}(S_i + \gamma)$ is the observed count rate with both the gamma-ray source and the activity of the LSC standard. The LSC standard efficiency ϵ_i is plotted versus $\text{NCps}(\gamma)$. For an unknown beta particle sample, the LSC sample efficiency is found by comparing the measured $\text{NCps}(\gamma)$ against the calibration curve. Afterwards, Eq. (13.43) is used to determine the sample activity. Note that it is important that all measurements are conducted for the same amount of time, and that the lower level discriminator is also kept constant during a set of measurements. Calibration sets can be acquired for different beta particles sources, the most common being ^{3}H, ^{14}C, and ^{36}Cl to cover low, medium, and high energy beta particles, respectively. Calibration sets usually have ten quench vials to a set, typically with one "unquenched" standard.

External Standard Channels Ratio Method As the name implies, the external standard channels ratio (ESCR) method combines an external gamma-ray source measurement with the channels ratio quench correction method. In a system with ESCR, there are three wide channels. One channel spans the beta particle spectrum. The other two channels are set higher than the beta particle spectrum, and are used to establish a quench calibration curve with the external gamma-ray source. Hence, the efficiency of the beta particle standard is plotted versus the channels ratio of the gamma-ray source. During a measurement of a beta source of unknown activity, the channels ratio is determined by the gamma-ray source and the beta particle activity is corrected from the quench calibration curve. As with other techniques, two measurements per vial must be conducted so as to subtract the beta particle counts from the gamma-ray spectrum.

Although the ESCR method is convenient, making it popular, its accuracy is less than either the channels ratio or external standard methods [Peng 1977]. Sources of error include dissimilar spectra between the beta particles and the gamma rays, drift in pulse height (mainly with polyethylene vials), vial thickness differences between the set of standards and the samples, and solution volume differences.

Pulse Height Spectrum Shift (H-Number) Method A quench method developed by Horrocks [1964] uses the inflection point of the Compton spectrum for quench identification. Instead of comparing the total counts in the gamma-ray spectrum from the external source, the endpoint channels of the Compton spectra from a multichannel analyzer are compared. Consider the Compton spectra of Fig. 13.45. The endpoint energy, typically designated as the inflection point at the end of the Compton continuum, moves to lower channels in the pulse height spectrum as the quench increases. The maximum energy transferred from a single Compton scatter is 477 keV for ^{137}Cs gamma-rays. Hence, the LSC system is calibrated such that an unquenched sample exposed to ^{137}Cs has the inflection point channel aligned with 477 keV. Quenched samples cause the inflection point to appear in a lower channel.

A quench curve is derived in a similar fashion as the external standard method, in which a set of quench standards is used, except now it is the difference in the inflection point channel that is correlated to the efficiency instead of the total counts. This difference in inflection point is defined as the "H number" (after Horrocks who developed it), where

$$H\text{-number} = \text{Ch}(\text{unquenched}) - \text{Ch}_i(\text{quenched}). \tag{13.46}$$

The efficiency of each vial in the set of standards is determined from Eq. (13.44), and is plotted versus the corresponding H-number for each calibrated vial in the set. For an unknown beta particle sample, the LSC sample efficiency is found by comparing the measured H-number against the calibration curve. Afterwards, Eq. (13.43) is used to determine the sample activity. Note that the H-number method does not require that the beta spectrum be subtracted from the Compton spectrum because only the end point in Compton

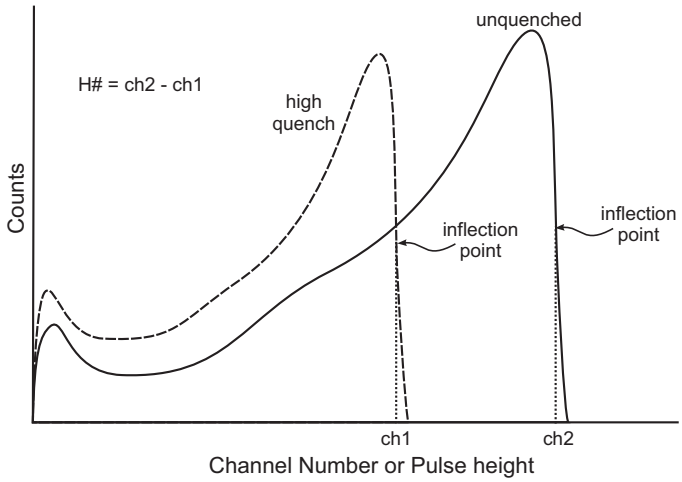

Figure 13.45. Depiction of different Compton spectra from a LSC system to determine the H-number.

continuum matters for the measurement.[29] Provided that sufficient counts are accumulated in the Compton continuum to produce meaningful data, the counting time can be varied between samples. The efficiency as a function of H-number changes tremendously for ^{3}H (18.3 keV) and ^{14}C (156 keV) beta particle sources. However, for high energy beta particles, such as for ^{32}P (E_{max} = 1710 keV) shown in Fig. 13.46, are less affected by quenching.

13.3.4 Plastic Scintillators

Initially introduced in 1950 by Schorr and Torney, plastic scintillators are in many ways similar to organic liquid scintillators in composition. Plastic scintillators contain both primary and secondary fluors in a solvent base that is subsequently polymerized to produce a plastic. This solvent may consist of a monomer that is polymerized by heating or by the addition of a solidifying catalyst. The first such reported plastic scintillators were produced by either introducing p-terphenyl into a hot solution of polystyrene $(C_8H_8)_n$, which was subsequently allowed to cool and solidify or, alternatively, by adding the catalyst 1% benzoil peroxide into a solution of styrene and fluors [Schorr and Torney 1950]. In like manner, methods of producing plastic scintillators from polyvinyl toluene [Koski 1951; Swank and Buck 1953; Buck and Swank 1953], 2,4-dimethylstyrene [Sandler et al. 1960]; and from polymethylmethacrylate (PMMA) [Kienzle et al. 1975; Klawonn et al. 1982; Salimgareeva and Kolesov 2005] were developed. Buck and Swank [1953] show that purity of starting materials has a profound effect upon luminosity, with clean and fresh chemicals producing higher light yields.

Contamination from air and the use of some catalysts that assist with polymerization degrade light yield. Removal of contaminants is performed by vacuum distillation of the starting materials. Fischer [1955] describes a method of passing nitrogen through the monomer solution before polymerization. If the plastic scintillator is not properly processed such that the monomer is completely polymerized, Pichat et al. [1953] showed that aged specimens have long-term oxidation that led to light self-absorption and reduced luminosity. It has also been reported that the process temperature to form plastic scintillators can significantly affect

[29] This convenience requires that the maximum beta particle energy is well below 477 keV. Otherwise, the beta particle counts still must be subtracted to ensure that the inflection point is properly identified.

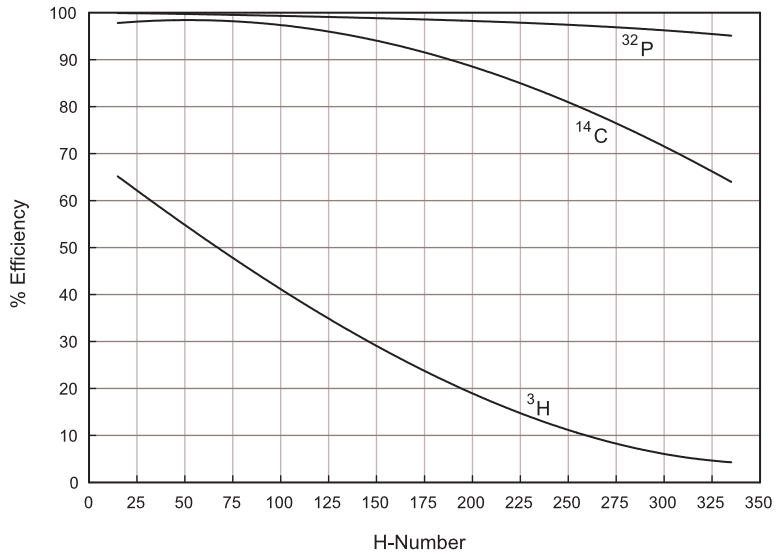

Figure 13.46. Calibration efficiency curves from a commercial LSC as a function of H-number for ^{3}H, ^{14}C, and ^{32}P beta particles. Data are from [Beckman 1985].

light yield [Basile 1957; Funt and Hetherington 1959]. Further, there is indication that light yield decreases for polymer molecular weights below about 100,000, becoming strongly dependent on molecular weight below 50,000 [Funt and Hetherington 1959].

Modern commercial plastic scintillators are based on similar chemistry, but the actual types and concentrations of primary and secondary fluors are kept proprietary. A casual glance at the varied types and specifications of plastic scintillators listed in Table 13.3 illustrates the variations in performance that can be achieved. Many of the legacy plastic scintillators originally developed by Pilot Chemical Co. and Nuclear Enterprises, Inc., are still being produced by contemporary vendors. Polyethylene naphthalate (poly(ethylene 2,6-naphthalate) or PEN) is a recently reported polymer capable of emitting scintillation photons without the assistance of fluor additives [Nakamura et al. 2011]. It has a light yield of about 10,500 photons/MeV with a λ_{max} of 425 nm. The density of PEN is 1.33 g cm^{-3} and has a refractive index of 1.65 that yields a critical angle of 65.4° at a glass interface. The simplicity of PEN can potentially offer a low cost alternative to traditional plastic scintillators.

Plastic scintillators have multiple advantages, namely they can be fabricated or machined into a variety of different shapes, they are relatively inexpensive, they are chemically stable and nonhygroscopic, and they are relatively fast (τ_f of about a few nanoseconds). The emission wavelengths are designed to couple well to conventional PMTs (λ_{max} near 425 nm). The refractive index for most commercial plastic scintillators is around 1.58, which yields a critical angle of 71.7° at a glass interface. Commercial plastic scintillators have a mass density of 1.038 g cm^{-3}. Many plastic scintillators also have a long decay component, similar to organic crystals, and can be used for PSD between neutron and gamma-ray events. The interaction efficiency of radiation particles can be increased by loading plastic scintillators with additional absorbers. For instance, neutron interaction rates can be increased by loading the monomer solution with ^{10}B, ^{6}LiF, or Gd. Gamma-ray interactions can be increased by loading the monomer solution with Pb or Sn. There is, of course, a limit to the amount of additional material that can be added, or otherwise the added material can

decrease the luminosity of the plastic. Another notable use for plastic scintillators is that it can be used as a fast neutron detector with special plastics designed for PSD. Because they are composed of hydrogenous material, they can perform as fast neutron detectors through (n, p) reactions.

The multiple shapes and sizes of plastics include fibers and thin sheets. Scintillating optical fibers can be used to detect radiation and subsequently transport the luminescent signals relatively long distances to a light detector. The plastic fibers are typically composed of polystyrene with a refractive index of 1.58. In order to facilitate light propagation over long distances, a cladding material with lower refractive index must be applied to produce internal reflection. For instance, PMMA ($n = 1.49$) or fluorinated PMMA ($n = 1.42$) are often used as cladding materials. Plastics can also be manufactured as ultra-thin slices. These thin detectors are thin enough to allow the passage of relatively heavy charged particles, attenuating only a small portion of energy; hence can be operated as ΔE detectors for heavy ions such as protons and alpha particles. Thin film organics scintillators are available commercially, some with a thickness as low as 0.25 microns (see Table 13.3).

Recall that Birks' hypothesized non-linearity in light yield was due to damage by heavy ions, and indeed radiation damage can be of concern for plastics used over extended periods of time or in high dose environments. Over time, radiation damage, manifested as broken molecular bonds, cause a decrease in light yield. The effect may be directly due to damage of the base material, the primary fluor, or secondary fluors, and either the light emission is decreased or the transparency is decreased from internal absorption. Bross and Pla-Dalmau [1992] report that plastics operated in air (oxygen) are more affected by radiation damage than those operated in an inert atmosphere, and they hypothesize that oxygen reacts with radical species formed under irradiation as it diffuses into the plastic, and that these oxidation products contain carbonyl and hydroxyl groups which absorb at longer wavelengths and decrease transparency. Bross and Pla-Dalmau [1993] also report on radiation hard 3-hydroxyflavone (3HF) polystyrene plastic scintillators that had about 10% light loss after 10 Mrad of radiation exposure with ^{137}Cs. Studies performed by Vasil'chenko et al. [1996] on numerous (about 70) different polystyrene plastic scintillator formulations indicate that radiation hardness can depend upon the fluor type. Plastics that also contained plasticizers seemed to have higher radiation resistance, some withstanding little change after an exposure of 7 to 9 Mrad of gamma radiation from ^{137}Cs. Alternative polystyrene plastics were studied by Senchishin et al. [1995], who found that radiation hardness can be improved by the addition of diffusion enhancers (such as diphenyloxide). They also conclude that plastics prepared with polystyrene pellets rather than a monomer have superior radiation hardness.

13.4 Gaseous Scintillators

Fluorescence in air has been observed by humans living in northern and southern latitudes for millenia. However, the origin of the northern lights or aurora borealis or of the southern lights or aurora australis was unknown until the twentieth century. Protons and electrons emitted by the sun are usually deflected by earth's magnetic field. But at both poles the magnetic field is weaker and these charged particles can reach earth's atmosphere where they excite oxygen and nitrogen atoms and molecules. At high altitudes up to 200 miles the solar wind interacts with atomic oxygen producing 630.0 nm (red) light, but at lower altitudes the 630 nm emissions are suppressed and 557.7 nm (green) emissions dominate. Both the 557.7 and 630.0 nm emissions correspond to forbidden transitions of atomic oxygen and have decay constants of 0.7 s and 107 s, respectively. Thus, the red and green emissions are really phosphoresence. At even lower altitudes atomic oxygen is uncommon and the solar wind interacts with molecular nitrogen and excited molecular nitrogen to produce light in both the red and blue parts of the spectrum with 428 nm (blue) dominating. That air can be made to fluoresce by radiation particles is shown dramatically in Fig. 13.47. Monoenergetic deuterons emerging from the cyclotron travel in almost straight lines and have a well-defined range as can be seen from the abrupt ending of the fluorescent plume.

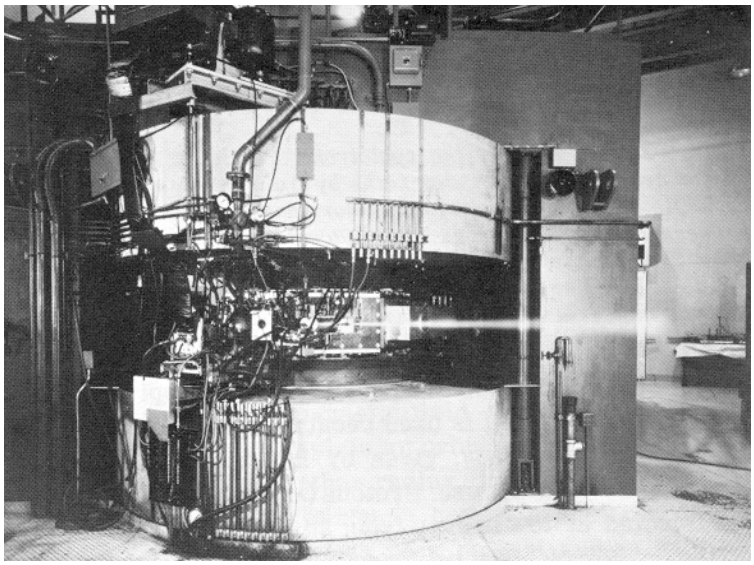

Figure 13.47. The white horizontal misty line is a beam of deuterons emerging from the 60-inch cyclotron at Argonne National Laboratory. The beam is visible because of excitation of air molecules by the energetic deuterons. From Kernan [1969].

13.4.1 Development of Gas Scintillator Counters

Discussed in Chapters 9 through 11 are three basic types of gas-filled detectors that operate on the concept of induced current from charge collection. Note that gas-filled detectors also release photons through deexcitation. Ordinarily these photons are purposely quenched to suppress the formation of additional electronic pulses. However, when the gas is used as a scintillator, this light quenching is undesirable.

The development of the first gas scintillation counter is generally credited to Grün and Schopper [1951]; however, the initial discovery of gas scintillation is not so well defined. It appears that the earliest mention of radiation induced luminosity from gas was reported by Huggins and Huggins [1903a; 1903b; 1905; 1906] who studied alpha particle induced (from radium bromide) luminosity from nitrogen, hydrogen, and air. They deduced that the familiar glow from the radium salt is actually caused by the fluorescing of the surrounding gas. Numerous studies were conducted on the emission spectra from various gases in the intervening years between the work of Huggins and Huggins and that of Grün and Schopper. These investigations are briefly described by Birks [1964]. Grün and Schopper [1951] used purified gases, H_2, Ar, N_2, O_2, and CO_2, which were irradiated with alpha particles, and the light emissions were monitored with a commercial PMT. They noted that impurities, including organic gases, caused a decrease in luminosity.

Gas scintillation detectors have some advantages over other types of detectors, especially when used to detect heavy ions. Gas scintillation detectors are relatively fast, usually having decay times on the order of a few nanoseconds. They also have a proportional response to energy deposition by heavy ions, an attribute generally not shared by other types of scintillators (organic and most inorganics). Multiple authors, outlined by Birks [1964], report a proportional response to charged particles over a wide range of stopping powers $-dE/dx$ regardless of the radiation type, and that the proportionality is superior to other scintillators (solid or liquid). Another important attribute is that gas scintillation detectors can be constructed in large sizes, which can be challenging to produce with solid-state scintillation and semiconductor detectors. Hence, for

large, fast, and proportional detectors needed for the detection and energy spectroscopy of heavy ions, gas scintillation detectors may be a good choice.

13.4.2 Theory of Gas Scintillation Counters

The luminescent quantum efficiency, described by Stern and Volmer [1919], and modified by Birks [1964], can be expressed as follows. From the ideal gas law,

$$\frac{p_a V}{pV} = \frac{n_a RT}{nRT}, \tag{13.47}$$

where T is the absolute temperature, R is the gas proportionality constant, V is the volume, and p_a and n_a are the pressure and molar concentration, respectively, at STP. Rearrangement of terms, the molar concentration n of gas molecules for a closed container (V = constant) at constant temperature is

$$n = \frac{n_a p}{p_a}. \tag{13.48}$$

Stern and Volmer [1919] express the luminescent efficiency, without collisional quenching, as

$$\epsilon_1 = \frac{k_f}{k_f + k_i}, \tag{13.49}$$

where k_f is the rate constant for luminescent emissions and k_i is the internal quenching rate constant both with units of s^{-1}. The mean decay time is then

$$\tau_1 = \frac{1}{k_f + k_i}. \tag{13.50}$$

Birks [1964] adds the product nk_c to describe the quenching loss rate caused by collisions.[30] With collisional quenching, Eq. (13.49) is modified as

$$\epsilon' = \frac{k_f}{k_f + k_i + nk_c} = \frac{\epsilon_1}{1 + p/p'}. \tag{13.51}$$

where p' is defined as

$$p' = \frac{p_a(k_f + k_i)}{n_a k_c}. \tag{13.52}$$

Eq. (13.51) indicates that at low pressures, the intrinsic properties of fluorescence and quenching dominate the luminous efficiency, while at high pressures the collisional quenching becomes important and possibly dominant. A similar effect can be observed with the luminescent mean decay time

$$\tau' = \frac{1}{k_f + k_i + nk_c} = \frac{\tau_1}{1 + p/p'}. \tag{13.53}$$

With the above formulation for luminescence efficiency, the light yield for a gas can be computed as follows. Given a specific volume, the total number of ion pairs produced by a charged particle with energy E is

$$N_{ion} = \frac{E}{w}, \tag{13.54}$$

[30] The unit dimensions of k_c are not those of k_i and k_f, but must also include a factor to account for the gas density or pressure.

where w is the average energy required to produce an ion pair. The value of w is intrinsic to the gas atom (or molecule), and is not a function of the gas density. The number of ions produced for a partial energy loss ΔE is

$$N'_{ion} = \frac{\Delta E}{w}. \tag{13.55}$$

Hence, the scintillation yield per partial energy ΔE_i deposited is the product of the luminescent efficiency and the number of ion pairs produced, i.e.,

$$\frac{\Delta L}{\Delta E} \simeq A_i = \frac{\epsilon' \Delta E_i}{w}, \tag{13.56}$$

and the average light yield per unit energy is,

$$A = \frac{\epsilon_1}{1 + p/p'} \sum_i A_i = \frac{\epsilon_1 N_{ion}}{1 + p/p'}. \tag{13.57}$$

The light yield from a gas is linear with energy deposition as can be seen from Eq. (13.37). Because ΔE is proportional to p, the light yield for an energy deposition of ΔE is [Grün and Schopper 1954]

$$\Delta L = A \Delta E \propto \frac{p}{1 + p/p'}. \tag{13.58}$$

This result indicates that at low p the light yield decreases to small values (an intuitive result) and at high $p \gg p'$ the light yield levels off to a nearly constant value. This type of dependence was demonstrated by Grün and Schopper [1954] for a pure N_2 backfilled detector and an Ar + 8% N_2 backfilled detector.

13.4.3 Factors Affecting Performance

Grün and Schopper [1954] showed that the spectral response can be improved by the addition of a small amount of N_2 to an Ar backfilled detector, although they did not observe such a benefit when N_2 was added to a Xe backfilled detector. The reason for the improvement is a shift in wavelength from the short wavelength UV emission, characteristic of Ar (see Table 13.7), to the longer wavelength emission of N_2, thereby improving spectral matching to a PMT. The wavelength shift is most probably a consequence of ion collisions transferring energy from Ar to N_2 rather than UV photon absorption and reemission [Birks 1964]. Although there is apparent improvement in response with a slight amount of N_2 added to Ar, this result is an artifact of the measurement. In reality, the total number of photons emitted decreases because N_2 acts as a quenching gas; however, the total number of photons detected by the PMT light sensor used in the study increased. Also shown was that the presence of O_2 in small amounts works to reduce performance of Ar-filled gas scintillators.

Table 13.7. Properties of some gas scintillators at 0.974 atm irradiated with 4.7-MeV α particles.

Gas	w (eV/ion pair)	λ_m (nm)	Decay Time (ns)	Light Yield (photons per MeV)	Reference
He	42.3	390	$\leq$20	234	K1,B
Ar	26.4	250	$\leq$20	234	K1,B
Kr	24.1	318		447	K1,B
Xe	21.9	325		787	K1,B
N_2	35	390	$\leq$20	170	K1,B

B: Birks 1964; K1: Koch and Lesueur 1958.

Because the wavelengths emitted by almost all noble gases are in the UV range and do not match well to a PMT response (the exception is He), it is common to employ a wavelength shifter. These λ shifters are either coated upon the PMT window or upon the chamber walls. Several scintillating wavelength shifters that have been used including *trans*-stilbene, diphenylstilbene (DPS), *p*-terphenyl, *p*-quaterphenyl, POPOP, and tetraphenylbutadiene (TPB). Of these, Birks [1964] lists that DPS gives the best results when coupled to Ar, Kr, or Xe gas scintillators. There are precautions that should be implemented when using organic λ shifters. In particular, the outgassing of organic vapors contaminates the gas and causes a deleterious quenching

effect that, consequently, lowers light output. Hence, the λ shifter should have a low vapor pressure to reduce outgassing, or the system can be cooled to also reduce the rate of outgassing. Alternatively, gas-flow chamber can be employed in which the scintillation gas is continuously replenished with fresh gas, or instead, the gas can be filtered and purified in a closed-loop system before re-entering the detector chamber. Finally, the light sensitivity can be increased by using PMTs with quartz windows through which the UV light has better transmittance than that of common soda-lime or borosilicate glass.

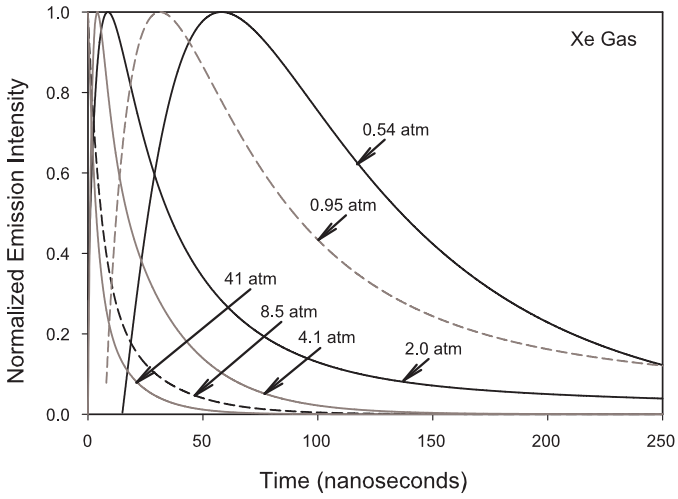

Figure 13.48. Normalized emission intensity for Xe gas as a function of gas pressure. [Parameters are from Koehler et al. 1974].

The emission efficiency and decay time are affected by the gas pressure, as can be seen from Eq. (13.51) and Eq. (13.53). Further, the purity of the gas also affects the emission spectrum, light yield, and decay time. A list of some gas scintillator values are provided in Table 13.7, although these values are limited to a specific case. The complex nature of energy transfer to luminescent levels in a gas scintillator proves difficult to model theoretically. However, Koehler et al. [1974] proposed the use of a summation of numerous exponential terms to model the scintillation decay response of Xe and Ar gases. They model the emitted light intensity by

$$I(t) = \sum_i A_i e^{-t/\tau_i}, \tag{13.59}$$

where A_i and τ_i are experimentally determined amplitudes and decay constants. The terms A_i and τ_i are listed in Koehler et al. 1974 for gas pressures ranging from 0.27 atm to 54.4 atm for Xe and ranging from 6.8 atm to 65 atm for Ar. The time responses for Xe gas at a few selected pressures, based on the work of Koehler et al. [1974], are plotted in Fig. 13.48.

13.4.4 Mixtures of Noble Gases

Gas mixtures of different noble gases have also been studied [See, for example Northrop and Gursky 1958b; Thiess and Miley 1974]. In general, the mixing of noble gases causes a decrease in light yield, with a mixture of He and Xe being the exception. Biondi and Brown [1949], Biondi and Holstein [1951], and Biondi [1952] propose that the dominating recombination process in a pure noble gas are (1) collisions between atomic ions and atoms that form stable molecular ions and (2) the subsequent capture of an electron by a molecular ion produces two atoms in excited states. These excited atoms can release scintillation photons. Apparently, the electron capture probability of the molecular ion is much greater than that of the atomic ion as suggested by the observation of significantly greater radiative recombination coefficients for the purified noble gases [Biondi 1952]. Recall from Chapter 10 (Table 10.6) that the ionization potentials of noble gases decrease with increasing atomic weight. In a gas mixture, the positive charge is transferred in collisions from the lighter gas molecule to the heavier molecule because the heavier gas always has the lower ionization potential. With the addition of small amounts of heavy gas to a lighter gas, the charge is rapidly passed to the heavy gas in a similar fashion as described for quenching gases in proportional counters. Because the concentration of heavy gas atoms is lower than in the pure condition, the probability of ion-atom collisions producing molecular ions is decreased, and consequently, the production of excited atoms is decreased. Consequently, the light yield typically decreases. The exceptions are a mixture of Xe-He, within a pressure ratio range of about 8%

to 100% Xe, and a mixture of Xe-Ne, within a pressure range of about 40% to 60% Xe. The optimum light yield was reported as about 10% Xe in He and yielded over 20% increase in light yield compared to that of pure Xe [Northrop and Gursky 1958b]. Shown in Fig. 13.49 are light yield curves for different gas mixture ratios of Xe fluoresced with alpha particles from ^{234}U. Other gas mixture combinations of He, Ne, Ar, and Kr produced lower light yield than the Xe mixtures.

13.4.5 Liquid and Solid Noble Elements

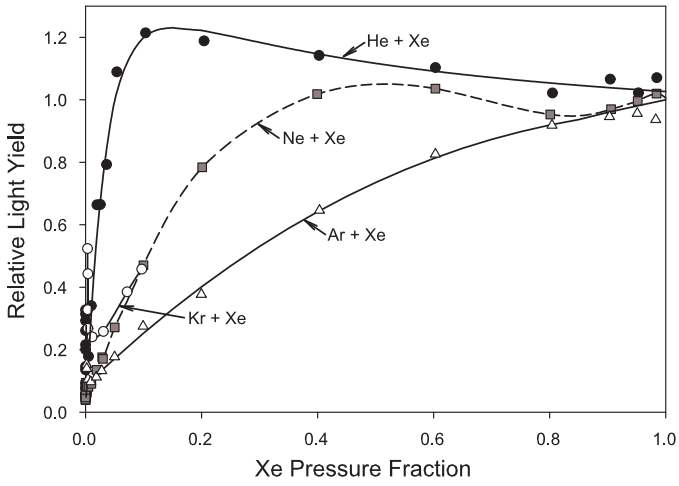

Figure 13.49. Light yield of noble gas mixtures to that of pure Xe gas. Shown are mixtures with the gas pressure fraction of Xe added to He, Ne, Ar, and Kr. Wavelength shifters were used in the work; diphenylstilbene for He-Xe, Ne-Xe, Ar-Xe, and *p*-quaterphenyl for Kr-Xe. Data are from [Northrop and Gursky 1958b].

The noble elements at high pressures have also been studied both in the liquid and solid state phases [see Aprile et al. 2006]. According to the observations of Simmons and Perkins [1961], the emission spectrum from liquid He is different than that from the gas phase and is in the far UV region (less than 160 nm) well below the transmission cutoff of quartz glass (about 180 nm). Similarly, Ar and Xe at high pressures (34 bar) were found to emit light centered at 126 nm and 169 nm, respectively [Koehler et al. 1974]. For such high energy UV photons, caution should be exercised to ensure that the photons are not reabsorbed in the detecting medium and can pass through the glass enclosure of the PMT. Consequently, soda-lime, borosilicate and even quartz windows should not be used for the detection of these emissions because they are effectively absorbed at these short wavelengths. However, the introduction of a wavelength shifter on the chamber walls and PMT window can effectively overcome this problem. The results reported by Northrop et al. [1958a] are listed in Table 13.8 for noble element scintillators when irradiated by alpha particles. Several cases are shown, including a comparison to NaI:Tl, which lists the use of a UV sensitive PMT (DuMont K1306) and a common bialkali PMT (DuMont 6292) with and without the assistance of a *p*-quaterphenyl wavelength shifter. Light yields from liquid and solid Xe were notably high, with liquid Xe having nearly the same light response as NaI:Tl and solid Xe having nearly twice the light response as NaI:Tl. Northrop et al. [1958a] note that the results of Table 13.8 were difficult to reproduce, but do reveal a trend in performance. More recent results by Doke et al. [1990] confirm Northrop's earlier work, reporting a light yield of about 4×10^4 photons/MeV for both liquid Ar and Ne. From the work of Kubota et al. [1978] and Hitachi and Takahashi [1983], fast and slow decay times have been observed for liquid Ar ($\tau_f = 6$ ns; $\tau_s = 1590$ ns) and liquid Xe ($\tau_f = 2.2$ ns; $\tau_s = 27$ ns). There is some indication that these decay times change with radiation type, but the differences reported by Hitachi and Takahashi [1983] were small. However, a relatively large difference in the light intensity ratio I_f/I_s was reported, with electrons yielding a small ratio (0.05), and increases for heavy charged particles for which $I_f/I_s = 0.45$ for alpha particles and $I_f/I_s = 1.6$ for fission fragments. Because of the low temperatures required to form liquid and solid noble elements, light coupling can be challenging. Although PMTs can be used, special models must be used that are capable of operating at cryogenic temperatures along with possessing enhanced sensitivity at UV wavelengths.

Table 13.8. Efficiencies of some noble element scintillators irradiated with α particles. Properties are normalized as compared to NaI:Tl without wavelength shifters.

13.4.6 Gas Proportional Scintillation Counters

It can be advantageous to apply voltage within the chamber of a gas scintillation detector. With an applied electric field, the liberated electrons can be drifted through the gas, much like as in an ion chamber. If the electric field is kept below the critical field required to produce avalanching, then collisions with bound electrons in the gas can be excited to higher energy levels, but do not produce impact ionization. As these excited electrons drop through lower states and eventually to the ground state, they lose energy sometimes by the emission of photons. Hence, this energy transfer produces a type of scintillation light gain. This operation is the basic principle behind a gas proportional scintillation counter (or gas PS counter) [Policarpo 1977].

An interesting advantage to the gas PS counter is its improved energy resolution over traditional proportional counters. Although the name given to the device is the "gas proportional scintillator counter," it is usually not operated in the proportional region of the gas pulse height curve. If operated in the proportional region, where avalanche multiplication occurs, the statistical fluctuation in electron production increases above that of the initial density of electron-ion pairs (see Chapter 10). Hence, the fluctuation in light production also increases thereby diminishing energy resolution. Policarpo et al. [1972] and Policarpo [1977] show that the gas PS counter can produce relatively good energy resolution for low-energy photons and for alpha particles. If a Gaussian model is assumed, the energy resolution of a detector can be approximated by

$$\text{FWHM} = 2\sqrt{2\ln(2)}E(\sigma_{eh}^2 + \sigma_{pe}^2 + \sigma_g^2)^{1/2}, \tag{13.60}$$

where E is the radiation particle energy, σ_{eh}^2 is the fractional variance of ionization production, σ_{pe}^2 is the fractional variance of photo-electron production, and σ_g^2 is the fractional variance photomultiplier gain.

Equation (13.60) can be rewritten as,

$$\text{FWHM} = 2\sqrt{2\ln(2)}E\left[\left(\frac{\sqrt{Fn_0}}{n_0}\right)^2 + \left(\frac{\sqrt{n_{pe}}}{n_{pe}}\right)^2 + \left(\frac{\sigma_G}{G}\right)^2\right]^{1/2}, \tag{13.61}$$

$$= 2\sqrt{2\ln(2)}E\left[\frac{Fw}{E} + \frac{w}{EL\epsilon_c\epsilon_{pe}} + \frac{\sigma_G^2}{G^2}\right]^{1/2},$$

where the FWHM is in units of energy, F is the Fano factor, and w is the average ionization energy, L is the light yield at the operating voltage, ϵ_c is the light collection efficiency, ϵ_{pe} is the photoelectron emission efficiency, G is the PMT light collector gain, and σ_G^2 is the variance in the PMT gain. Typically, the largest statistical variance in gain is the fluctuation in the initial number of photoelectrons produced, accounted for in the second term of Eq. (13.62); hence the third term is usually small so that

$$\text{FWHM} \simeq 2\sqrt{2\ln(2)Ew}\left[\frac{FL\epsilon_c\epsilon_{pe} + 1}{L\epsilon_c\epsilon_{pe}}\right]^{1/2}. \tag{13.62}$$

As previously discussed, noble gas mixtures usually have reduced light yield. However, Alkhazov et al. [1967] show that optimized mixtures of noble gases can decrease the Fano factor. One can observe from Eq. (13.62) that a reduction in F improves the energy resolution, while a decrease in L works to degrade energy resolution; therefore, a proper optimization of the gas mixture should be developed for best results.

There are numerous configurations for the gas proportional scintillation counter [see Aprile et al. 2006 for examples], yet they almost all share a few attributes. The gas chamber has a drift volume designed with a fairly constant electric field which is adjacent to a high field scintillation region. Interactions in the constant field drift region produce electron-ion pairs. The electrons are drifted into the high field region where they gain enough energy to excite more electrons to upper energy levels of the noble gas, but not enough to produce more ionization (or a Townsend avalanche). The high field region is usually small by comparison to the drift region, and can be achieved with small diameter anodes in a similar fashion as in a proportional gas-filled counter. The scintillation light is usually measured with a PMT, although alternative structures with photodiodes have been explored. Other types of gas proportional counters may use microstrip or microgap detectors, or even gas electron multipliers (GEMs). In any event, the goal is to produce scintillations adjacent to a light sensing device with minimal reabsorption loss. As mentioned earlier, impurities can seriously quench the scintillation process, so gas proportional scintillation counters are usually operated as gas-flow detectors in which the high-purity gas is constantly replenished. Wavelength shifters applied to the PMT (or other light collector), and to the chamber walls can help enhance the luminescent response. Excellent energy resolution has been realized, on the order of 9.7% FWHM for 5.89 keV gamma rays [Palmer 1975] and 1.6% FWHM for 8.1 MeV alpha particles [Conde and Ferreira 1975].

PROBLEMS

1. Given that $S_e = S_g$ and $\omega_e = \omega_g$, derive the result for Eq. (13.9).

2. Determine the light conversion efficiency for NaI:Tl photoelectric absorption 898 keV gamma rays. Assume the maximum wavelength and light yield from Table 13.1 apply.

3. Prove Eq. (4.58) reduces to Eq. (13.35) for non-relativistic particles ($v_i \ll c$).

4. A beam of 1-MeV gamma rays is normally incident on a CsI crystal that is 30 mm thick. What is the probability that an incident gamma ray has one or more interactions in the crystal?

5. The dead time in a particular scintillator detector is 2 μs and in typical gas-filled detector is 250 μs. For a particular radionuclide sample, the gross counts obtained with the gas-filled detector suffer a 5% loss because of dead time. For the same source-detector geometry, what is the loss in the scintillator detector?

6. Given the task to efficiently detect gamma rays in the 30 to 60 keV range with a size restricted detector only 2 mm thick, which material would you use given the options of NaI:Tl, GSO, and LSO? Explain your selection choice.

7. Suppose you have a NaI:Tl detector with 7% FWHM energy resolution when operated with a 1 μs shaping time at 300K. What is the expected energy resolution if the temperature is increased to 325K?

8. Given a parallel beam of 662 keV gamma rays from a ^{137}Cs source, compare the efficiency for initial interactions in 1 cm thick slabs of NaI:Tl, $LaBr_3$:Ce, and LSO:Ce. What is it for 1.332 MeV gamma rays for these three scintillators?

9. The best choice of a scintillator material for a detector depends on many factors such as (a) cost, (b) availability, (c) response speed, (d) response linearity, (e) light output, (f) detector efficiency for high-energy photons, (g) radiation hardness, and (h) ability to discriminate between different types of radiation. Evaluate the attractiveness of a typical inorganic scintillator, such as NaI(Tl) and an organic scintillator, such as a plastic one, with regard to each of above performance factors.

10. Why are organic scintillators preferred for electron and beta-particle detection while inorganic scintillators are preferred for gamma-ray detection?

11. Explain the purpose of adding a trace amount of an activator element to an inorganic scintillator. Why is an activator not needed in organic scintillators?

12. A set of 10 vial standards, each having an activity of 0.1 μCi ^{14}C, has the following results for 10 second measurements in a LSC system:

ch1	ch2
420	26600
1000	23000
1600	20000
2000	17400
3500	13500
4200	11100
5000	8700
5900	6000
6800	3500
7800	1200

You then measure an unknown ^{14}C sample with 55120 in ch 1 and 106,000 counts in ch 2. What is the activity and standard error of the unknown sample?

Chapter 14

Light Collection Devices

We have learnt through experience that when an electrical ray strikes the surface of an atom, an electron, and in some circumstances a second and even a third electron, can be detached.

Johannes Stark

Scintillators have been used as a method to observe radiation interactions from the time that Röntgen, in 1895, first observed x-ray fluorescence from a plate coated with barium-platinocyanide ($BaPt(CN)_4$). Hans Geiger meticulously counted alpha particle interactions under a microscope, indicated by flashes of light from a glass slide coated with zinc sulphide (ZnS), a fatiguing technique that inspired Geiger to invent his famous gas-filled detector alternative [Rutherford and Geiger 1908]. Crooke's spinthariscope was a more useful hand-held version of the scintillation/microscope setup used by Geiger. The first hand-held x-ray imaging fluoroscopes used scintillator screens to view various densities of attenuator for medical purposes. In fact, for over 50 years since the time Röntgen first discovered x rays, scintillators had been used for some basic radiation detection purposes. Yet, it was not until the development of a reliable quantitative method of detecting light emissions, other than the human eye, did scintillators become a standard used in research and industry for radiation detection and spectroscopy.

A series of discoveries and inventions led to the technologies used today for quantitatively recording radiation-induced emissions from scintillators. The most popular and widely used of these technologies is the photomultiplier tube (PMT), which is a vacuum tube that incorporates multiple amplification stages to produce large signal amplifications through secondary electron emission. Another important technology, also based on the same idea of the multiplication of secondary electrons, uses microcapillary tubes coated with electron emissive materials. Finally, a third photosensitive technology is based on excitation of conduction electrons in a semiconductor solid. An entire book could be written on the design, operation and application of these technologies to a wide variety of uses; however, that simply is not the goal here. Instead, these basic technologies, in their various forms, are described in this chapter as they are used in radiation detection and measurement.

14.1 Photomultiplier Tubes

In 1887, Heinrich Hertz [1887] made the observation that the voltage required to produce an electric arc between electrodes decreased if assisted by visible light illumination. He also observed that electrical arcing would also occur only for certain wavelengths of light, regardless of the intensity of light. These observed effects were later explained by Albert Einstein with what is now known as the photoelectric effect. It was in 1902 that Austin and Starke [Bruining 1954] published the observation that an electrical current, when directed onto a metallic surface, could produce a greater number of electrons emitted than those impinging upon it, a process often referred to as "secondary electron emission."

It was J.A. Slepian who first published, as U.S. patents, inventions that used the "Stark effect" to produce a current amplification device [Slepian 1923]. In the original description, a heated filament provided a thermionic stream of electrons, guided by magnetic and electric fields into an intermediate anode. Electrons striking this second electrode would then eject more electrons, thereby causing an increase in current, which was subsequently collected at another anode. Although the patent drawing is a simple device with only one electrode producing secondary electrons, Slepian explains that numerous intermediate electrodes can be inserted to increase the gain further, or in his words, "indefinitely." The Slepian device is the predecessor of modern day photomultiplier tubes (PMTs).[1]

During the 1930s, L.A. Kubetsky also designed several working prototypes of secondary emission amplifiers, all of which were based on Slepian's original concepts [Kubetsky 1937]. Kubetsky has been credited with demonstrating the first working electron amplification device, having built the first unit in 1930 [Lubsandorzhiev 2006], although these early "Kubetsky tubes" were more closely akin to microchannel plates than photomultiplier tubes. Various photomultiplier versions were later described by Kubetsky in his 1937 publication as having gains of greater than 10^3.

Also, in 1934, Krebs [1934] introduced a type of Geiger-Müller (GM) tube into which a photocathode was inserted so that the tube could respond to scintillation light. Photons striking the photocathode would eject electrons, which would subsequently produce a Geiger discharge. By 1941, Krebs had improved the device somewhat [Krebs 1941; Daggs et al. 1952], although these devices were largely dismissed due to limited spectral sensitivity. Further, they were mainly based on placing a scintillating ZnS screen near the tube to produce scintillation light which would then fall on the photocathode. However, such a radiation-to-light conversion device proved to have limited efficiency for gamma rays, although it worked well for alpha and beta particles [Daggs et al. 1952].

A chemical process introduced in 1948 by Scherb [1948] extended and improved the spectral response of the photo-sensitive GM tubes, which seemed to provide a promising method to produce a photo-sensitive detector for scintillators. Advancements also included the incorporation of scintillation materials as an integral part of the GM tube [Mandeville and Scherb 1950, Krebs 1955]. Photon-sensitive GM counters were commercially available during the early 1950s for scintillation counter measurements.[2] However, because GM counters do not preserve energy deposition information, these GM counters could be used only as radiation counters and could not function as spectrometers.

Meanwhile, work at the Radio Corporation of America (RCA) led to the demonstration of a single stage electron amplifier based on secondary electron emission that used electric fields to focus and guide electrons [Iams and Salzberg 1935]. The device had an average gain of approximately 8 and did not receive much interest. However, continued research on electron amplifiers eventually led to the demonstration of multistage photomultiplier tubes [Zworykin et al. 1936]. These early PMTs used magnetic and electric fields to accelerate and direct the electrons, a technique which proved difficult to control.

Some early attempts were made to wed charge amplification with vacuum tube technology [Zworykin and Rajchman 1939; Rajchman and Snyder 1940], but it was not until 1941 that the RCA Company released the first commercially successful multistage photomultiplier amplification tube that used secondary electron emission as the amplification mechanism [Janes and Glover 1941, Glover 1941]. The RCA Type 931, shown in

[1] There seems to be some contention regarding the inventor of the PMT, whether it is rightfully Kubetsky [1937] or the RCA group consisting of Zworykin, Morton, and Malter. Lubsandorzhiev [2006] writes in his short review paper that Zworykin visited Kubetsky's laboratory during 1934, implying that Zworykin was inspired by Kubetsky's work on electron amplifying tubes, thereby suggesting that Kubetsky is the originator. However, it was Slepian [1923] that suggested the use of multiple electrodes to increase the gain, as acknowledged by Kubetsky [1937]. Hence, by the authors' estimation, the fundamental operation of a PMT was actually first described by Slepian.

[2] The Nuclear Research Corp. of Philadelphia, Pennsylvania, for instance, commercialized these photon-sensitive GM tubes.

Fig. 14.1, was originally used as a signal amplifier for electronics, in particular it was used to jam radar during the second world war. Shortly thereafter, Curran and Baker [1944] reported the use of a PMT placed adjacent to a ZnS scintillator screen to detect alpha particles. This application is the first reported use of a PMT for radiation detection. A few years later, Marshall et al. [1947] demonstrated the use of a PMT wrapped in a fluorescent material to detect x rays.

Further, Marshall and Coltman [1947] and Coltman and Marshall [1947] demonstrated the coupling of various different scintillating screens to PMTs to detect alpha particles, beta particles, x rays, gamma rays, and neutrons. That same year, Broser and Kallman [1947a] also coupled scintillating screens to a PMT to detect alpha particles, and later that same year reported the use of the organic scintillator naphthalene with a PMT [Broser and Kallman 1947b]. Throughout the following few years, numerous groups reported on the advantage of coupling a light-collection of PMT amplifiers to radiation scintillators. Notably, Hofstadter [1948] discovered the inorganic scintillator NaI(Tl), which when coupled with a PMT produced the first practical solid-state gamma-ray spectrometer.

It is the introduction of the PMT that led to the practical realization of scintillation spectrometer detectors (see articles by Morton [1975a, 1975b]. Even today a PMT is the most popular light measuring device for most scintillating materials, mainly because of their high gain and low dark current.[3]

Figure 14.1. The RCA 931A was the first commercially available PMT.

14.1.1 Basic Design

The basic design of a photomultiplier includes (1) a transparent envelope, typically constructed of glass, (2) a photocathode, (3) a series of dynodes, and (4) an anode. Each component, described in the following sections, plays an important role in the efficiency, timing, and ultimate energy resolution of the spectrometer. The photomultiplier is a simple device to understand. The basic PMT, depicted in Fig. 14.2, has a photocathode that is located so as to absorb light emissions from a light source such as a scintillating material. When photons of light strike the coating on the photocathode, they emit electrons that can diffuse through the coating to the surface facing the vacuum of the tube. A fraction of these diffusing electrons then escape the surface and enter the vacuum tube. A voltage applied to the tube guides the liberated electrons to an adjacent electrode called a *dynode*. As an electron approaches the dynode, it gains speed and energy from the electric field formed by the applied voltage. Hence, when it strikes the dynode, it again causes more electrons to become liberated into the tube. These newly liberated electrons are then guided by the electric field to the next dynode where more electrons are liberated and so on. As a result, the total number of electrons released is a function of the number of dynodes in the PMT and the photoefficiency of the photocathode and the dynodes.

The total charge released in the PMT is

$$Q = q_e N_0 G^M \tag{14.1}$$

where q_e is the charge of an electron, N_0 is the initial number of photo electrons released at the photocathode, G is the number of electrons released by a dynode per incident electron (the gain), and M is the total number

[3] In 1941, RCA was the first company to introduce a commercial PMT into the marketplace. The RCA plant, located in Lancaster PA, was purchased by GE in 1986, whereupon in 1987 the former RCA management team purchased the PMT facility and technology, forming Burle Industries. Burle was later purchased by Photonis in 2005. Unfortunately, in 2009, Photonis discontinued the PMT line. ADIT Electron Tubes, a division of Ludlum Measurements Inc., purchased the production equipment and presently offers PMTs designed primarily for radiation detection.

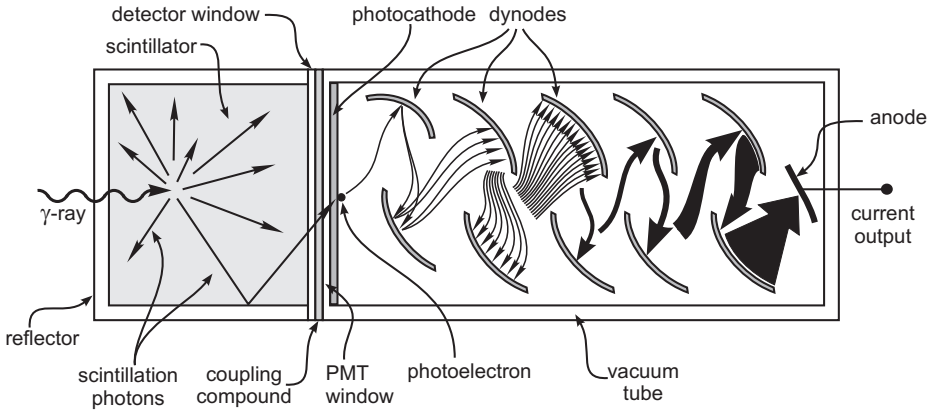

Figure 14.2. The basic mechanism of a photomultiplier tube (PMT). An absorbed γ ray causes the emission of numerous light photons which can strike the photocathode. A scintillation photon that strikes the photocathode creates a photoelectron. The photoelectron is accelerated and guided to the first dynode by an electric field, where it strikes the dynode and ejects more electrons. These electrons are accelerated to the next dynode and excite more electrons. The process continues through the dynode chain until the cascade of electrons is collected at the anode whose output current is used to produce a voltage pulse.

of dynodes in the PMT. For instance suppose that a PMT has 10 dynodes each operated with a gain of 4. An event that initially releases 1000 electrons (N_0) causes over 10^9 electrons to emerge from the PMT! Shown in Fig. 14.3 are the components of a NaI(Tl) detector (top) along with a complete detector (bottom). Also shown in Fig. 14.4 are the internal components of a NaI:Tl scintillation detector.

The photomultiplier tube is an extremely important tool in radiation detection because it is the device that allowed scintillation materials to become practical detectors. The PMT can take a small amount of light produced in a scintillator from a single radiation absorption and turn it into a large electrical signal. It is this electrical signal, typically converted to a voltage pulse, that is measured.

PMTs are stable and electronically quiet (low noise). Modern varieties have exceptional photocathode and dynode efficiencies, often referred to as the *quantum efficiency*, with gains that can exceed 30. However, there is an important design consideration. PMT materials used as photocathodes are generally fabricated from alkaline metals, which are most sensitive to light with wavelengths in the 350 to 450 nm range. Scintillators emitting light outside this range can still be used under some circumstances, although their effectiveness can be severely compromised.

14.1.2 Light Collection and Coupling

So far PMTs are treated simply as light collection devices, with a brief cautionary note about wavelength matching between the PMT and the scintillation light. In this section, this important aspect in the design of PMTs is discussed in much greater detail.[4]

[4]Throughout this chapter, "light" is characterized either by its wavelength $\lambda = c/\nu$ or by the energy of its photons $E = h\nu$. To convert between these two characterizations, a useful relation is

$$\lambda E = hc = 1240 \text{ nm eV}.$$

Figure 14.3. An encapsulated NaI(Tl) crystal in a reflective canister is shown in the upper left and a photomultiplier tube is shown in the upper right. The two components are coupled together to form a scintillation counter such as the one shown in the lower half. The NaI(Tl) scintillation spectrometer is composed of a 2×2 inch NaI(Tl) crystal coupled to a PMT, both of which are sealed in the container together. The combined voltage divider and preamplifier unit is attached to the back (right side) of the PMT.

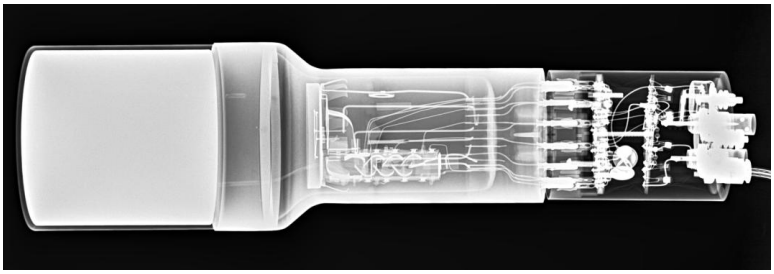

Figure 14.4. An x-ray photograph of a 3 in × 3 in NaI:Tl detector coupled to a linear focus PMT, resistive divider, and preamplifier.

Snell's Law

The *index of refraction* is defined as the ratio of light speed in vacuum to that in a particular medium,

$$n = \frac{c}{v}. \tag{14.2}$$

Snell's Law is a fundamental law describing the reflection and transmission of light at the interface between two adjacent optical surfaces. This law states, using the notation shown in Fig. 14.5(a),

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{n_2}{n_1} = \frac{v_1}{v_2}, \tag{14.3}$$

where n_i and v_i are the index of refraction and the speed of light in medium i, respectively. The index of refraction for some common window materials is given in Table 14.1.

Table 14.1. Index of refraction (at $\lambda = 410$ nm) and cut-off wavelength below which the transmission is less than 10% of the maximum.

Window material	Index of refraction	Cut-off wavelength (nm)
Soda Lime	1.536	300
Borosilicate	1.530	270
GE 214 (fused silica)	1.459	<160
Suprasil 310 (fused silica)	1.469	<155
Quartz	1.557	
Al_2O_3	1.785	145
MgF_2	1.383	115
LiF	1.398	105

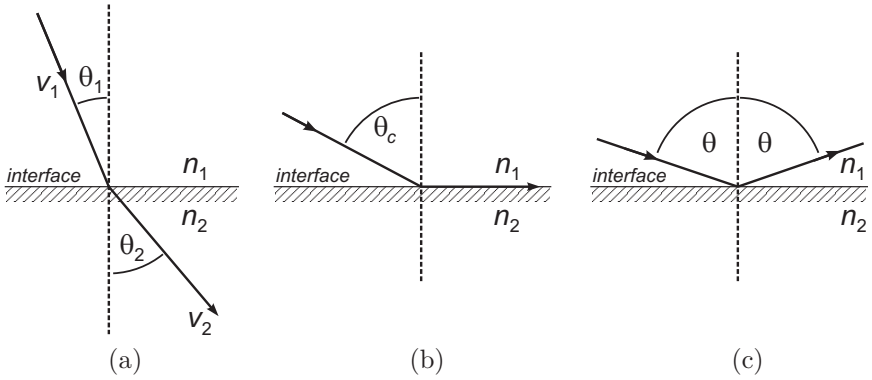

Figure 14.5. Snell's Law showing (a) refraction through two media, (b) total internal reflection at the critical angle, and (c) total internal reflection beyond the critical angle. In these figures it is assumed $n_1 \geq n_2$.

For the case $n_1 > n_2$, $\theta_2 > \theta_1$ as is shown in Fig. 14.5. There is a critical angle in medium 1, for which $\theta_2 = 90°$ beyond which no light is transmitted into medium 2 and all light is reflected back into medium 1. This critical angle for medium 1 is

$$\theta_{1c} = \sin^{-1}(n_2/n_1). \tag{14.4}$$

However, if $n_1 < n_2$, there is no critical angle for medium 1, i.e., light is transmitted for any incident angle.

Therefore, to reduce light losses from internal reflection at the scintillator/PMT interface, the index of refraction for the PMT window should closely match the index of refraction of the scintillation material. Because of a possible index mismatch between many common scintillation materials and PMT windows, a *coupling compound* is usually placed between the two materials. Coupling compounds are usually selected such that $n_{\text{coupling}} \simeq n_{\text{window}}$.

Example 14.1: Determine the critical angle for light propagating from common glass into air.

Solution:

The index of refraction for air is $n_2 = 1.0$, and glass has an index of refraction approximately equal to $n_1 = 1.5$. From Eq. (14.4),

$$\theta_c = \sin^{-1}(n_2/n_1) = \sin^{-1}(1.0/1.5) = 41.81^\circ.$$

Lambert's Cosine Law

It is usual for the scintillator to be encapsulated in a reflecting cannister in which some portion of the cannister has a transparent window for light to exit. For best results, the cannister window should have an index of refraction as close to those of the scintillation material and the entrance window to the PMT. Further, the relative amount of light (per unit energy deposited in the detector) that *enters* the PMT from the scintillator material should, ideally, be constant.

Consider a homogeneous half-space (a wall of the canister, for example) in which there is a constant light source emitting isotropically S photons cm^{-3} s^{-1}. As shown in Fig. 14.6, on the surface (the x-y plane) is a small area δA whose outward normal is the z-axis. The number δN of photons emitted per unit time from a differential volume dV a distance r from δA that pass through δA in a differential solid angle $d\Omega$ about $\mathbf{\Omega}$ is

$$\delta N = S\, dV \left(\frac{\delta A \cos\theta}{4\pi r^2}\right) \exp(-\mu r). \tag{14.5}$$

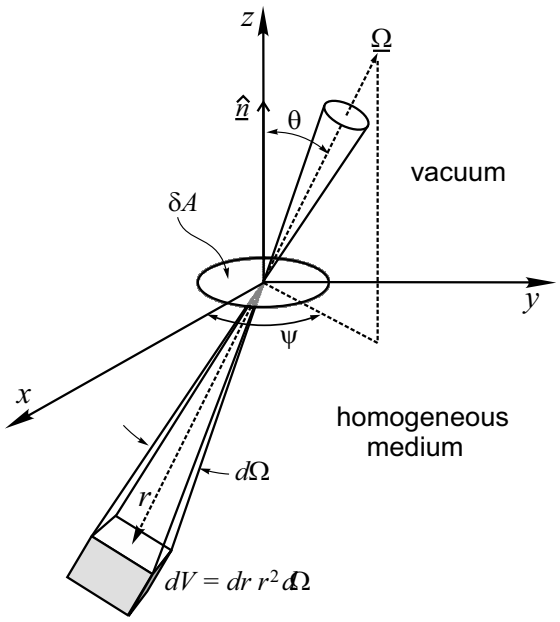

Figure 14.6. Coordinate system used to describe Lambert's cosine law.

Here $S\,dV$ is the number of photons emitted isotropically from dV per unit time. The term in parentheses is the probability photons emitted from dV are emitted towards δA, i.e., the fraction of the total solid angle subtended by δA at dV. The last term is simply the probability a photon travels to δA without interacting with the medium, which has an interaction coefficient μ.

The total flow through a unit area on the surface in direction $d\Omega$ about $\mathbf{\Omega}$ from all $dV = r^2 d\Omega dr$ is

$$J_n(\mathbf{\Omega})d\Omega = \int_0^\infty (\delta N/\delta A) r^2 d\Omega dr = \frac{S\cos\theta}{4\pi} d\Omega \int_0^\infty d^{-\mu r} dr = \frac{S\cos\theta}{4\pi\mu} d\Omega. \tag{14.6}$$

From this result it is seen that the probability a photon emerges in a unit solid angle about a direction θ is proportional to $\cos\theta$, i.e., the intensity of light emitted from the surface is $I(\theta) = I(0)\cos\theta$ W cm^{-2} sr^{-1}. Any surface emitting light whose intensity is proportional to $\cos\theta$ is called a *Lambertian* surface.

Lambertian surfaces have an amazing property. As shown in Fig. 14.7, if one views an area A on such a surface the projected area perpendicular to θ is $A/\cos\theta$ cm^{-2}. The *sterance*[5] or light L observed by the eye or other light detector is

$$L = \frac{I(0)\cos\theta}{A\cos\theta} = \frac{I(0)}{A}. \tag{14.7}$$

This means the surface appears equally bright no matter from what angle the surface is viewed. For example, the surface of the sun is a Lambertian surface, so the sun's disk appears uniformly bright from the center to the edge.

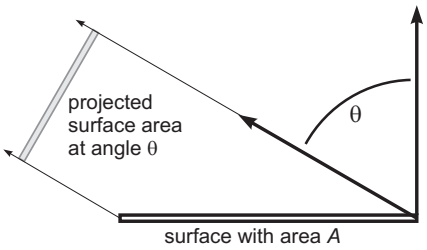

Figure 14.7. Depiction of projected area as a function of angle.

The important result of Eq. (14.7) indicates that the sterance from a Lambertian surface is constant, hence the reflected light from the cannister walls that reach the transparent interface between the scintillator and the PMT is almost constant regardless of where on the surface the reflected photons originated. Such is not true for a specular surface, at which the angle of light intersecting the transparent interface is a strong function of the initial location of the scintillation flash, thereby causing a large variance in the transmitted and internally reflected light. Hence, there is a larger variance in light transmitted into the PMT from a specular reflector compared to that from a Lambertian reflector.

Because energy resolution depends on the variance of the light entering the PMT, a Lambertian reflector wrapped around the scintillator produces better energy resolution than does a specular reflector. Common materials used to produce a near Lambertian surface include Teflon tape, Al_2O_3, TiO_2, and MgO powder. These materials produce a diffuse light reflection nearly independent of where the initial radiation interaction occurs in the scintillator. The product Spectralon®, a fluoropolymer, has nearly perfect Lambertian reflectance for wavelengths between 400 to 1500 nm.

Window Reflection and Transmission

After scintillation light transits the interface between the detector and the PMT, it must still pass through the transparent PMT window in order to reach the photocathode material. There are a variety of PMT window materials, each having a short wavelength cutoff beyond which photons with small wavelengths become strongly absorbed in the window (see Table 14.1). Many scintillators emit wavelengths near 40 nm (400 angstroms), which generally matches well to common glasses, including soda-lime and borosilicate glasses. However, there are many important scintillators that emit photons with wavelengths in the near UV region (300-400 nm) and are strongly absorbed by common glasses. The characteristic light response function of a scintillation detector can be severely compromised at short wavelengths simply by a poor choice of a PMT window.

Some of the light, with a wavelength λ, that impinges perpendicularly on an interface between two media undergoes reflection. The fraction of light reflected, or the *reflectance*, is [Hecht 1987]

$$R_{12}(\lambda) = \frac{[n_2(\lambda) - n_1(\lambda)]^2}{[n_2(\lambda) + n_1(\lambda)]^2}. \tag{14.8}$$

Here $n_1(\lambda)$ and $n_2(\lambda)$ are the refractive indices of the two media and both are functions of wavelength (see Fig. 14.8). Notice the reflectance is the same no matter from which medium the light is incident on the interface. The light not reflected is transmitted so the *transmittance* into the window is $T_{12} = 1 - R_{12}$.

[5] The sterance of a surface is the light-power emission rate per unit surface area per steradian and typically has units of W cm^{-2} sr^{-1}.

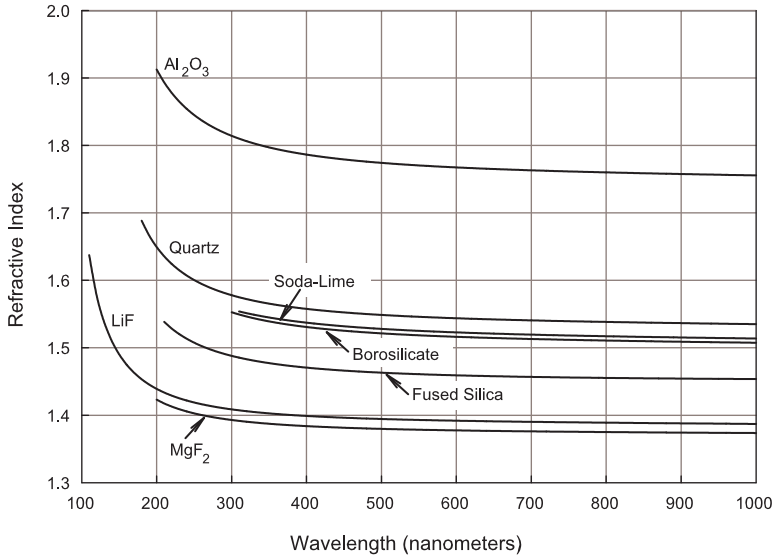

Figure 14.8. The index of refraction of a few PMT window materials as a function of wavelength. From [Polyanskiy, 2014].

As light passes from the scintillator (medium 1) through the window (medium 2) into the PMT (medium 3), it is reflected at the two surfaces of the window. If there is no absorption of light as it passes through the window, the minimum resulting *transmittance* T_{min} is

$$T_{min} = [1-R_{12}(\lambda)][1-R_{23}(\lambda)] = \left\{1 - \frac{[n_2(\lambda) - n_1(\lambda)]^2}{[n_2(\lambda) + n_1(\lambda)]^2}\right\}\left\{1 - \frac{[n_3(\lambda) - n_2(\lambda)]^2}{[n_3(\lambda) + n_2(\lambda)]^2}\right\}$$

$$= \frac{16 n_1(\lambda) n_3(\lambda) n_2^2(\lambda)}{[n_2(\lambda) + n_1(\lambda)]^2 [n_3(\lambda) + n_2(\lambda)]^2}, \tag{14.9}$$

where $n_3(\lambda)$ is the index of refraction of the medium light enters upon passing through the window (presumably a vacuum).

If one assumes medium 1 is air and medium 3 is a vacuum, then $n_1 \simeq n_3 = 1$, and Eqs. (14.8) and (14.9) reduce to

$$R(\lambda) = \frac{[n(\lambda) - 1]^2}{[n(\lambda) + 1]^2} \qquad \text{and} \qquad T_{min} \simeq \frac{16 n^2(\lambda)}{[1 + n(\lambda)]^4}, \tag{14.10}$$

where n is the window refraction index.

Actually, slightly more light is transmitted to the PMT than described by Eq. (14.10). Light reflected at the PMT/window surface can be reflected at the other surface and some of this light is then transmitted into the PMT after making three crossings in the window. Similarly, light can be reflected many times inside the window and eventually be transmitted to the PMT. Hence the total transmittance is

$$T(\lambda) = [(1 - R(\lambda))^2][1 + R^2(\lambda) + R^4(\lambda) + \ldots] = \frac{(1 - R(\lambda))^2}{1 - R^2(\lambda)}. \tag{14.11}$$

With absorption losses, light transmission through the PMT window can be approximated by

$$\phi' = \tau(\lambda)\phi_0 e^{-\alpha(\lambda)x}, \tag{14.12}$$

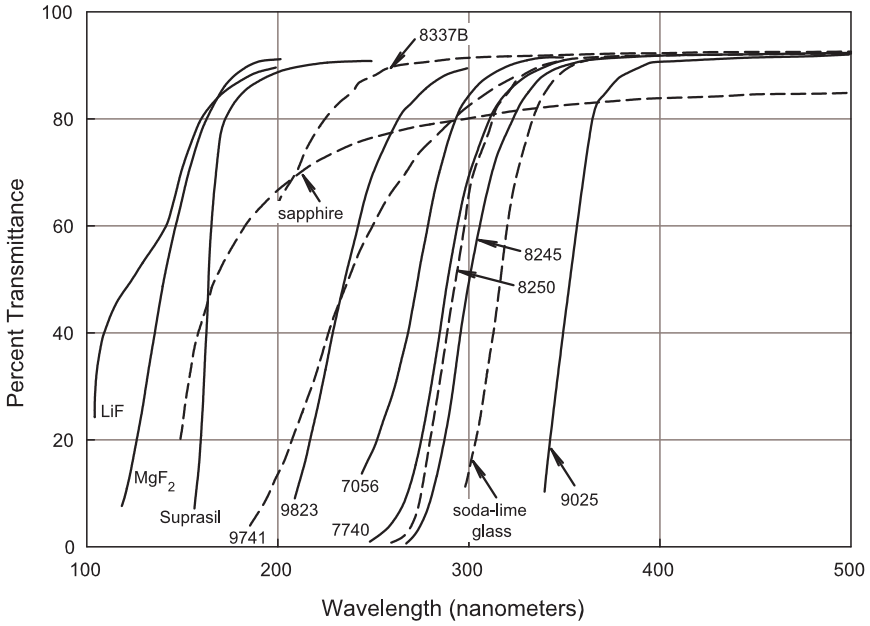

Figure 14.9. Transmission of light through various PMT windows, each 1 mm thick, as a function of wavelength. Corning borosilicate glasses 7740 (Pyrex), 7056, 9823, 9741 and Schott borosilicate glasses 8245 and 8250 have been usually used for PMT windows. Schott 8337B and Heraeus Suprasil (fused quartz) are often used for extended UV PMTs. Data are from Engstrom [1980], Donati [2000], and Schott [2014].

where ϕ' is the transmitted flux of light, ϕ_0 is the initial photon flux impinging perpendicular upon the surface, x is the glass thickness, and $\alpha(\lambda)$ is the wavelength-dependent attenuation coefficient. The reflectance $R(\lambda)$ is between 0.035 to 0.05 for most glasses for which the index of refraction $n \simeq 1.5$. The coefficient of reflective losses generally increases with increasing values of n.

For most scintillator detector applications, a window of borosilicate glass has a sufficiently low cutoff wavelength that adequately allows the transmission of scintillation photons. For instance, Pyrex (Corning 7740) efficiently transmits light with wavelengths above 350 nm (see Fig. 14.9). Common borosilicate glasses used for PMTs include Corning 7056, Corning 7740, Schott 8245, and Schott 8250. In high radiation fields, radiation damage to the glass can cause its clarity to change, slowly becoming brownish over time. PMTs with non-browning glass, such as Corning 9025, can be used in high radiation environments. The transmittance of a few materials used for PMT windows are shown in Fig. 14.9. In some applications, deeper UV emissions from a scintillator are of interest, but are attenuated by common borosilicate glasses. For deeper UV transmission, special PMT borosilicate windows with extended UV range are used, including Corning 9741, Corning 9823, and Schott 8337B glasses. Quartz and fused quartz (Suprasil) have excellent deep UV transmission properties and allow the passage of photons with wavelengths down to 160 nm. Further, the index of refraction is near 1.55, thereby producing minimal reflection losses. Because of their extended UV range, PMTs with fused quartz windows can be used as Čerenkov radiation detectors. Sapphire (Al_2O_3) windows also allow the transmittance of deep UV photons, but Al_2O_3 has a high index of refraction compared to that of glass and, thus, causes higher reflection losses, i.e., a higher $R(\lambda)$, especially at lower wavelengths.

For deep UV transmission, PMTs with either LiF or MgF_2 windows can be used. PMT windows manufactured from LiF windows transmit photons with wavelengths down to 105 nm, below which there is no transmittance. However, attenuation becomes significant below 120 nm, which has approximately 40% transmittance. LiF windows are fragile and expensive to produce; hence they are used only in special applications. LiF is also slightly hygroscopic, increasing so as the temperature increases, especially above 400°C.[6] Hence, precautions against moisture must be implemented. MgF_2 is not as fragile as LiF, and is perhaps a more popular solution for deep UV photon detection. This material allows transmission of UV photons with wavelengths down to 125 nm before significant attenuation losses occur. The cutoff wavelength for MgF_2 is about 115 nm. Finally, PMTs without windows must be used for the detection of UV light with wavelengths λ less than 105 nm.

Some PMT manufacturers emphasize the use of low background windows. For most applications, such a feature is probably unnecessary. However, for low background radiation measurements, contamination from ^{40}K, ^{238}U, or ^{232}Th may be an issue. Borosilicate glass often has considerable contamination from these radioactive elements, particularly from ^{40}K. Purified forms of borosilicate glass or fused silica (quartz), while more expensive, are offered as low background PMT windows.

14.1.3 Photocathode Materials and Design

The main function of a PMT is to convert photons into electrical charges. This conversion is accomplished by using the photoelectric effect, in which scintillation photons photoelectrically interact in a material coated onto a cathode in the PMT resulting in the ejection of a photoelectron.

Quantum Efficiency, η_{pc}

For PMT photocathodes, the *quantum efficiency* η_{pc} is defined as the number of electrons released from the photocathode per photon incident on the cathode,[7] and is usually defined at a specific photon wavelength. The quantum efficiency is affected by at least three different physical attributes of the absorber material, namely the absorption efficiency, the electron diffusion length, and the energy barrier.

Absorption efficiency can be affected by the glass enclosure, the type of photocathode, and, of course, the photocathode material. As just discussed in the section on window reflection and transmission, there are reflected and transmitted components of the light incident on the window. The size of these components generally depends on the wavelength of the light. Losses from reflection are generally near 8% when considering reflection on the inner and outer glass surfaces. Transmission is a function of wavelength, dropping to only 10% transmission at the cut-off wavelength. Hence, the η_{pc} can be severely reduced at photon wavelengths approaching the cut-off wavelength of the window. The absorption efficiency of the photocathode depends of the thickness of the material coating the photocathode. For semi-transparent (or transmission) photocathodes, a thin layer of photosensitive material is coated upon the inner portion of the glass window, usually only a few nanometers thick. An alternate design, less common for use with radiation detectors, is the internal opaque photocathode, which is not coupled to the PMT window, but rather is set apart inside the structure.

Photon absorption is restricted to those wavelengths with sufficient energy to elevate electrons into higher electronic energy levels. For instance, if a photon has sufficient energy to elevate an electron from the band of valence electrons into the band of conduction electrons, then the photon can be absorbed.

[6] Many manufacturers of LiF optics warn against using the material above 400°C due to being attacked by atmospheric moisture.

[7] The term *quantum efficiency* has several alternative definitions. It is also used to define the fraction η_λ of excited charge carriers that radiatively recombine to release photons, a definition generally used for photon emitting devices such as LEDs and laser diodes. For semiconductor photon detectors, quantum efficiency is also defined as the number of electron-hole pairs produced per unit photon energy at λ. In an attempt to remedy this confusion, the authors distinguish among the various definitions with an appropriate subscript.

Table 14.2. Properties of a few common photocathodes. Data are from Flyckt and Marmonier [2002] and Engstrom [1980].

Photocathode	Composition	Window	Emission threshold (nm)	λ_{max} (nm)	Radiant sensitivity (mA/W)	$\%\eta_{pc}$ at λ_{max}

Note that absorption of such a photon may still fail to give the electron sufficient energy to escape the conversion material. For most metals, electrons must absorb enough energy to surmount an energy barrier at the vacuum interface of the photocathode in order to enter the vacuum of the PMT. Semiconductors, by contrast, have relatively few electrons in the conduction band; hence electrons are generally excited from lower energy bands (such as the valence band), and must have sufficient energy to surmount both the energy gap between the bands plus energy to surmount the energy barrier at the vacuum interface. Long wavelength photons may fail to transfer the required energy to surmount the vacuum barrier and, thus, generally defines the long wavelength cut-off for many photocathodes.

Photoelectrons created very near the vacuum interface need diffuse only a short distance to the interface where, if they have an energy above the energy barrier, they escape into the PMT. However, electrons may diffuse in any random direction; hence, some electrons created very near the interface may diffuse in directions away from the vacuum interface. Also, electrons produced deeper in the photocathode material must diffuse greater distances to reach the vacuum interface, during which migration they lose energy from collisions with ambient electrons. If these electrons reach the vacuum interface, but no longer have sufficient energy to surmount the barrier, they de-excite to lower energy levels and can no longer escape into the vacuum and contribute to the PMT photocurrent. All of these processes tend to reduce the overall quantum efficiency of the photocathode. Listed in Table 14.2 are properties of a few common photocathode materials.

Work Function, ϕ_m

Photoemission is the process in which the absorption of photons in some material results in the ejection of energetic electrons from the material. Most PMTs use metals with low ionization energies as the photocathodes, although many PMTs also use special semiconducting materials.

To understand the photoemission process, consider the energy level diagrams shown in Fig. 14.10. In Fig. 14.10(a) an interface between a metal and vacuum is depicted based on the Sommerfeld model [Dekker 1957]. For an electron to escape from the metal into the vacuum, it must gain enough energy to reach the vacuum level, E_0. The energy difference between electrons at rest in the metal and electrons at rest in the

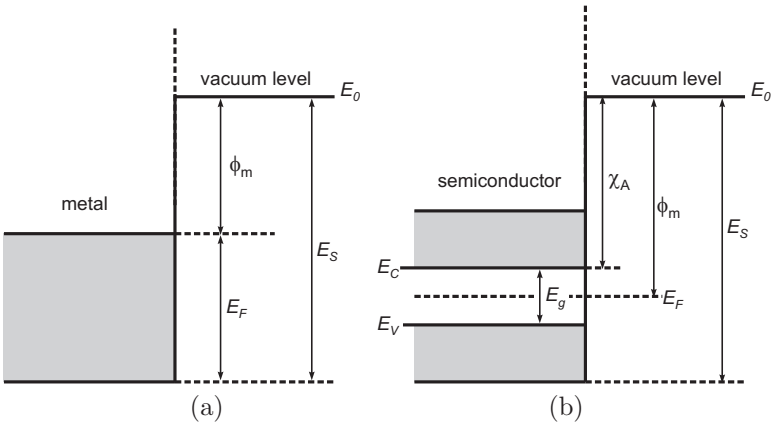

Figure 14.10. Simplified (a) band diagram of a metal based on the Sommerfeld model, and (b) a band diagram of a semiconductor/vacuum interface.

vacuum is denoted as E_S. The Fermi energy level E_F is defined as the energy below which all states are filled and above which all states are empty at absolute zero (0 K). The minimum energy required for electrons to move from the metal to the vacuum level is $E_S - E_F$, and is referred to as the metal *work function*, ϕ_m. The energy required to move an electron at rest in the metal to the vacuum level is referred to as the *outer work function* and equals E_S.

The probability that an electron occupies a state with energy E is given by the Fermi-Dirac distribution function of Eq. (12.118), repeated here for convenience,

$$f_{\mathcal{FD}}(E) = \frac{1}{1 + \exp\left[\dfrac{E - E_F}{kT}\right]},$$

where k is the Boltzmann constant, T is the absolute temperature, and E_F is the Fermi energy. At absolute zero, the Fermi-Dirac distribution function is a step function, i.e.,

$$f_{\mathcal{FD}}(E) = \begin{cases} 1 & E \leq E_F \\ 0 & E > E_F \end{cases}. \tag{14.13}$$

As the temperature increases, thermal energy allows some electrons to exceed the Fermi energy, provided that energy states are available.

With the method described in Sec. 12.5.3, the density of available states about differential energy dE in a metal is found to be (see Eq. (12.115))

$$N(E)dE = \frac{\sqrt{2}m_e^{3/2}}{\pi^2\hbar^2} = \frac{4\pi(2m_e)^{3/2}}{h^3}E^{1/2}dE, \tag{14.14}$$

or

$$N(E)dE = \frac{\sqrt{E}}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}dE, \tag{14.15}$$

where h is the Plank constant and m_e is the electron rest mass. The product of $N(E)$ and $F(E)$ yields the filled state density as a function of energy and temperature, as shown in Fig. 14.11. The total number of

Table 14.3. Valence, Fermi energy, and work function for metals often used in PMTs.

Metal	Valence	Fermi Energy E_F (eV)	Work function ϕ_m (eV)
Li	1	4.72	2.9
Na	1	3.23	2.36
K	1	2.12	2.29
Rb	1	1.85	2.26
Cs	1	1.58	2.14
Cu	1	7.07	4.45
Ag	1	5.5	4.46
Ba	2	3.8	2.51
Al	3	11.7	4.20

filled states (electrons) per unit volume can be determined by integrating the product $N(E)F(E)$ over all possible energies,

$$n = \int_0^\infty N(E) f_{\mathcal{FD}}(E) dE = \frac{4\pi(2m_e)^{3/2}}{h^3} \int_0^\infty f_{\mathcal{FD}}(E) E^{1/2} dE. \tag{14.16}$$

At absolute zero, Eq. (14.16) simplifies to

$$n = \frac{4\pi(2m_e)^{3/2}}{h^3} \int_0^{E_F} \sqrt{E}\, dE = \frac{\pi}{3} \left(\frac{2m_e E_F}{h^2} \right)^{3/2} = 4.55 \times 10^{21}\ E_F^{3/2}\ \text{cm}^{-3}. \tag{14.17}$$

If the inner wall of the PMT tube is coated with an electron emissive material, electrons are more readily emitted by incident low-energy photons by using a material with a relatively low work function. Inspection of Fig. 14.12 reveals that the best candidates for photocathodes are the alkali metal elements, or mixtures thereof. Values of the Fermi energy and the work functions for these elements are given in Table 14.3. The overall spectral response to various photon wavelengths for the alkali metals is shown in Fig. 14.13. Some alkali earth elements (Group II in the Periodic Table) also have low work functions, and are sometimes used in PMTs as electron emissive materials.

Thermionic Emission

At a temperature of absolute zero, the Fermi-Dirac distribution indicates that all free electrons require an energy equal to the work function ϕ_m to surmount an energy barrier and escape into "vacuum" (see Fig. 14.11). As the temperature is increased, the probability that electrons are in states above the Fermi energy E_F increases. Such electrons require less energy than the work function to escape to the vacuum level. The process whereby thermal energy in the material leads to the liberation of electrons is referred to as *thermionic emission*.

The general expression for thermionic emission current density is described by the Richardson-Dushman equation

$$J = A(1 - \alpha_r) T^2 e^{-\phi_m / kT}, \tag{14.18}$$

where T is the absolute temperature, α_r is a reflection coefficient that quantifies the quantum mechanical reflection of the electron wave function at the barrier interface. The quantity $A(1 - \alpha_r)$ is generally referred to as the "effective Richardson constant." It is this thermionic emission that contributes most to the thermal noise, or "dark current," of the PMT device. As described by Eq. (14.18), the dark current increases as ϕ_m decreases. However, at room temperature it turns out that the thermionic current is small and usually of

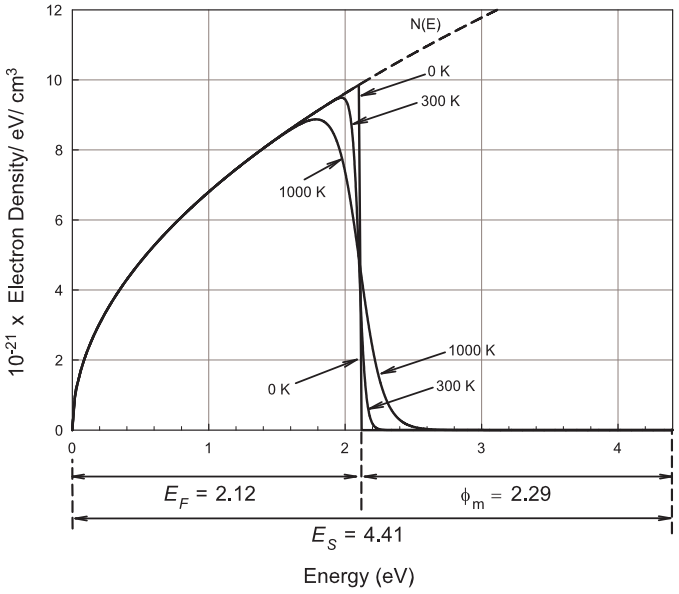

Figure 14.11. The density of filled states for potassium at absolute zero, 300 K, and 1000 K as a function of energy according to the free electron model.

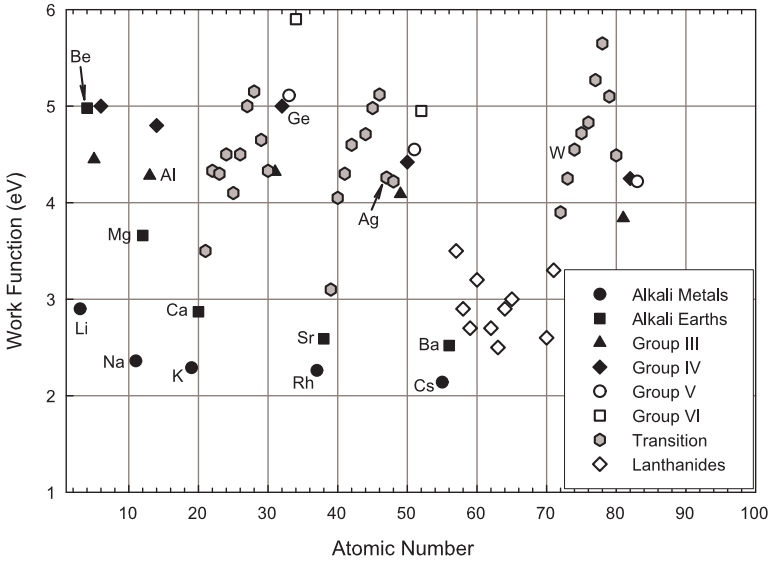

Figure 14.12. Work functions of most elements. Data are from Halas and Durakiewicz [1998].

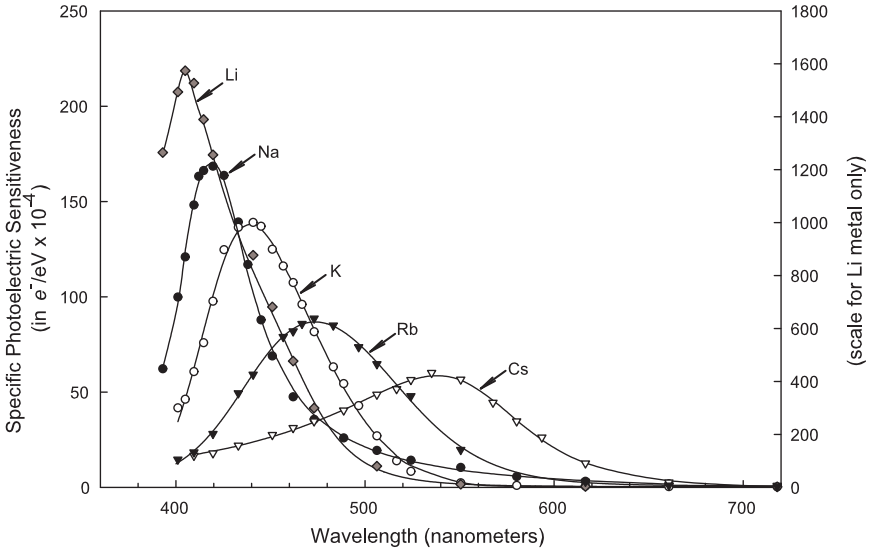

Figure 14.13. Measured relative spectral response for the alkali metals. Data are from Seiler [1920].

little consequence. With careful attention to the selection of the photocathode material, the production of ultra-low-noise PMTs is possible.

Photoemission

Photons interacting in a photocathode material can be absorbed by free electrons. If the photon energy is greater than the work function ($h\nu > \phi_m$), then electrons can be elevated to energies above the potential barrier, and are sometimes referred to as "hot electrons." If the electrons are excited from the Fermi energy E_F, then the resulting electron energy is simply

$$E_e = h\nu - \phi_m. \tag{14.19}$$

However, for electrons excited from deeper in the energy band, the electron energy is less, namely,

$$E_e = h\nu - (\phi_m + E'). \tag{14.20}$$

where E' is the additional energy required for the electron to reach the vacuum level. The probability that an electron is excited to the vacuum level from lower energy levels diminishes as E' increases. In order to actually escape the material, these excited electrons must first diffuse to the metal/vacuum interface and then still retain enough energy to surmount the barrier. Hence, it is less probable for electrons excited deep in the energy band to escape as they lose energy, through scattering from ambient electrons, as they diffuse to the boundary. Further, the deeper in the photocathode material that an electron interacts with a photon, the less likely it is to reach the surface with sufficient energy to escape, because of the longer diffusion path length it must travel and the increased number of energy loss interactions it undergoes as it diffuses. Hence, a combination of diffusion effects and energy losses produce a low energy tail in the photoelectron response distribution, as shown in Fig. 14.14.

The photocathode work function and the wavelength of photons impinging upon the photocathode generally determine the electron cutoff energy for a PMT. Photons that do not have adequate energy to excite

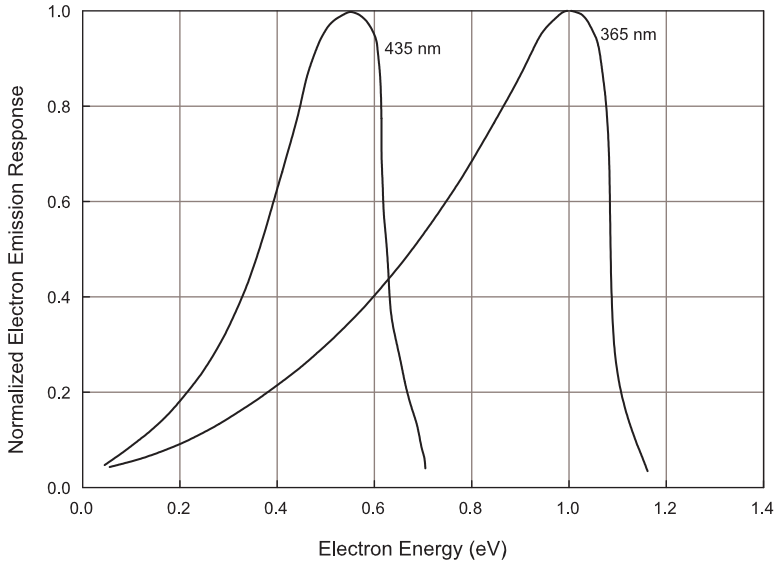

Figure 14.14. Normalized electron response for K for two light wavelengths, 435 nm and 365 nm. Data are from Brady [1934].

electrons above the potential barrier cannot produce photoexcition. Under ideal circumstances, such a cut-off should be represented by a step function. However, the high energy tail of the Fermi-Dirac distribution function indicates that some free electrons in the material occupy states that exceed the Fermi energy. Consequently, for photons of any given wavelength with $h\nu \geq \phi_m$, there are some electrons emitted with energies greater than $h\nu - \phi_m$, as is shown in Fig. 14.14.

Electron Affinity χ_A

Certain compounds of alkali metals form narrow gap semiconductors. These materials offer extended sensitivity for electron excitation, but, consequently, do not follow the Sommerfeld band model. Unlike a pure metal, electrons cannot freely flow between the valence and conduction bands, but must instead surmount an energy gap E_g, or the *band gap*, between the upper edge of the valence band and the lower edge of the conduction band. Shown in Fig. 14.10(b) is an energy band diagram for a semiconductor surface terminated at the vacuum level. The work function of the semiconductor is still defined as the difference between the vacuum energy level and the Fermi energy level.[8] However, the Fermi energy E_F is determined by the concentration and type of *dopants* introduced into the semiconductor. If the concentration of negative-type, or *n-type*, dopants (N_D) is greater that the concentration of positive-type, or *p-type*, dopants (N_A), then the Fermi energy level moves towards the conduction band edge energy E_C. Consequently, the work function decreases. If instead the concentration of p-type dopants is greater than the concentration of n-type dopants, then the Fermi energy level moves towards the edge energy of the valence band E_V, thereby causing the work function to increase.

Overall, both the Fermi energy level and the work function in a semiconductor are not constant, but instead are variable depending on the doping concentration. Consequently, the work function is difficult to use when calculating electron emission and escape probabilities. However, the electron affinity can be

[8] The physics of semiconductor devices is covered in Chapter 15. However, it is important to introduce some of these concepts here to further the understanding of a negative electron affinity photocathode.

treated as a constant value, defined as

$$\chi_A = E_0 - E_C, \tag{14.21}$$

where E_0 is the vacuum level energy. To calculate the energy barrier heights for semiconductors, it is the electron affinity that is typically used as a reference energy relative to the vacuum level. Hence, the photon energy generally required to excite an electron over the vacuum barrier is

$$h\nu > E_g + \chi_A = E_T, \tag{14.22}$$

where E_T is the threshold energy. Note that there is a considerable concentration of electrons in the conduction band that can be excited above the vacuum level, thereby allowing some electrons to be excited over the barrier with an energy of only χ_A. However, the concentration of these conduction band electrons is orders of magnitude below the concentration of electrons in the valence band, and, consequently, most of the excited charge comes from electrons elevated from the valence band.

Finally, it should be mentioned that not all photocathodes are constructed from alkali metals or metal compounds. Some photocathodes are constructed from more traditional semiconductors, such as *p*-type GaAs and *p*-type Cs_2Te. Listed in Table 14.4 are properties of a few semiconductors used as photocathodes, and shown in Fig. 14.15 are the absolute responsivities for many common photocathodes.[9]

Negative Electron Affinity $-\chi_A$

To construct some photocathodes, certain *doped* semiconductors are used. These semiconductors form no energy barrier at the vacuum interface! To understand the physics that cause this phenomenon, it is recommended that the reader study Fig. 14.16.

Most semiconductors have a number of unbounded states on the surface. These states fill with electrons up to a particular energy level, namely that of Fermi energy. In other words, the Fermi energy becomes

[9] The absolute responsivity, or radiant sensitivity, is defined as the photoelectric current generated by the photocathode divided by the number of incident photons, usually in units of mA/watt.

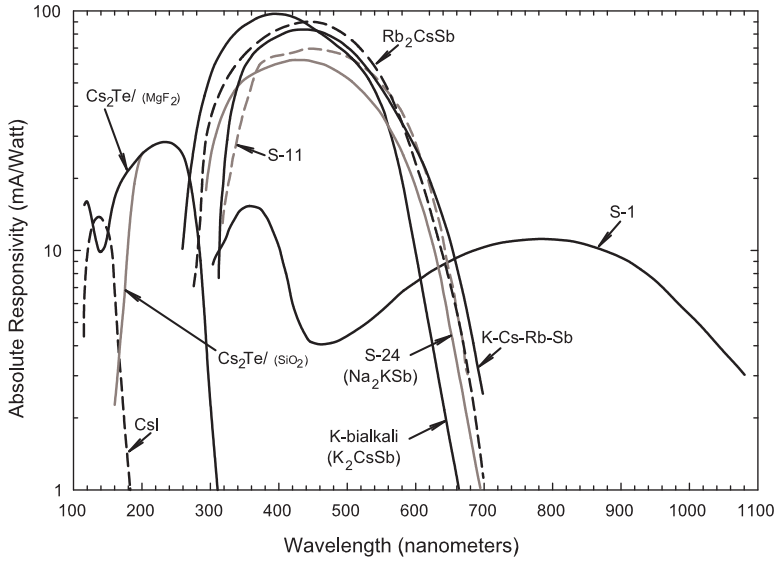

Figure 14.15. Response functions for several photocathode materials. The window material is soda-lime glass most of the responses. However, the S-24 response is for a 7056 borosilicate window, the CsI response is for a MgF_2 window, and the Cs_2Te responses are with either a MgF_2 or quartz window as marked. Data are from Engstrom [1980] and Hamamatsu [2007].

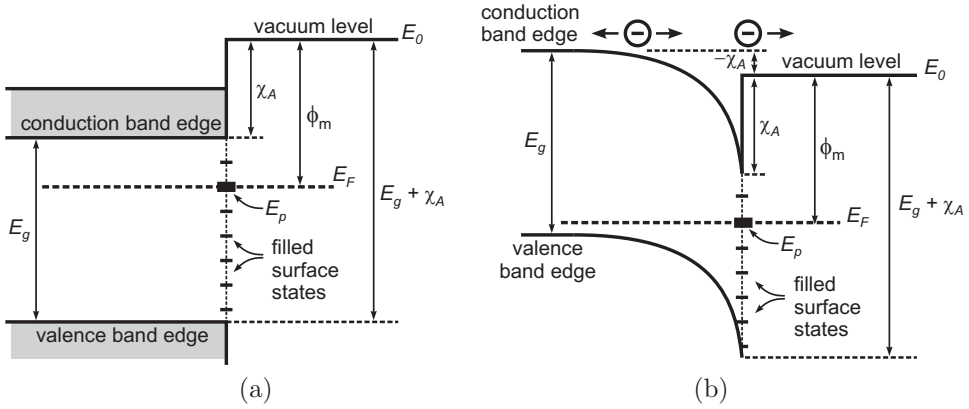

Figure 14.16. Semiconductor band diagrams for a surface pinned to a surface state energy E_p, showing (a) n-type material and (b) p^+-type material with negative electron affinities.

pinned at the energy E_p, below which states are filled and above which states are empty. Note, these energy states exist in the band gap *at the surface* as a consequence of unbound surface states, a condition that generally does not exist in the semiconductor material far from the interface.

The quantity N_D, used for n-type dopants, is an atomic density of impurity atoms that *donate* electrons to the conduction band, thereby increasing the density of negative charge carriers (electrons) in the conduction band. The quantity N_A, used for p-type dopants, is the atomic density of impurity atoms that *accept* electrons from the valence band, thereby removing electrons from the valence band and increasing the density of positive charge carriers (holes) in the valence band.

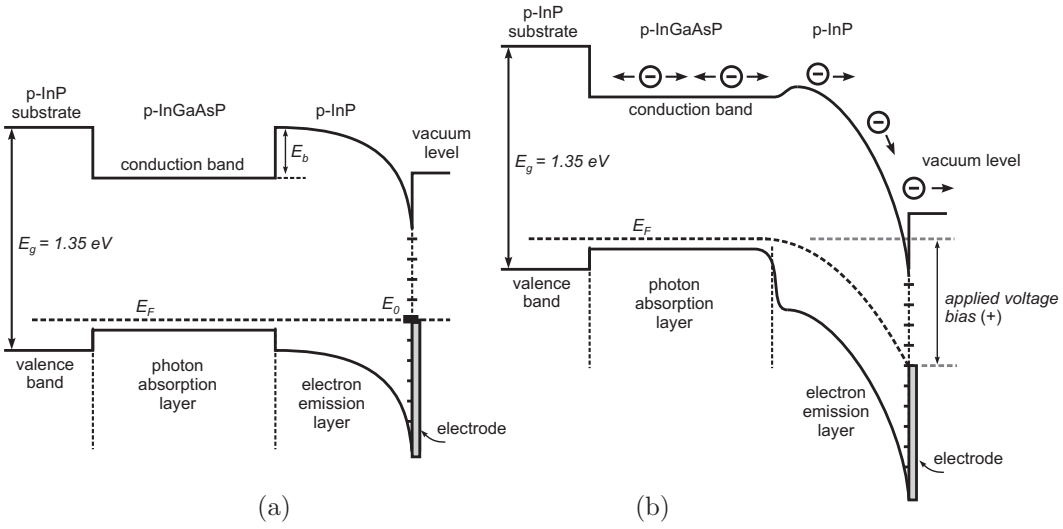

Figure 14.17. Semiconductor band diagrams for a field-assisted InP/InGaAsP/InP heterostructure photocathode (a) under zero bias and (b) under reverse bias operation.

By strongly doping a p-type semiconductor, the Fermi energy level in the *bulk* semiconductor is lowered close to E_V as shown in Fig. 14.16(b). At equilibrium, the Fermi energy must be constant across the interface and, hence, the energy bands bend accordingly to satisfy this condition such that the Fermi energy level in the bulk aligns with the pinned Fermi energy level at the surface. Consequently, the vacuum level E_0 at the surface moves below E_C in the bulk semiconductor, producing a *negative electron affinity* as calculated from Eq. (14.21). As a result, electrons can now move from the semiconductor bulk at energy E_C into the vacuum without encountering an energy barrier [Rougeot and Baud 1979].

Heterostructure negative electron affinity (NEA) photocathodes take advantage of semiconductor band-gap engineering to extend the IR response of PMTs while maintaining relatively high sensitivity. The structures are fabricated by growing an epitaxial p-type InP layer upon a p-type InGaAs or InGaAsP layer, as depicted in Fig. 14.17. The InP semiconductor layer has a much wider band-gap than the InGaAs (or InGaAsP) layer [Niigaki et al. 1997]. Because these epitaxial crystals are thin, typically with thicknesses of 0.2 to 0.5 μm, it is usual to grow them upon relatively thick InP substrates so they are forced to function as opaque (reflection) type photocathodes. Front windows with InP-based semi-transparent type heterostructure semiconductor photocathodes are also manufactured, but because of their poor absorption of photons above 1.35 eV, they suffer reduced sensitivity for photon wavelengths below 900 nm. The surface of the p-type InP layer forms a NEA boundary at the vacuum boundary, but there is still a barrier to surmount at the InGaAs/InP (or InGaAsP/InP) interface, as shown in Fig. 14.16(a). Application of a bias voltage to the photocathode lowers the conduction band barrier, thereby allowing electrons to more easily to pass into the vacuum, as shown in Fig. 14.16(b). These NEA photocathodes have sensitivity at photon wavelengths extending up to 1400 nm for the InGaAsP/InP type and up to 1700 nm for the InGaAs/InP type [Hamamatsu, 2007]. Advanced heterostructure photocathodes can operate up to 2300 nm [Niigaki et al. 2014]. Unfortunately, heterostructure semiconductor photocathodes also have a high dark current when used at room temperature; hence they must be cooled to temperatures between $-60°$ C and $-80°$ C during operation.

NEA photocathodes enable electrons to diffuse greater distances before dropping back to the conduction band edge and recombining with holes. This greater diffusion distance allows thicker photocathodes to

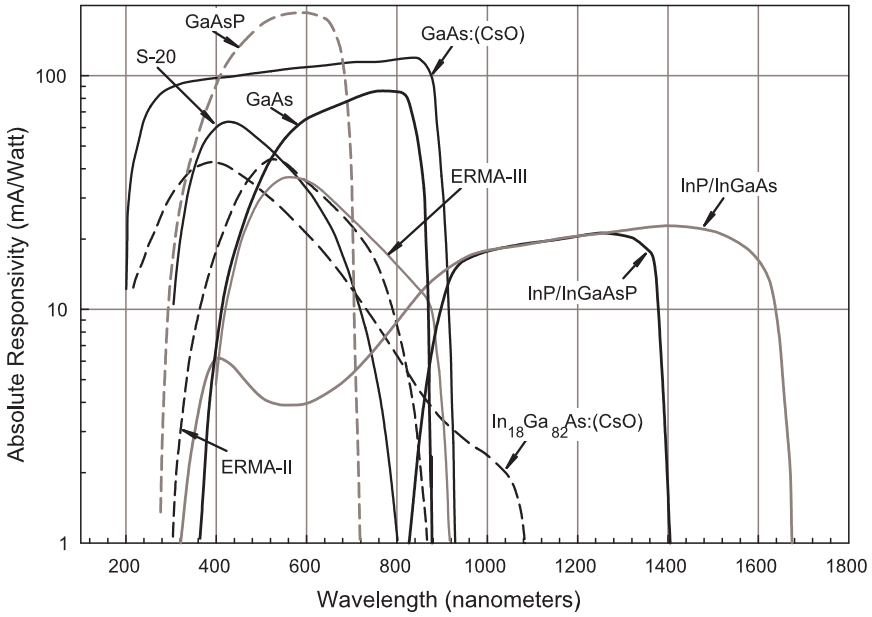

Figure 14.18. Response functions for several photocathode materials that are usually used for detection of longer wavelength light. Data are from Engstrom [1980] and Hamamatsu [2007].

be used while improving the electron emission. Hence, NEA photocathodes can have much higher photon response than common alkali metal photocathodes, especially in the long wavelength region, as can be seen from Fig. 14.18.

Semi-Transparent and Opaque Photocathodes

Photocathodes are either applied directly to the inner surface of the entrance window to the PMT enclosure or upon an internal secondary surface within the enclosure. Photocathodes applied to the inner surface of the transparent envelope are designed with thicknesses on the order of only a few electron diffusions lengths (tens of nanometers) and, therefore, are *semi-transparent*. Internal photocathodes are set back from the entrance window do not suffer the same problem and can have thicker material layers laid upon a substantial conductive backing, and are, therefore generally *opaque*. There are advantages and disadvantages to both of these designs.

Semi-transparent photocathodes are deposited upon the inside surface of the PMT entrance window, a geometry that enables the scintillation material to be placed adjacent to the photosensitive material. This usual arrangement serves to increase the solid angle between the light source and photosensitive area, thereby maximizing the detector signal. Such an arrangement is depicted in Fig. 14.2 and shown in Fig. 14.3. Because photoelectrons are ejected into vacuum from the side of the photocathode material opposite that upon which light is incident, this type of photocathode is sometimes called a *transmission* photocathode.

The thickness of a semi-transparent photocathode must be carefully controlled. If the photocathode is too thick, then photons can be absorbed beyond the critical escape depth for photoelectrons. Hence, any additional material serves only to decrease the electron signal. If the photocathode is too thin, then many of the incident photons pass through the photocathode without producing photoelectrons.

For opaque photocathodes, electrons are ejected from the same side as that upon which the light is incident. These photocathodes are often called *reflective photocathodes*. In these photocathodes the self-

absorption of photoelectrons is no longer a limiting factor, and opaque photocathodes can be applied as thicker layers. However, because they are set back from the PMT entrance window, opaque photocathodes may suffer loss of light because of a decreased solid angle with respect to the light source.

Optical power transmission through the photocathode material is described by

$$P(x) = P(0)e^{-\alpha(\lambda)x}, \tag{14.23}$$

where $\alpha(\lambda)$ is the attenuation coefficient at a specific wavelength λ and x is the distance from the cathode surface along the direction of light travel. The inverse of $\alpha(\lambda)$ is the attenuation length in which a fraction $1-e^{-1} \simeq 63\%$ of the incident photons are absorbed. Optical power absorption is greatest at the vacuum interface for opaque photocathodes, whereas it is least at the vacuum interface for semi-transparent photocathodes. If one assumes that the number of photoelectrons is proportional to the profile of absorbed light energy, the distribution of electron-hole pairs created in the photocathode is

$$F_e(x) = k_e\alpha(\lambda)P(0)e^{-\alpha(\lambda)x}dx, \tag{14.24}$$

where k_e is a constant. Once a photon has been absorbed, and presumably produced an excited electron-hole pair, photoemission from the photocathode occurs only if (a) the photoelectron energy is greater than the threshold energy $E_T = E_g + \chi_A$, and (b) the photoelectron can diffuse to the vacuum boundary while retaining $E \geq E_T$.

It is possible for an electron to become excited from photon absorption but with an energy $h\nu < E_T$. However, the photoelectron does not have sufficient energy to surmount the energy barrier depicted in Fig. 14.10 and, consequently, cannot reach the vacuum. The threshold wavelength is defined as

$$\lambda_T = \frac{hc}{E_g + \chi_A} = \frac{1239.8}{E_T} \quad \{\text{nm}\}, \tag{14.25}$$

where E_T is expressed in eV. The threshold wavelength for many photocathode materials are listed in Table 14.4.

The photoelectrons must also be able to diffuse to the vacuum boundary while maintaining sufficient energy to surmount the energy barrier. Although the threshold energy E_T is the theoretical minimum energy limit, photoelectrons actually require much more initial energy than E_T to escape the photocathode in order to compensate for energy losses experienced during their diffusion to the interface. Because the electrons diffuse in random directions, many photoelectrons diffuse away from the vacuum boundary. Also, as the photoelectrons diffuse through the photocathode material, they lose substantial energy with each scatter reaction. A scatter can also cause the electrons to radically change directions. Each scatter may result in the energy of an electron dropping below E_T or change direction so it diffuses away from the vacuum boundary, either case negating photoemission. Overall, for a wide spectral response, the initial energy E_{pe} of the photoelectron should be greater than the threshold energy, i.e.,

$$\frac{hc}{\lambda} = E_{pe} \gg E_T. \tag{14.26}$$

14.1.4 Dynode Materials

Energetic electrons, such as accelerated photoelectrons, impinging onto a surface can cause the emission of secondary electrons, provided that the energy transferred to secondary electrons is greater than the vacuum barrier. The secondary electron yield δ is defined as

$$\delta = \frac{N_s}{N_p}, \tag{14.27}$$

where N_s is the number of emitted secondary electrons and N_p is the initial number of primary electrons striking the material.

There are similarities between photoemission and secondary electron emission, the distinctive difference being that photoelectrons are a result of the photoelectric effect and secondary electrons are created through coulombic interactions between the incident primary electron and the ambient electrons of the material. Because a single primary electron can scatter from many secondary electrons in the material, there is a possibility that many electrons acquire enough energy to surpass the vacuum barrier. Some of the energetic secondary electrons may, in turn, interact with other electrons transferring sufficient energy to allow them to also escape. Thus, if the primary electron has sufficient initial energy, the gain of Eq. (14.27), is greater than unity.

Typically photoelectrons emerging from the photocathode surface do not have sufficient energy to produce secondary electron emission. However, this situation is easily remedied by applying a secondary electron emission material upon an electrode, referred to as a *dynode*, and applying an accelerating voltage to it. The photoelectron can then gain sufficient kinetic energy as it is attracted to the anode to promote secondary electron emission.

Secondary Electron Emission

As with photoelectron emission, a series of processes must take place for successful secondary electron emission. These processes include, (a) the primary electron acquiring an energy greater than E_T of the dynode material, (b) the excited secondary electrons then must diffuse in the direction of the vacuum barrier, and (c) the secondary electrons, upon reaching the vacuum barrier, must still retain an energy greater than E_T.

As the energy of the primary electron is increased, the maximum depth of secondary electron generation also increases. Consequently, secondary electrons generated deep in the dynode material must diffuse relatively long distances to reach the vacuum boundary compared to those secondary electrons generated near the surface. If the primary electron is normally incident on the dynode, the maximum depth a primary electron can reach in the dynode material is the continuous-slowing-down-approximation range R_{CSDA} discussed earlier in Sec. 4.6.3. To reach this maximum depth the electron trajectory must be almost a straight line, i.e., no large angle scatters. However, very few of the incident electrons produce such trajectories and reach such depths. Of more utility is the mean forward or projected range R_p defined as the expected or average maximum depth of penetration in the direction of the incident electron. However, the calculation of R_p from first principles requires detailed electron transport calculations that take into account quantum mechanical and electron binding effects in the ambient atoms. Alternatively, the CSDA range R_{CSDA} can be multiplied by the appropriate detour factor to give R_p. But tabulations of detour factors are hard to find and their calculation also requires extensive electron transport calculations. Because primary photons generated in a PMT seldom have energies above a few keV, it is better to base range calculations on experimentally determined ranges.

Young [1956] experimentally determined the primary electron penetration mass thickness in Al_2O_3 is described by

$$\rho R = 0.0115 E_o^{1.35}, \tag{14.28}$$

where E_o is in keV and ρR is in units of mg cm^{-2}. From Fig. 4.23 it is seen that the *mass-thickness* range for any given monoenergetic electron is nearly the same for a wide range of materials ranging from air to gold. Thus, the penetration range for all dynode materials can be estimated by

$$R \simeq \frac{1.15 \times 10^{-5}}{\rho} E_o^{1.35}, \tag{14.29}$$

where R is in cm, ρ is the dynode material density (g cm^{-3}) and E_o is in units of keV.

Example 14.2: Calculate the electron range as a function of energy for Al_2O_3, MgO, BeO, and GaP for accelerating voltages between 0 to 5 keV.

Solution:

The densities of Al_2O_3, MgO, BeO, and GaP are 3.99, 3.58, 3.01, and 4.14 g cm^{-3}, respectively. From Eq. (14.29), the penetration depth for Al_2O_3 is,

$$R \simeq \frac{1.15 \times 10^{-5}}{3.99 \text{ g cm}^{-3}} E_o^{1.35},$$

yielding the results depicted in Fig. 14.19. The ranges for the other materials are found in the same manner. These results indicate that, for accelerating voltages less than 1000 volts, the penetration depth R is limited to less than 50 nm for these materials.

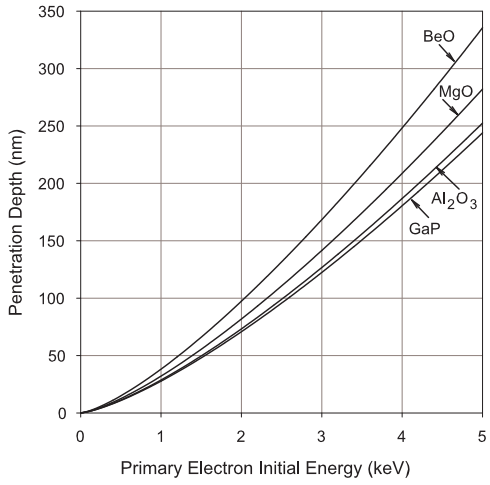

Figure 14.19. Calculated penetration depths for Al_2O_3, MgO, BeO, and GaP as a function of primary electron energy.

Models for Secondary Electron Emission

The secondary electron emission yield δ, defined as the ratio of emerging secondary electrons to impinging primary electrons, can be described by [Dekker 1958]

$$\delta = \int n(x, E_o) f_{esc}(x) dx. \tag{14.30}$$

Here $n(x, E_o)dx$ is the number of secondary electrons produced at depths in dx about x by a primary electron of initial energy E_o, and $f_{esc}(x)$ is the probability that a secondary electron produced at depth x reaches the vacuum interface and is emitted or escapes. The escape probability of secondary electrons, to a first approximation, may seem to be a simple solid angle problem defined by the diffusion length and excitation distance from the surface. However, the complex nature of electron scattering and transport causes the probability of emergence to be somewhat complicated [Simon and Williams, 1968].

Table 14.5. Maximum yields δ_{om} of secondary electrons and optimum initial energy E_{om} of the incident primary electron for some elements. From Dekker [1958].

Material	δ_m	E_{om} (eV)	Material	δ_m	E_{om} (eV)	Material	δ_m	E_{om} (eV)
Li	0.5	85	Be	0.5	200	B	1.2	150
Mg	0.95	300	Al	0.95	300	Si	1.1	250
K	0.7	200	Ti	0.9	280	Fe	1.3	400
Co	1.2	500	Ni	1.3	550	Cu	1.3	600
Ga	1.55	500	Ge	1.15	400	Rb	0.9	350
Zr	1.1	350	Nb	1.2	375	Mo	1.25	375
Pd	>1.3	>250	Ag	1.4	800	Cd	1.1	450
Sn	1.35	500	Sb	1.3	500	Cs	0.7	400
Ba	0.8	400	Ta	1.3	600	W	1.3	650
Pt	1.8	700	Au	1.4	800	Hg	1.3	600
Tl	1.7	650	Pb	1.1	500	Bi	1.15	550

For any element the yield δ of secondary electrons varies with the energy E_o of the incident primary electron. There is an optimum energy E_{om} that produces the maximum yield δ_m of secondary electrons for a particular element. Some optimum yields and energies are given in Table 14.5.

There are many models describing secondary electron emission yield. For example see Dekker [1958] and Adamson [1993]; however, only two of the more important models are described here, namely, the *power law* model and the *constant loss* model.

Power Law Model Baroody [1950] developed a theory for secondary electron yield based on the concepts that (1) the production of secondary electrons per unit pathlength of travel by the primary electron is proportional to the rate of energy loss $-dE/dx$, and (2) these secondary electrons are exponentially absorbed in the target material as they diffuse towards the surface. Hence, the secondary electron yield per incident primary electron is given by

$$\delta = -K \int_0^R \frac{dE}{dx} e^{-\alpha x} dx, \tag{14.31}$$

where K is a proportionality constant and α is the electron absorption coefficient. According to Whiddington's Law [Whiddington 1912], the energy loss per unit distance for the primary electron is inversely proportional to the energy at depth x from the surface, i.e.,

$$-\frac{dE(x)}{dx} = \frac{A}{E(x)}, \tag{14.32}$$

where A is a constant dependent on the dynode material. Rearrangement and integration yield

$$E(x) = \sqrt{E_o^2 - 2Ax}. \tag{14.33}$$

However, according to Lye and Dekker [1957], Whiddington's Law does not produce reliable results, and instead they proposed that Eq. (14.32) should be modified to

$$-\frac{dE(x)}{dx} = \frac{A}{E^n(x)}, \tag{14.34}$$

where again A is a constant dependent on the material. Rearrangement and integration then gives the energy of the primary electron at depth x as

$$E^{n+1}(x) = E_o^{n+1} - A(n+1)x. \tag{14.35}$$

Because $E^{n+1}(R) = 0$ setting $x = R$ in Eq. (14.35) gives the primary electron range as

$$R = \int_o^{E_o} \frac{E^n}{A}\, dE = \frac{E_o^{n+1}}{A(n+1)}. \tag{14.36}$$

Note that Eq. (14.36) with $n = 0.35$ agrees with the experimental result of Eq. (14.28).

With the assumption that the production of secondary electrons is proportional to $-dE/dx$, and that the function $f_{esc}(x)$ is proportional to $e^{-\alpha x}$, then Eq. (14.31) becomes

$$\delta = K \int_0^R -\frac{A}{E^n(x)} e^{-\alpha x} dx. \tag{14.37}$$

After much manipulation and change of variables, this equation can be written as

$$\delta = K \left[\frac{A(n+1)}{\alpha}\right]^{1/(n+1)} F_n(r), \tag{14.38}$$

where the function $F_n(r)$ is defined as

$$F_n(r) \equiv e^{-r^{(n+1)}} \int_0^r e^{y^{(n+1)}} dy, \tag{14.39}$$

and r is defined as

$$r^{n+1} = \alpha R = \frac{\alpha E_o^{n+1}}{A(n+1)}. \tag{14.40}$$

The maximum secondary electron yield δ_m is found by setting $d\delta/dE_o = 0$. The result is [Lye and Dekker 1957]

$$\delta_m = K \left[\frac{A(n+1)}{\alpha}\right]^{1/(n+1)} \frac{1}{(n+1) r_m^n}, \tag{14.41}$$

where r_m is the value of r at the maximum secondary electron yield. Lye and Dekker [1957], combined Eqs. (14.38) and (14.41) to obtain a normalized curve yield that is independent of the material properties, namely,

$$\frac{\delta}{\delta_m} = (n+1) r_m^n F_n(r) = \frac{F_n(r_m E_o/E_{om})}{F_n(r_m)}, \tag{14.42}$$

where E_{om} is the initial energy that maximizes the secondary electron yield, and $E_o/E_{om} = 1$ when $\delta/\delta_m = 1$.

Baroody [1950] evaluated Eq. (14.39) for $n = 1$ by using a series expansion to obtain

$$F_1(r) = e^{-r^2} \int_0^r e^{y^2} dy = \sum_{i=0}^{\infty} \frac{(-1)^i r^{2i+1}}{i!(2i+1)}, \tag{14.43}$$

although today with our PCs $F_n(r)$ is readily evaluated numerically. Baroody [1950] determined that $F_1(r)$ had a maximum value at $r_m = 0.92$, hence,

$$\frac{\delta}{\delta_m} = \frac{F_1(0.92 E_o/E_{om})}{F_1(0.92)} = 1.85 F_1(0.92 E_o/E_{om}). \tag{14.44}$$

Baroody's treatment followed the general trend for secondary electron yield, but had large deviations from experimental data for $E_o/E_{om} > 1.1$, as can be seen from Fig. 14.20. Later, Lye and Dekker substituted $n = 0.35$ into Eq. (14.42), based on the findings of Young [1956], to yield a power law solution that agrees considerably better with experimental values than does Baroody's model. A comparison of these two power law models is shown in Fig. 14.20.

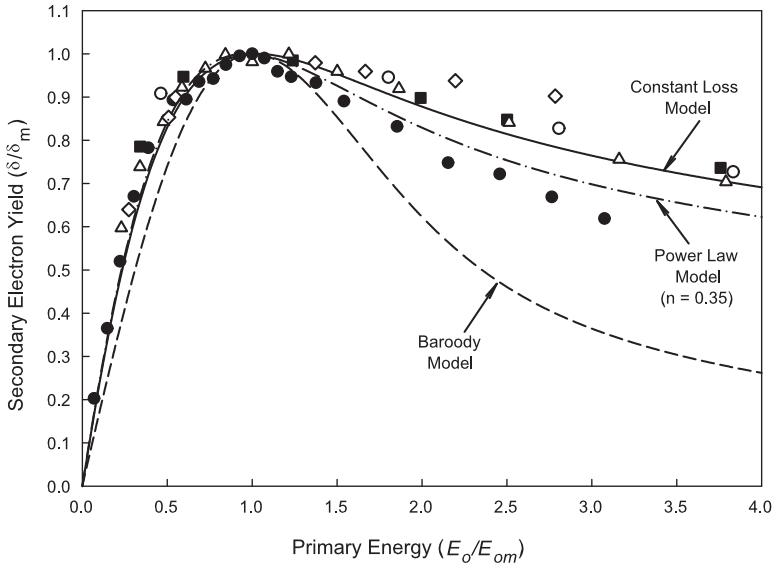

Figure 14.20. Comparison values of δ/δ_m for experimental data and theoretical models. Experimental data: △ Ge, ● MgO, ■ Mo, ◇ Pt, ○ Li; and are taken from from Kollath [1937], Baroody [1950], Whetten and Lamponsky [1957], Lye and Dekker [1957], Johnson and McKay [1954], and from Simon and Williams [1968].

Constant Loss Model The secondary production rate $n(x, E_o)$ in Eq. (14.37), according to Eq. (14.31), is given by

$$n(x, E_o) = -\frac{1}{w}\frac{dE}{dx}, \tag{14.45}$$

where w is the average absorbed energy needed to create an ion-electron pair, and the electron escape function $f_{esc}(x)$ in Eq. (14.37) is

$$f_{esc}(x) = B_1 B_2 e^{-\alpha x}, \tag{14.46}$$

where $1/\alpha$ is the mean-free-path length of secondary electrons or, equivalently, α is the probability, per unit differential path length of travel, a secondary electron is absorbed. B_1 is the probability that an electron diffuses in the direction of the vacuum boundary, and B_2 is the probability that upon reaching the vacuum boundary that the secondary electron still has sufficient energy to surmount the vacuum boundary, i.e., an energy above E_T. The term B_1 is assumed to have the value of approximately 0.5; however, when considering scattering and solid angle effects, B_2 should be a function of the depth at which the secondary electron is liberated. For simplicity, Simon and Williams [1968] treat B_2 as a function independent of x, thereby greatly reducing the complexity of calculating δ. For a secondary electron created at the surface $x = 0$, the product $B_1 B_2 = 0.5$. If it is assumed that energy loss of the primary electron is approximately constant over the primary electron range,[10] the change in energy with travel distance can be expressed as,

$$-\frac{dE}{dx} \simeq \frac{E_o}{R}. \tag{14.47}$$

[10] The assumption of a constant stopping power is valid for electrons with energies above 1 MeV, but not strictly true for lower energy electrons. In Sec. 4.6, a more rigorous treatment of electron ranges and stopping powers is presented.

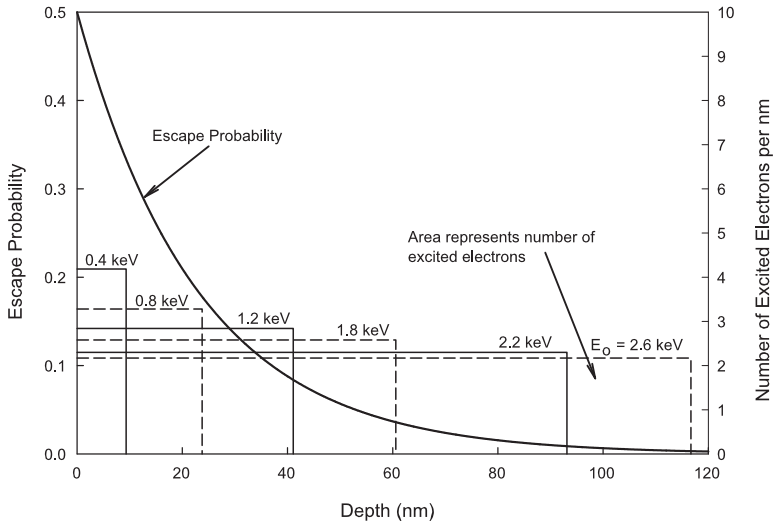

Figure 14.21. Escape probability and number of electrons liberated in MgO as a function of primary electron energy. After Simon and Williams [1968].

Substitution of Eqs. (14.45), (14.46), and (14.47) into Eq. (14.30) yields,

$$\delta = \int_0^R \frac{B_1 B_2}{w} \frac{E_o}{R} e^{-\alpha x} dx = \frac{B_1 B_2 E_o}{w \alpha R} \left(1 - e^{-\alpha R}\right). \tag{14.48}$$

Because it is assumed that there is a constant energy loss as the primary electron travels through the material, the total number of excited secondary electrons is E_o/w, and the number of electrons excited, per unit pathlength of the primary electron, is

$$-\frac{1}{w}\frac{dE}{dx} = \frac{E_o}{wR}. \tag{14.49}$$

In Fig. 14.21 $f_{esc}(x)$ and secondary electron production are shown for MgO.

From Eq. (14.36), the primary electron range can be written as $R = C_m E_o^{n+1}$ where C_m is a constant, so that Eq. (14.48) is rewritten as

$$\delta = K_m E_o \left[\frac{1 - e^{-\alpha C_m E_o^{n+1}}}{-\alpha C_m E_o^{n+1}}\right]. \tag{14.50}$$

where K_m is a combination of constants. There is some value E_o at which δ reaches a maximum value δ_m. This value can be found by setting $d\delta/dEo = 0$. Again the total gain of secondary electron emission, as a function of E_o, reaches a maximum value, beyond which δ begins to decrease.

To find a normalized dependence of δ on E_o, Lye and Dekker [1957] define a variable $z \equiv \alpha C E_o^{n+1}$ so, from Eq. (14.50) it is seen that δ is proportional to the function

$$f_n(z) \equiv \frac{1 - e^{(-z^{n+1})}}{z^n}. \tag{14.51}$$

Hence, the general normalized dependence of δ on E_o is given by

$$\frac{\delta}{\delta_m} = \frac{f_n(z_m E_o / E_{om})}{f_n(z_m)}. \tag{14.52}$$

Table 14.6. Secondary electron emission properties of some materials. From Dekker [1958].

Material	Density (g cm^{-3})	δ_m	E_{om} (keV)	$1/\alpha$ (nm)	w (eV)
Pt	21.45	1.8	0.7	2.0	80
Ge	5.35	1.15	0.4	3.5	71.5
MgO	3.58	24	1.2	23	10.25

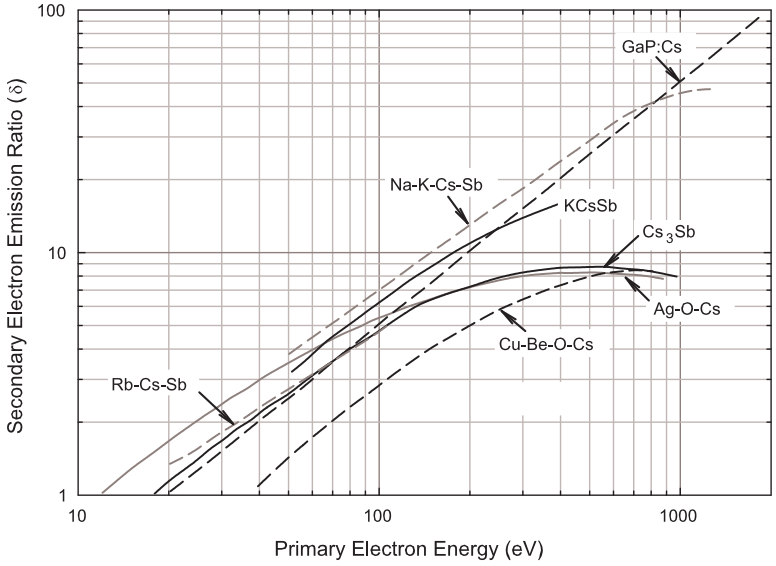

Figure 14.22. Secondary electron emission ratios for many materials used as dynodes in photomultiplier tubes. After [Engstrom 1980].

A plot of Eq. (14.52) with $n = 0.35$ is shown in Fig. 14.20. From the results in Fig. 14.20, it is seen that the constant loss model yields the best agreement with experiments, particularly when compared to the power law model and Baroody's analysis. Values of some model parameters for three materials are given in Table 14.6.

What important lessons are learned from the above analysis? Mainly, for any given dynode material, there is an optimum primary electron energy that yields the highest secondary electron yield. Further, the secondary electron emission yield of most materials can be described by a universal reduced yield curve, as shown in Fig. 14.20. The *yield ratio* is the number of secondary electrons emitted per incident electron. Experimentally measured yield ratios for many dynode materials are plotted in Fig. 14.22.

14.1.5 PMT Dynode Designs and Configurations

The shape and placement of the dynodes within the PMT determine the efficiency by which electrons are liberated and collected from each dynode stage. Calculated results can lead to efficient high-gain designs. It is interesting to note that, before the era of the modern electronic computers, such calculations were assisted with mechanical models, which included stretched rubber diaphragms and electrical resistor models [Engstrom 1980]. By arranging stretched rubber diaphragms between the "electrode" stage in the model,

Table 14.7. Properties of some common dynode designs. After Hamamatsu [2007].

Dynode design	Rise time response (ns)	Pulse linearity at 2% (mA)	Uniformity	Collection efficiency	Main characteristic
circular cage	0.9–3.0	1–10	poor	good	compact and high speed
box-and-grid	6–20	1–10	good	very good	high collection efficiency
venetian blind	6–18	10–40	good	poor	large diameter
linear focus	0.7–3	10–250	poor	good	high speed and high linearity
mesh	1.5–5.5	300–1000	good	poor	high magnetic immunity and high linearity
metal channel	0.65–1.5	30	good	good	compact and high speed
Micro-channel plate	0.1–0.3	700	good	poor	high speed

the height (potential energy) was adjusted to correspond to the electrical potential, and balls released upon the platform would follow the general path expected for electrons within the PMT. Hence, a simple dynode configuration could be designed with this tool. Electrically based models used a network of resistors in a grid pattern. By setting those resistors corresponding to a dynode plane in the model to a uniform potential, the electric potential between these planes could be directly measured between the electrodes.

Computer simulations of electron trajectories, voltage potentials, photocathode shape and focusing electrodes, dynode shapes and materials, are now routinely used for design of modern PMTs. Electrons emitted from the photocathode are focused onto a small area of the first dynode. Afterwards, secondary electrons emitted from the first dynode are directed to the next dynode, and so on until they reach the anode. The anode is specially designed to improve collection efficiency while suppressing space charge limitation effects. Most modern PMT designs have electron collection efficiencies η approaching 100%.

Designs for the Electron Optics

There are numerous photocathode and dynode geometries employed in PMTs, a few of which are described here. More details on these designs can be found elsewhere [Engstrom 1980; Flyckt and Marmonier 2002; Hamamatsu 2007]. A summary of some important properties of the different geometric designs, discussed below, is provided in Table 14.7.

Circular Cage Design The first successful commercial PMT was the 931A, developed by RCA and shown in Fig. 14.1, which used the circular cage design. This dynode design, shown in Fig. 14.23, is relatively compact and can be used for both the transmission or reflection type of PMTs. The original design had an opaque photocathode, depicted in Fig. 14.23(left), which was illuminated from the side. The 931A and 931B PMTs, both 9 stage circular cage dynode devices, are relatively small with diameters of 1.125 inches. Both provide high gains (931A $\simeq 5.5 \times 10^6$, 931B $\simeq 6 \times 10^6$), and can be used for scintillation samples that do not require coupling to a large photocathode. The envelope is composed of soda-lime glass. However, the photoresponses are different, mainly because the 931A has an Cs_3Sb photocathode and the 931B has a K_2CsSb photocathode. Typically, the 931B offers higher photocathode quantum efficiency, higher anode sensitivity, and lower dark current than the 931A. The compact sizes ensure a rapid time response or short

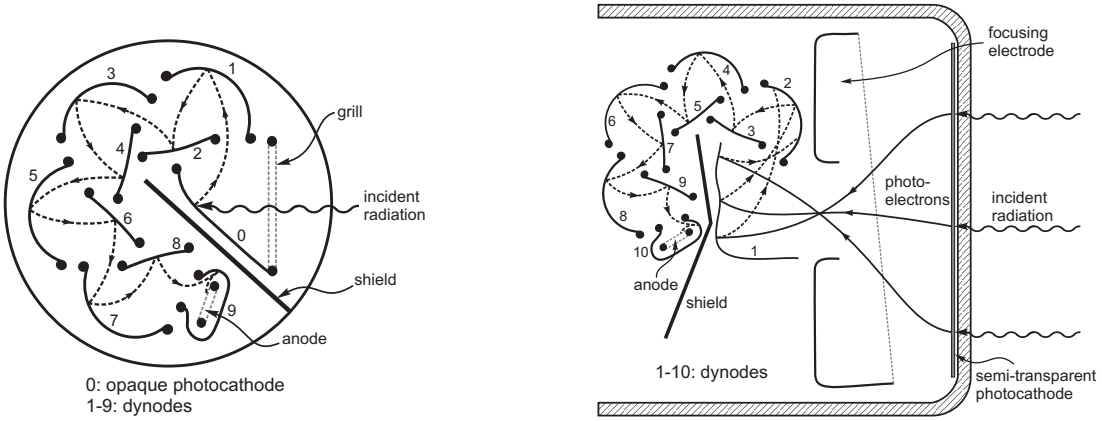

Figure 14.23. The circular cage dynode configuration showing (left) an opaque (reflection) photocathode arrangement and a (right) semi-transparent (transmission) photocathode arrangement. After [Engstrom 1980].

transit time of about 18 ns for the 931 tube series. The electron *transit time* is defined as the time interval between a photo-impulse impinging on the photocathode and the corresponding output pulse at the anode terminal to reach its peak amplitude. Advanced versions of the circular cage PMT have faster response times that range between 0.9 and 3.0 ns. A weakness in the design is the existence of a small electrostatic field at the apex of the grill and photocathode shown in Fig. 14.23(left). This field causes poor photoelectron collection efficiency in that region.

An alternative design of the circular cage dynode bank is shown in Fig. 14.23(right), in which the device has a much larger primary dynode and a semi-transparent photocathode. The flat semi-transparent photocathode allows a relatively large scintillation crystal to be directly coupled to the PMT. The design also has a focusing electrode, which, along with the large primary dynode, improves the photoelectron collection efficiency. Although this configuration of the PMT still has a rapid time response, the electron transit time is lengthened compared to the traditional circular cage dynode design because of the extra time required for electrons to traverse the distance between the photocathode and the primary dynode.

Venetian Blind Design The venetian blind design, see Fig. 14.24, offers excellent photoelectron collection and is ideally suited for "head-on" photomultiplier tubes because of its large photocathode diameter. The large photocathode permits good photon collection and is positioned relatively far from the first set of dynode blades. The photoelectrons are focused with steering electrodes onto the first set of dynode blades so as to achieve collection efficiency of nearly 100%, a feature necessary for good gamma-ray spectroscopy. Secondary electrons emitted from the dynode surfaces are steered into the next set of dynode vanes with accelerating grids. Consequently, some secondary electrons can be lost by collisions with these grids, thereby reducing overall secondary electron collection efficiency (ϵ_i) between dynode stages. Further, the potentials across the dynode paths are relatively low, thereby reducing the electron speeds and causing the transit time and response time of the PMT to lengthen. In summary, the venetian blind design enables PMTs to be coupled to relatively large scintillation crystals, offers high photoelectron collection efficiency, but has a relatively slow time response. Because of the slow response, this type of PMT now has somewhat limited use.

Box and Grid Design The box and grid design (Fig. 14.25), widely used in head-on photomultiplier tubes, has better photoelectron collection efficiency than most PMTs. This design incorporates a relatively large entrance window and photocathode. Accordingly, photomultiplier tubes using this dynode offer high detection efficiency and good uniformity. Similar to the venetian blind design, photoelectron collection is nearly

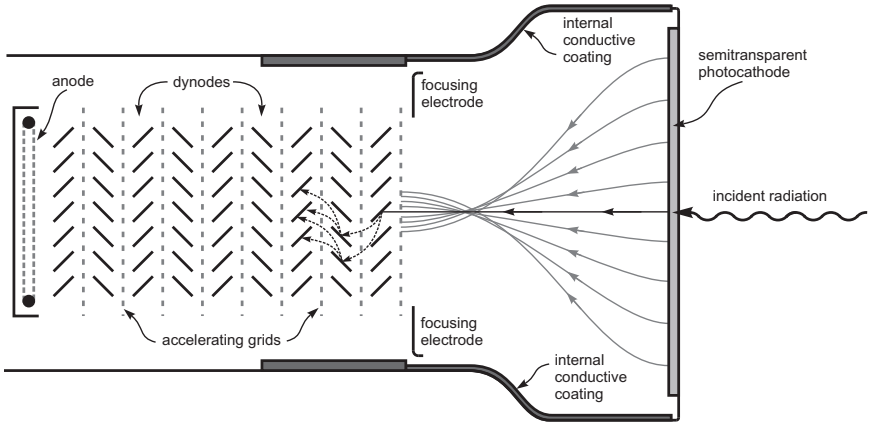

Figure 14.24. The venetian blind dynode configuration for a semi-transparent (transmission) photocathode. After [Engstrom 1980].

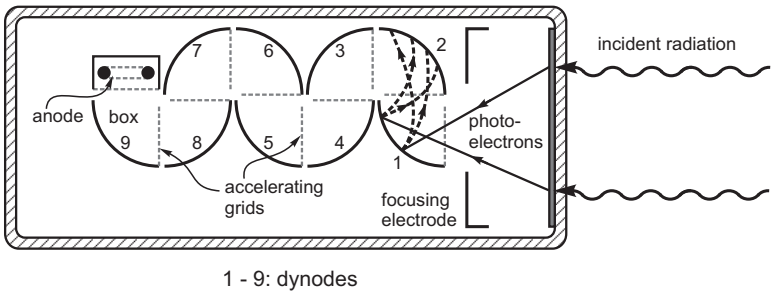

Figure 14.25. The box and grid dynode configuration for a semi-transparent (transmission) photocathode. After [Engstrom 1980].

100%, an attribute necessary for good gamma-ray spectroscopy. Each dynode has a grid electrode at the entrance, which assists with electron acceleration and steering. However, the weak electric fields between dynodes reduce electron speeds and, thus, produce a relatively slow time response. Regardless, this type of PMT still is used today as the light sensor for many scintillator/PMT detectors.

Linear Focus Design The linear focus, or in-line, dynode configuration is widely used in head-on photomultiplier tubes. Its attractive features include fast time response, good time resolution and excellent pulse linearity. A linear focus PMT attached to a NaI:Tl crystal is shown in Fig. 14.4. The linear focus dynode configuration is often employed with a curved photocathode as depicted in Fig. 14.26. The curved photocathode reduces the variance in electron pathlengths, as compared to a common flat photocathode. This smaller pathlength variance, in turn, reduces the variance in arrival time of electrons striking the first dynode. However, a curved photocathode makes it difficult to couple the PMT to scintillation crystals. As a consequence, linear focus dynode PMTs are also available with a flat photocathode surface. The dynodes aligned in the linear focus arrangement also reduces the variance in the arrival time of electrons as they eventually arrive at the anode. This compensation is accomplished with curved interposed dynodes designed to alternate between the longer and shorter electron pathlengths moving through weaker and stronger elec-

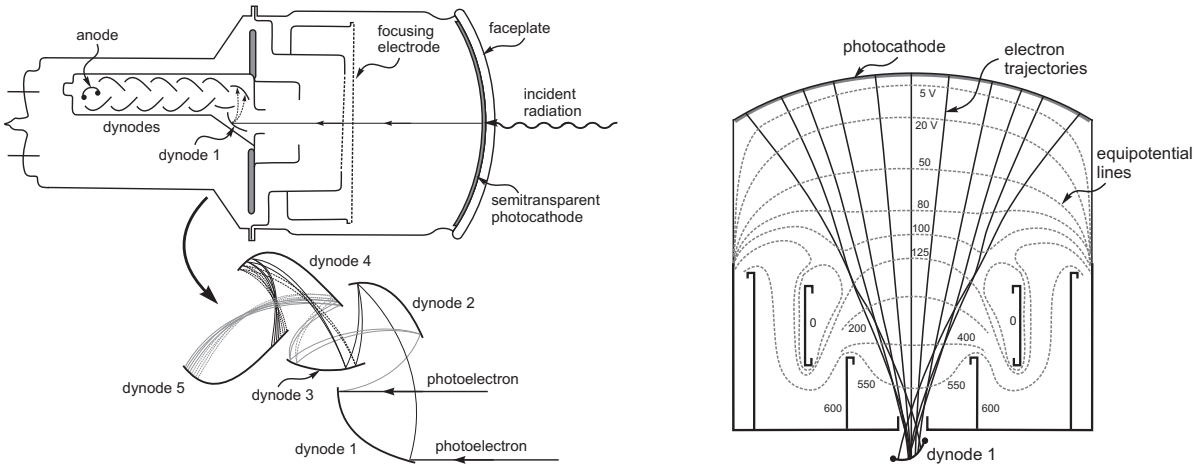

Figure 14.26. The linear focus dynode configuration showing (left) the dynode arrangement and (right) the focused electron trajectories from the curved photocathode. After [Engstrom 1980].

tric fields. Consequently, the total electron transit times for electrons passing through the dynode bank are nearly equal. An electron trajectory sequence is depicted in Fig. 14.26(bottom left). Overall the electron transit times and their variance are superior to most PMT designs.

Compact Dynode Designs A compact dynode configuration allows PMTs to be fabricated in relatively short containers. They typically have higher resistance to magnetic field interference, but they have lower gains. These compact PMTs are available as single channel PMTs or position sensitive PMTs. The dynodes most often used are described below.

Mesh Dynodes The mesh dynode is composed of interspersed parallel wire planes that form a system with the appearance of a wire screen; however, the wire planes are stacked, not interwoven. The wires may have a triangular cross section and are coated with secondary electron emission materials, as shown in Fig. 14.27(left). Each electrode layer is rotated 90° to the prior layer such that they are oriented in the x and y directions. Multiple stacked layers are used in close proximity to form a compact dynode array that can be used to provide x and y position information for imaging purposes. There are basically two types of design: a coarse mesh type and a fine mesh type. Both are excellent in output linearity and have good immunity to magnetic fields. Position sensing versions have either cross wire anodes or multianodes and can provide the location of photon interactions upon the photocathode. However, the devices generally have poor spatial resolution because of the spatial spread of the electron cascade, which is about 8 to 9 mm. Fine mesh types are developed primarily for photomultiplier tubes that are used in high magnetic fields. Some versions have magnetic immunity up to 1500 mT. The electric field and voltage drop between stages are low, hence the gain is typically lower than that of conventional PMTs. Gains on the order of 10^5 or more are achievable for systems with many stages (≥ 12).

Metal Foil Channel Metal foil channel dynodes are made with perforated foils coated with materials that produce secondary electrons. PMTs using these dynodes have properties similar to those of venetian blind PMTs, including the problem with electron collection. These dynodes can be used as position sensing PMTs with resolutions better than those of PMTs using mesh dynodes. With a resistive divider circuit, spatial resolution of approximately 4 to 5 mm can be achieved. The electric field and voltage drop between stages are low; hence, the gain is typically lower than conventional PMTs. Because the foils can be stacked in close proximity, metal foil channel PMTs can be fabricated in compact packages for special applications.

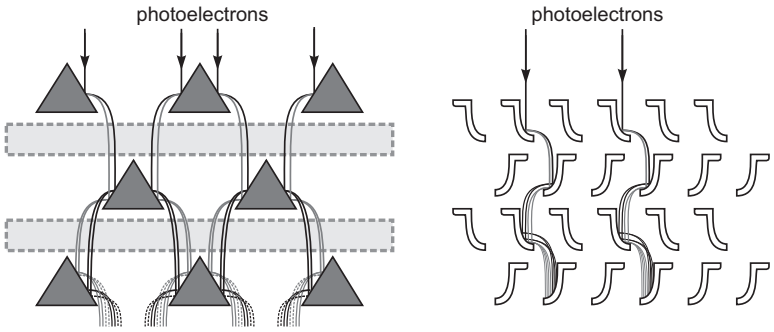

Figure 14.27. Compact photomultiplier dynode configurations, showing the basic scheme for (left) wire mesh dynodes and (right) metal foil channel dynodes.

Further, metal foil channel PMTs have higher magnetic immunity than most PMTs (up to fields of about 5 mT), except for mesh dynode PMTs. Gains on the order of 10^5 or more are achievable for systems with many stages (≥ 12).

Microchannel Plates Use of microchannel plates is another method for amplifying signals from a scintillator and are closely akin to the Kubetsky tube. Microchannel plates are bonded clusters of glass tubes, each usually having a diameter between about 15 to 50 μm, whose inside is coated with materials that emit secondary electrons as is shown in Fig. 14.28. The individual channels are referred to as "continuous channel electron multipliers" [Wiley and Hendee 1962]. A voltage is applied across the tube length which causes electrons to cascade down the tube. When an electron strikes the tube wall, more electrons are emitted, much as with dynodes in a PMT. Hence, a single electron can cause a cascade that can eventually produce more than 10^6 electrons that reach the other end of the tube. Typically, thousands of these continuous channel electron multipliers are bonded together to form a PMT.

At sufficiently high gains, the pulse can also become saturated, thereby compromising the pulse height distribution. In other words, regardless of the photon electron density striking the microchannel plate, all output pulses have nearly the same amplitude. A study conducted by Schmidt and Hendee [1966] indicates that space charge accumulation of electrons in the channel causes this saturation effect. Emission of energetic electrons can also cause sputtering as they strike the walls or anode, thereby liberating positive ions into the channel. These positive ions can travel in the opposite direction of the electrons and cause more electron emissions as they strike the walls, a process termed as "ion feedback." Consequently, the pulse rise time is extended by successive waves of secondary electrons, often over ten times the expected values. It was found that bending the continuous channel electron multipliers would remedy this feedback problem [Evans 1965], because electrons can drift towards the anode around the bend whereas ions cannot drift backwards before striking the wall with insufficient energy needed cause secondary electron emission. Modern microchannel plates used in PMTs are often arranged in a chevron configuration to eliminate ion feedback. Regardless, space charge effects can appear for gains of more than 10^7 and can still produce pulse height spectra saturation.

The microchannel plate can be substituted for the staged-dynode bank inside a vacuum tube to operate as a PMT [Chevalier et al. 1970]. Energetic photoelectrons entering can cause the ejection of secondary electrons, which cascade down the microchannels to liberate millions more electrons. The main advantage of a microchannel plate is its compact size. A microchannel plate only one-inch thick can produce a signal of similar strength as a conventional staged-dynode PMT. Microchannel plates have relatively fast rise times [Piétri 1975], typically between 100 and 300 ps, and a relatively small spread of transit times, usually less

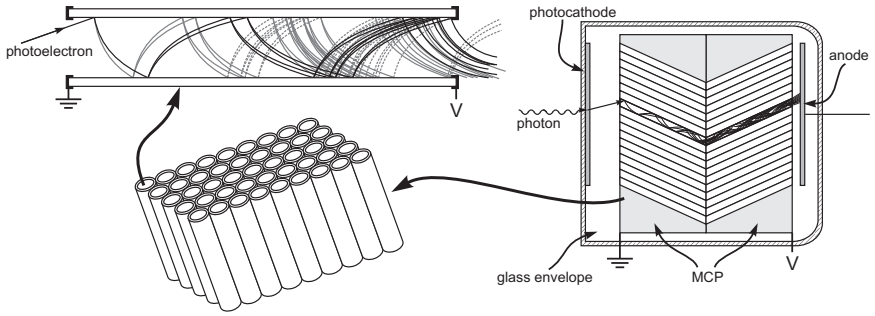

Figure 14.28. (left) Depiction of electron multiplication in a microchannel. (right) Depiction of a microchannel plate PMT.

than 100 ps. Further, microchannel plates have found use as image intensifiers, in which their compact and small channels provide excellent spatial resolution. The main problem with using microchannel plates is that the signal produced, per monoenergetic radiation event, is statistically much noisier than that produced by a PMT. Hence, spectroscopic energy resolution is usually worse than that produced by a multistage dynode PMT.

14.1.6 Gain

The *gain* G of a PMT is defined as the average total number of electrons collected at the anode N_a divided by the average total number N_{pc} of photoelectrons initially ejected from the photocathode, i.e.,

$$G = \frac{N_a}{N_{pc}} = \frac{q_e N_a}{q_e N_{pc}} = \frac{Q_a}{Q_{pc}}, \tag{14.53}$$

where q_e is the unit charge, Q_{pc} is the average charge emitted from the photocathode and Q_a is the average charge delivered to the PMT anode. The number of collected electrons N_a can be calculated from the dynode charge collection efficiency η and secondary emission factor δ for each dynode. The charge collection efficiency for the ith dynode located within the dynode chain is defined as

$$\eta_i = \frac{\text{no. electrons collected by dynode } i}{\text{no. electrons emitted from dynode } i-1}, \tag{14.54}$$

and the secondary emission factor for the same dynode is defined as

$$\delta_i = \frac{\text{no. electrons emitted by dynode } i}{\text{no. electrons collected by dynode } i}. \tag{14.55}$$

Suppose that η_1 is the charge collection efficiency of the first dynode for those electrons initially ejected from the photocathode N_{pc}, then the average number of electrons emitted by the first dynode N_1 is

$$N_1 = N_{pc}\eta_1\delta_1. \tag{14.56}$$

For a PMT with M number of dynodes, each with its own charge collection efficiency and secondary emission factor, the total number of electrons collected at the anode is

$$N_a = N_{pc}(\eta_1\delta_1)(\eta_2\delta_2)\ldots(\eta_{M-1}\delta_{M-1})(\eta_M\delta_M)\eta_a, \tag{14.57}$$

where η_a is the final charge collection efficiency of the anode. From Eq. (14.53), the average total gain is

$$G = \frac{N_a}{N_{pc}} = \eta_a \prod_{i=1}^{M} (\eta_i \delta_i). \tag{14.58}$$

The emission coefficient is strongly dependent upon the accelerating voltage, for it is the accelerating voltage that determines the energy of the electrons that strike the dynode. Further, the electron trajectories are also strongly dependent upon the applied voltage. In both cases, the overall dynode gain, $\eta_i \delta_i$, increases with interdynode voltage, and can be generally described by

$$G_i = \eta_i \delta_i = k_i V_i^{\alpha}, \tag{14.59}$$

where k_i is a proportionality constant and V_i is the voltage applied between dynode $i-1$ and i. Insertion of Eq. (14.59) into Eq. (14.58) gives the PMT gain as

$$G = \frac{Q_a}{Q_{pc}} = \eta_a \prod_{i=1}^{M} (k_i V_i^{\alpha}). \tag{14.60}$$

Values of α are typically reported between 0.6 and 0.8. Equation (14.60) is often simplified with the assumption that η_i and η_a are unity, i.e., 100% collection efficiency, and that δ_i and the interdynode voltages V_i are identical for all dynodes. With these assumptions Eq. (14.60) reduces to

$$G = \frac{N_a}{N_{pc}} = \delta^M = (k V_d^{\alpha})^M. \tag{14.61}$$

where V_d is the voltage applied to each dynode. Note that the assumptions used to derive Eq. (14.61) are not applicable to all PMTs. For instance, the interdynode voltage is often divided such that the highest possible η and optimum δ are achieved and this voltage is not always identical for each interdynode spacing.

Example 14.3: Given a 10-stage PMT where all $\eta_i = 0.97$, $\eta_a = 0.98$, $\delta_i = 3.5$ for the first 5 stages, and $\delta_i = 4.2$ for the last 5 stages, determine average gain for a single photoelectron.

Solution:

The gain is calculated from Eq. (14.60) as

$$G = \eta_a \prod_{i=1}^{M} (\eta_i \delta_i) = (\eta_a)(\eta_i)^{10} \left[\prod_{i=1}^{5} \delta_i\right] \left[\prod_{i=6}^{10} \delta_i\right] = (0.98)(0.97)^{10} (3.5)^5 (4.2)^5 = 4.96 \times 10^5.$$

14.1.7 Factors Affecting the Performance of a PMT

The performance of a PMT is affected by properties such as tube size, the glass enclosure, response speed, transit time spread (TTS), dark current, optimum wavelength, operating voltage, number of stages, and gain. These properties are usually reported by commercial manufacturers. However, there are other factors that affect the performance of PMTs such as dynode glow, space charge accumulation, and environmental effects. Summarized in the following subsections are descriptions of these other properties.

Commercial Specifications

Depending on the intended PMT usage, an operator must select the PMT that works best with the scintillator of choice. For instance, the sensitivity of the PMT must match well to the emission spectrum of the scintillator and the timing of the response speed must also match the decay constant of the scintillator. If the PMT has significant wavelength mismatch, then the overall gain and energy resolution suffer, whereas space charge build-up and spectral crowding occur for slow PMTs matched to high-speed scintillators. The reader is directed to Table 14.8 for a list of specifications for some PMTs used in radiation detection.

Dark Current and Noise

The dark current of a PMT is the current that flows in the cathode or anode circuits in the absence of light. The dark current flow of electrons is a source of random electromagnetic fields that add to electronic noise. The current that flows to the anode in total darkness has three main origins, namely (a) leakage current on the PMT surfaces, (b) intermittent emission of electrons, and (c) regenerative effects. The causes of these dark current contributions vary greatly with the operating conditions and also the prior storage conditions of the PMT. The dark current is dominated by leakage current under low voltage conditions, by thermionic emission at typical operating voltages, and by regenerative effects at higher voltages. These components are discussed in more detail below.

Ohmic Leakage Leakage current, sometimes referred to as "ohmic leakage," refers to current flow across the glass envelope and insulators when the PMT has voltage applied to it. Under dark conditions, it can be recognized by its nearly linear increase as the applied voltage is increased linearly. Although the leakage current is usually small, there may be residual conductive material remaining in the PMT from the photocathode and dynode manufacturing process. This residual material becomes an intrinsic property of the device. A controllable source of leakage current is surface contamination, which may be a result of water vapor, dirt, grease, or other foreign material that provides conduction paths. Thorough cleansing of the PMT with isopropyl alcohol (2-propanol) can eliminate such contaminants and reduces this portion of the leakage current. In humid environments, high voltage may cause arcing between electrodes. Precautions may be taken to insulate the base connectors with moisture resistant coatings. Most commercial scintillation detectors come as a single hermetic sealed unit, as a detector and PMT (see Fig. 14.3), thereby eliminating the arcing problem. Overall, the ohmic leakage current dominates the dark current at low voltages and also at low temperatures.

Thermionic Emission A thermally dependent source of sporadic electrons is thermionic emission of electrons from the surfaces of the photocathode and dynodes. The current density from thermionic emission, without gain, is described by Eq. (14.18). From Eq. (14.18), it is found that lowering the work function of photocathode materials increases thermionic emission. Hence, photocathode materials designed for low energy (extended red) photon sensitivity have a higher thermionic emission current. At low voltage, the thermionic emission current is negligible; however, once the voltage is sufficiently high to amplify the current through secondary electron emission, the thermionic current contribution becomes important. As the voltage is increased, thermionic emissions eventually dominate the dark current. Electrons emitted from the photocathode experience the entire gain described by Eq. (14.61), whereas electrons emitted from any one of the dynodes have the gain reduced by the number of dynodes skipped in the chain. Also, the photocathode surface is usually much larger than the dynode surfaces. As a result, most of the overall thermionic dark current comes from the photocathode emissions. Because the overall current increase is a function of the PMT gain, the thermionic current appears to also increase in proportion to the PMT gain. Thermionic emission from common photocathodes may range between 10^{-19} to 10^{-15} amps cm^{-2} over the maximum sensitivity range between 300 and 500 nm. For extended red photocathodes, such as the AgOCs S-1 response (see Table 14.2 and Fig. 14.15), thermionic emission can exceed 10^{-13} amp cm^{-2}. Finally, because thermionic

P: Anode rise time (ns)

Q: Transit time (ns)

NR = not reported

emission is also a function of temperature, the thermionic effect can be reduced by cooling the PMT during operation.

Background Radiation Another contribution to dark current is due to background radiation from external and internal sources. When cosmic rays, primarily protons and alpha particles, interact with the Earth's atmosphere, they can produce a shower of secondary ionizing particles, composed mainly of neutrons, pions, positrons, and muons. Intersection of these particles with the PMT glass envelope can produce Čerenkov radiation, which can subsequently cause photoelectron emission from either the photocathode or the dynodes. Because significant energy is released from by Čerenkov radiation interactions, a pulse from such an event can be significant. Čerenkov radiation is emitted in a conical shape along the direction of the particle trajectory; hence dark current from Čerenkov radiation events is higher for a PMT pointing upwards rather than downwards.

Radioactive contaminants in the PMT glass envelope (mainly ^{40}K) can also cause electron emission from the photocathode and dynodes. Some commercial vendors offer PMTs with low concentrations of potassium in the glass envelope by using fused silica, for example, to reduce the intrinsic radiation background. Finally, radiation emitted by building walls and floors, again usually from ^{40}K and perhaps from other radioactive sources in the vicinity, can add to spurious counts and dark current. Usually direct interaction of background radiations with the PMT structure are rare and, thereby of little consequence. Background suppression becomes important for situations requiring low background counting, and perhaps for liquid scintillation counting in which the scintillation light output can be relatively small.

Exposure to Ambient Light Exposure of a PMT to normal lighting conditions while under operation can cause catastrophic damage to the PMT and, consequently, should always be avoided. However, exposure to typical lighting conditions, even while the PMT is not under bias, can cause an extended, but temporary, increase in anode dark current. This increase is a consequence of exciting the photocathode, glass envelope, and internal parts of the PMT, which may phosphoresce over an extended period of time. The intensity and length of the exposure dark current is a function of the exposure wavelength and exposure duration. Dark current produced by ambient light exposure decays somewhat exponentially with time. Exposure to short wavelength photons can cause exposure dark currents over two orders of magnitude higher than exposure to longer wavelength photons. Even a short burst from an intense source of UV photons can cause appreciable temporary dark current. PMTs stored in sunlight may need several days in complete darkness before the dark current is reduced to the usual unexposed condition. Overall, unused PMTs should always be stored in total darkness and never subjected to intense light, even while not in use.

Regenerative Effects Regenerative effects normally appear at potentials exceeding the recommended operating voltage of the PMT. These include field emission, afterpulsing, dynode glow, glass charging, and helium penetration. Operation with voltages in which regenerative effects appear can permanently damage a PMT.

Field emission occurs at irregularities and pinnacles formed on the photocathode and dynode surfaces. A strong electric field is formed at these points, thereby promoting the emission of electrons. The theory for this emission was first addressed by Fowler and Nordheim [1928]. Later this theory was modified to include the Schottky barrier effect and introduced two approximations to the Fowler-Nordheim model to make the emission model more numerically tractable [Spindt et al. 1976]. In this revised model, the current density J (A/cm^2) of emitted electrons is given by

$$J \simeq \frac{A\mathcal{E}^2}{\phi} \exp\left[-B\frac{\phi^{3/2}}{\mathcal{E}}v(y)\right], \tag{14.62}$$

where $A = 1.4 \times 10^{-6}$ and $B = 6.87 \times 10^7$ are constants, ϕ is the work function in eV, $\mathcal{E}$ is the electric field in V/cm, and y is the Schottky lowering of the work function barrier. Finally, the function $v(y)$ is approximated

by $v(y) \simeq 0.95 - y^2$. Note that the applied electric field has a substantial effect on field emission, with a combined exponential and $\mathcal{E}^2$ increase. Field emitted electrons can fluoresce the surfaces inside the PMT, causing emissions of photons that may reach the photocathode. Field emission can also cause permanent damage and significantly shorten the life of a PMT.

Afterpulsing is the production of minor spurious pulses following a main event. There are two main sources of afterpulsing, luminous and ionic [Morton et al. 1967; Krall 1967]. Luminous afterpulses are produced by energetic electrons causing the anode or dynodes to fluoresce. Fluoresence photons can travel back to the photocathode and cause a subsequent event, usually lower in magnitude than the main event. Luminous afterpulses are delayed by the sum of the electron and fluorescent light transit times through the PMT, typically between 20 and 100 ns.

Ionic afterpulsing is caused by contamination gases in the tube becoming ionized and subsequently striking the photocathode. The sources of the contamination gases may be outgasing of components, desorption from the PMT walls, and residual gases remaining after the evacuation process. Energetic electrons drifting through the PMT can cause ionization of these trace gases, thereby producing positive ions. These positive ions, having much lower mobility than electrons, drift much more slowly than do electrons and, hence, strike the photocathode with a delay between 200 ns to over 1 μs. When these ions strike the photocathode, they can release numerous secondary electrons, which in turn produce another electronic avalanche and pulse. The magnitude of an ionic afterpulse is a function of the positive ion kinetic energy; hence the ionic afterpulse magnitude is strongly dependent upon the applied voltage. Troubling gas ions include N_2^+ and H_2^+, and gas sources may include N_2 from residual air and detachment of H_2 from water moisture. Under some conditions, CH_4^+ and He^+ may be present, also causing afterpulsing. Modern manufacturing procedures are set in place to reduce the concentration of these residual gases. For ordinary scintillation counting and spectroscopy, afterpulsing is usually of little consequence. However, for measurements requiring critical timing information, afterpulses can prove to be an annoyance. Techniques to suppress afterpulses are described in the literature [Lamaze et al. 1975; Mirzoyan et al. 1997].

If the PMT is operated or stored in an environment with high He concentrations, it is possible for the He to diffuse through the glass or connecting regions into the PMT enclosure. Because He is a non-reactive inert gas, He does not attach to the PMT structure, hence is not gettered. As He concentrations build, it may become a problem by producing afterpulsing when ionized. Relatively high concentrations of He^+ can cause electrical breakdown, and ultimately, render the PMT useless.

At high enough operating voltages, electron bombardment upon the dynodes can cause the emission of light, recognized as a blue glow, and occurs particularly in the latter stages of the dynode chain. Photons from this dynode glow can scatter back to the photocathode, thereby becoming an additional source for noisy current [Krall 1967]. This effect is largely suppressed by including shields in the PMT that work to block light from reaching the photocathode.

Acceleration of electrons, or ions, into the PMT glass envelope can produce the photoemission of secondary electrons, an effect referred to as *glass charging*. This particular problem occurs if the glass envelope has a positive potential that competes with that of the anode and can arise from external voltage sources. Installation of shielding material around the PMT reduces the problem of glass charging. The conductive shield should be grounded to the same potential as the cathode; otherwise, should the shield maintain a positive potential, there is a risk of permanently damaging the PMT [Engstrom 1980].

Timing

The timing characteristics reported for PMTs are the *transit time*, *rise time*, *fall time* (or decay time), and *statistical spread*. The transit time is the time between a delta-function light pulse striking the photocathode and when the output current from the PMT reaches peak amplitude [Frank 1977], as shown in Fig. 14.29.

The transit time has many components, including the diffusion time required for electrons excited in the photocathode material to reach the vacuum interface, the time for electrons to transverse the space between the photocathode to the first dynode, and the multiple transverse times between dynodes. Emission times for common alkali metal emissive materials is about 10 ps. However, the diffusion times of NEA materials, because of the longer electron mean free paths, may extend beyond 100 ps. Yet, these emission times have little consequence compared to collection times between dynodes. The longest transit time component is usually the time required for electrons to travel from the photocathode to the first dynode. This is especially true for configurations with large photocathode surfaces because large photocathodes must be placed further away from the dynodes to allow efficient focusing of electrons.

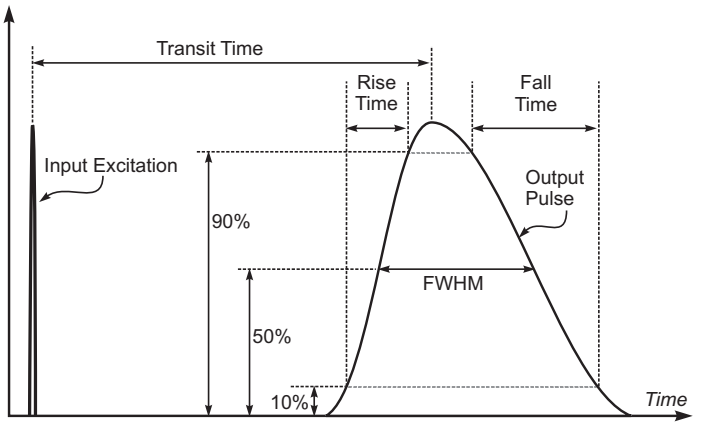

Figure 14.29. The different time constants used to characterize the output pulse from a PMT produced by a delta-function input.

The rise time of the PMT is mean time required for the output pulse to increase from 10% maximum to 90% maximum. It is the charge density and the charge collection time measured between the last dynode and the anode that determines the rise time, mainly because the anode output current is induced almost entirely from charges drifting between these last two electrodes (see Sec. 8.5 on weighting potentials). Rise times for common PMTs range between 1 and 20 ns. The PMT rise time is typically smaller than the fall time, and provides higher accuracy for timing measurements. The fall time of the PMT is the mean time required for the trailing edge of the output pulse to fall from 90% maximum to 10% maximum.

The statistical time spread is the full width at half maximum (FWHM) of the PMT output pulse. Contributions to statistical spread time include the time spread of the scintillation light source, time spread in electron trajectories from the photocathode to the first dynode, and time spread in the multiplication process as electrons move through the dynode chain. The light source time spread is a function of the decay time for the scintillation process, a physical process that cannot be altered for a given scintillation material. The time spread for electrons traveling between the photocathode and the first dynode can be minimized by including a curved inner photocathode, thereby providing nearly equidistant electron trajectories. The time spread from secondary electron emission between dynodes is complicated by the differences in electron emission speeds and directional trajectories. Overall, the timing resolution is determined mainly by the statistical spread in the secondary electron emissions.

The speed of an electron reaching a dynode is directly proportional to the applied electric field or voltage between the adjacent dynodes. Hence, the transit time is inversely proportional to voltage. Consequently, the time spread of electrons between dynodes is dependent on $1/V_i$ where V_i is the voltage between dynodes $i-1$ and i. If it is assumed that the speeds of electrons reaching a dynode have a Gaussian distribution, the standard deviation in speeds is proportional to $1/\sqrt{V_i}$. Hence, the broadening of the output pulse decreases with increasing voltage, and the timing characteristics of a PMT are usually maximized at the highest recommended operating voltage.

Fluctuations in the transit time between pulses, referred to as *jitter*, determines the accuracy limit for timing measurements. The variance in the transit time for a delta-function light input is described by

$$\sigma_{tt}^2 = \sigma_1^2 + \sigma_2^2, \tag{14.63}$$

where σ_1^2 is the variance for the cathode-to-first-dynode collection time, and σ_2^2 is the time variance of the combined collection times for the remaining interdynode spacings. The variance σ_1^2 has several contributions, mainly, absorption depth variance, emission location/trajectory variance, and chromatic variance. The variance in absorption depth affects the variance in the energies of the emitted electrons. Electrons that must diffuse far to the vacuum interface may have barely enough energy to surmount the energy barrier, whereas electrons excited at the vacuum interface may be emitted with the total residual energy $\phi - h\nu$. These electrons are emitted into the vacuum envelope in various directions, some directly towards the first dynode and others at varying angles away from the first dynode. Additionally, the emergence point on the photocathode may be anywhere on its surface. All together, the different diffusion times for the photoelectrons to reach the surface of the cathode and the different emergent locations and directions determine the variance in the time required for an electron leaving the photocathode surface to reach the first dynode. Wavelength variance is of little consequence for monochromatic light; however, scintillators emit light over a spectrum of energies, thereby adding to the variance in photoelectron energies.

Suppose a single electron is released from the photocathode. If the interdynode characteristics are assumed identical, then the variance in collection time between the dynodes as a function of transport between dynodes is [Gatti and Svelto 1966],

$$\sigma_d^2 = \frac{\sigma_{t1}^2}{\delta} + \frac{\sigma_{t2}^2}{\delta^2} + \frac{\sigma_{t3}^2}{\delta^3} + \ldots + \frac{\sigma_{tM}^2}{\delta^M}, \tag{14.64}$$

where σ_{ti}^2 is the variance in flight times from dynode $i-1$ to dynode i and the last term is the contribution to the flight time from the last dynode to the anode. Note that the last term is generally negligible, mainly because of the large value of δ^M and that charge induction only initiates as electrons travel towards the anode from the last dynode. If, in addition to the assumption that $\delta_i = \delta$ for all dynodes, one also assumes $\sigma_{ti} = \sigma_t$ for all dynodes, then for large values of M, Eq. (14.64) reduces to,

$$\sigma_d^2 \simeq \frac{\sigma_t^2}{\delta - 1}. \tag{14.65}$$

If the variance in gain is also included, then Gatti and Svelto [1966] show that the collection time variance for the dynode bank is,

$$\sigma_2^2 \simeq \frac{\sigma_t^2}{\delta - 1}\left(1 + \frac{1}{\delta - 1}\right) = \frac{\sigma_t^2 \delta}{(\delta - 1)^2}. \tag{14.66}$$

The total variance in the transit time, given by Eq. (14.63), is

$$\sigma_{tt}^2 = \sigma_1^2 + \frac{\sigma_t^2 \delta}{(\delta - 1)^2}. \tag{14.67}$$

Substitution of Eq. (14.59) into Eq. (14.67) yields,

$$\sigma_{tt}^2 = \sigma_1^2 + \frac{\sigma_t^2 k V^\alpha}{(kV^\alpha - 1)^2}, \tag{14.68}$$

which for large voltages reduces to

$$\sigma_{tt}^2 \simeq \sigma_1^2 + \frac{\sigma_t^2}{kV^\alpha}. \tag{14.69}$$

This result clearly shows that an increase in the operating voltage decreases the fluctuations in the transit time.

For typical scintillation spectroscopy with relatively slow inorganic scintillators, such as NaI:Tl, most PMTs have sufficiently fast responses that the time response of the photomultiplier is inconsequential compared to the decay time of the scintillator. However, with recent advances in producing scintillators with fast decay times, the transit and rise times of the PMT become important. Hence careful selection of a fast PMT is important for these short decay-time scintillators. In the case that a slow PMT is used with a relatively fast inorganic scintillator, such as $LaBr_3$, the high density of charge in the PMT can cause serious gain distortions and non-linear behavior, thereby distorting the resulting pulse height spectrum.

Photocathode Non-uniformities

The photocathode coating usually has non-uniformities across the surface that produce a variation in light response across the photocathode. For radiation spectroscopy, scintillation light striking different regions of the photocathode can produce a varied response, thereby degrading energy resolution. For PMTs with large photocathode surfaces, usually used for radiation detection applications, the light response decreases abruptly near the photocathode periphery. Scanning measurements across the surface of PMTs indicate that the variance is relatively small for well-processed photocathodes ($\pm$ 3%) [Engstrom 1980]. This variation in response is usually least at the optimum peak wavelength, but can be much larger and erratic as the photon wavelength is increased from the optimum wavelength.

There are still two principal reasons for the non-uniform photon response: (1) variations in the photocathode layer thickness produced by the physical vapor deposition used to form the coating, and (2) the design of the electron optics used to guide the photoelectrons to the first dynode. Light response uniformity is improved by producing a diffusive layer at the glass/photocathode interface, accomplished by sandblasting the inner surface of the glass before the photocathode material is applied. Light is scattered over a wider area, thereby decoupling the point of intersection from the overall photoresponse. Other methods to decrease the effects of photocathode non-uniformity include the installation of a permanent ring magnet or solenoid around the photocathode, thereby defocusing electron emissions around the periphery and nullifying their contributions. Also, placing a stopped-down aperture between the scintillator and photocathode reduces the sensitive photocathode region that contributes to the photocurrent and, thereby reduces effects from photocathode non-uniformities.

14.1.8 Ancillary Equipment

Support equipment needed to operate a PMT properly include the tube base, output electronics, and shielding. This ancillary equipment is briefly discussed in this section. Photomultiplier specification sheets typically provide a recommended socket and voltage divider configuration that is dependent on the PMT application. The socket serves as an electrical connector to the PMT dynode pins. Although separate sources can be used to provide voltage to each PMT dynode stage, such a configuration is somewhat impracticable. Instead, the applied high voltage is usually divided amongst the focusing electrodes, the anode, and the dynodes.

Sockets and Voltage Dividers

PMTs have various electrical pin configurations; hence, matching the PMT to the proper socket is, of course, mandatory. These sockets can be acquired with or without mounting flanges, depending on the intended application. For instance, the mounting flange allows the PMT to be installed on a stand-alone base, whereas sockets without the mounting flange must be connected directly to a circuit board. The preferred voltage divider can be connected directly to the socket and changed according to application.

Voltage Divider There are two basic types of voltage dividers, namely, resistive and active types. The resistive dividers consist of a series of resistors that divide the voltage between the electrical parts of the PMT. Of these, there are three main types of resistive divider: the uniform type, the progressive (or tapered) type, and the intermediate type. After the initial region between the photocathode and the first dynode,

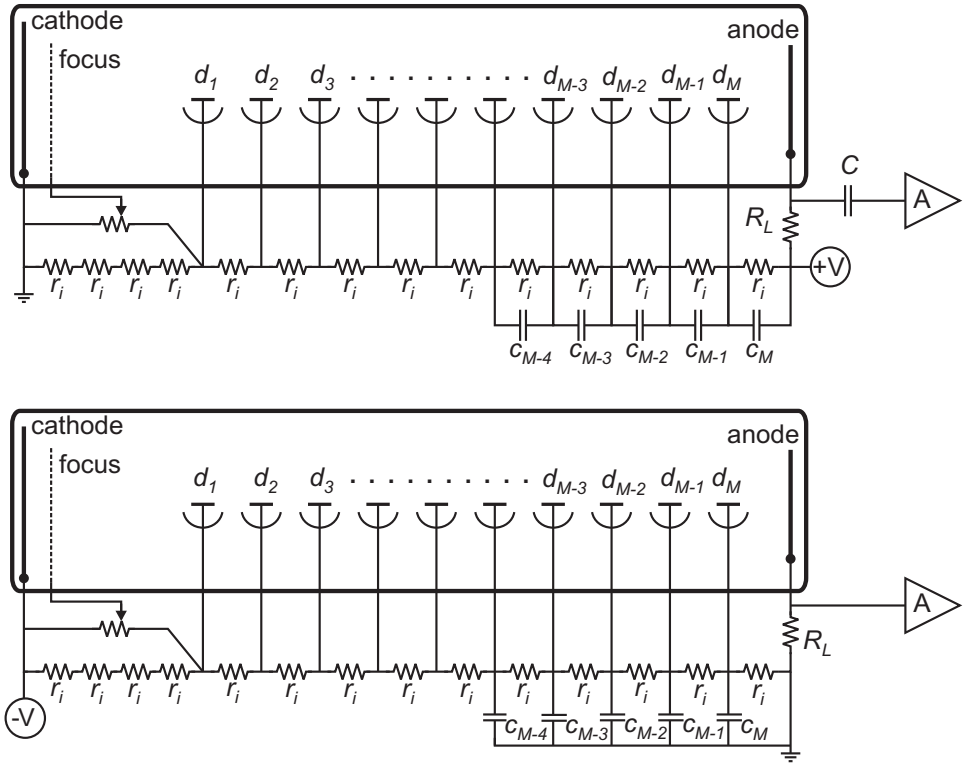

Figure 14.30. Voltage divider configurations with (top) positive high voltage applied to the anode, grounded cathode, and with series decoupling capacitors, and (bottom) negative high voltage applied to the cathode, grounded anode, and with parallel decoupling capacitors.

the uniform divider distributes the applied voltage equally over the dynodes stages. The uniform divider yields the highest gain of the three types of dividers, and is the most frequently used configuration for radiation measurements. The progressive divider increases the applied dynode voltage in the direction of the anode. The progressive divider helps overcome space charge effects and non-linear behavior for high current; however, the gain is typically lower than that of uniform dividers. Finally, the intermediate divider applies the same voltage to the first several dynodes stages, but then provides progressively larger voltages to the latter dynode stages. Intermediate dividers are used for fast response PMTs.

An active divider consists of a string of high impedance resistors connected in parallel with a string of field effect transistors [Kerns 1977; ET 2011]. These transistors help regulate the voltage between the dynodes to keep the potential drop constant. An active voltage divider ensures constant gain up to the maximum allowable current (about 100 μA). Power consumption is low, about 100 mW, so that portable PMTs can be realized. Active dividers often have current limiting circuitry to prevent damage to the PMT. An ideal active divider can sense the dynode voltages over the entire PMT dynamic range.

The applied PMT high voltage is often a positive bias applied to the anode with the photocathode region grounded. However, the PMT can work equally well with negative high voltage applied to the cathode with the anode grounded, as shown in Fig. 14.30. Specifications made by PMT manufacturers give the preferred bias arrangement along with recommended voltage dividers and sockets. The applied high voltage is often positive, thereby allowing the glass envelope and photocathode to remain at zero potential. One benefit of applying positive high voltage is the suppression of spurious pulses from glass electroluminescence. Further,

it is typical that a scintillation crystal attached to the PMT be at zero potential, and the positive high voltage configuration practically eliminates spurious pulses from high-voltage leakage to nearby grounded objects. However, there are important cases when negative high voltage is preferred. With negative high voltage, the coupling capacitor at the output is no longer necessary because the anode is grounded. This divider then allows the resistive divider and PMT to be directly coupled to the output circuitry. The negative bias configuration is used for fast pulse applications in which the output is impedance matched to the transmission line, and for current mode operation with DC-coupling.

Decoupling Design of the resistive divider circuit depends upon the high voltage supply, the required voltage distribution, and the expected anode current (characterized by the FWHM of the output pulse). Variations in anode output current can be minimized by ensuring that $i_{leak}/i_A \geq 100$, where i_A is the anode output current and i_{leak} is the leakage current flowing through the resistive divider [Flyckt and Marmonier 2002]. The leakage current associated with the diode divider circuit can be estimated as

$$i_{leak} \simeq V_{bias} \Big/ \sum_{i=1}^{N} r_i \tag{14.70}$$

where the r_i are the resistances of the divider.

Example 14.4: Consider a 10-dynode PMT with a normal operating gain of 10^5 at 1000 volts potential and an anode output current FWHM of 10 ns. For a uniform resistive divider in which the voltage drop between the photocathode and the first dynode is five times the interdynode potentials, what is the minimum resistance required for each resistor in the divider?

Solution:

A single electron escaping the photocathode produces 10^5 photoelectrons. The anode current produced by a single electron is then,

$$i_A = \frac{qG}{t_A} = \frac{(10^5)(1.6 \times 10^{-19}\ \text{C/e}^-)}{10^{-8}\ \text{s}} = 1.6\ \mu\text{A}.$$

where G is the gain and t_A is the anode rise time. Conforming to the recommendation that $i_{leak}/i_A \geq 100$,

$$i_{leak} \geq 100\ i_A \approx 160\ \mu\text{A},$$

and the total resistance must be

$$\sum_i r_i = \frac{(1000\ \text{V})}{(160 \times 10^{-6}\ \text{A})} = 6.25\ \text{M}\Omega.$$

With 9 dynodes and the photocathode space, the voltage divisor is $9 + 5 = 14$, so that the interdynode resistance must be at least 446.43 kΩ.

Although high resistances can be employed, it is far more usual to use capacitors to decouple the dynodes from the resistive divider circuit. By so doing, the instantaneous anode current, or the currents between the dynode stages, can greatly exceed the average divider current. Decoupling may be accomplished by inserting capacitors either in parallel or series with the divider circuit resistors. Either configuration works; however, capacitors arranged in parallel require much higher voltage ratings. These decoupling capacitors function as

charge storage to make up for the current drain from the voltage source as the electron cascade progresses through the PMT.

Suppose that the maximum allowable change in voltage at any dynode is ΔV and the expected anode current is

$$i_A = nq_eGt_A, \tag{14.71}$$

where n is the number of photoelectrons. Then the decoupling capacitance for the last dynode is

$$C_M = \frac{nq_eG}{\Delta V}. \tag{14.72}$$

where M is the number of dynodes. Consider the case in which all dynode gains are equal; then the required limiting capacitance for each dynode stage is,

$$C_i = \frac{nq_eG}{\delta_i \Delta V} = \frac{C_M}{\delta_i^{M-i}}, \tag{14.73}$$

where C_i and δ_i are the decoupling capacitance and gain from dynode number d_i, respectively. Typically, a safety margin equivalent to the stage gain is multiplied by the capacitance to yield,

$$C_i' = \delta \frac{C_M}{\delta_i^{N-i}} = \frac{C_M}{\delta_i^{N-i-1}}. \tag{14.74}$$

for all coupling capacitors except C_M. In most cases these decoupling capacitors are needed only if the required C_i is greater than the dynode stage capacitance (about 20 pF). The first several stages do not need decoupling capacitors, consequently only the latter stages of the divider circuit require these decoupling capacitors.

Preamplifier

Commercial scintillation/PMT units often come with a preamplifier, not to be confused with the voltage divider. In some circumstances, the output pulse may be large enough without further amplification, or the application may require current mode operation rather than pulse mode operation. However, for typical radiation detection measurements, it is important to amplify and shape the output pulse from the PMT. The preamplifier provides a small amount of gain, shape the output pulse (typically a tail pulse), and couple the PMT to the main amplification electronics for pulse mode operation.

Magnetic Shield

Photomultiplier tubes are affected by external magnetic and electrostatic fields because such fields can deflect the electrons from their designed trajectories. The end result is a loss of gain, and for radiation spectroscopy, deterioration in energy resolution from increased statistical spread of photoelectrons reaching the first dynode. Magnetic field effects generally become smaller as the high voltage increases, but usually not enough to eliminate the performance degradation of the PMT. In short, PMTs must be shielded against magnetic fields. Obviously, because the electrons within the tube are guided through successive potentials, external electric fields must also be shielded from the PMT. Most often the PMT is wrapped with "mu-metal" to terminate these fields and prevent them from interfering with the electron trajectories.[11] To prevent problems with glass charging and electroluminescence, the magnetic shield is kept at the same potential as the photocathode. Note that operation with the magnetic sleeve shield held at a high voltage (the situation when the cathode is operated at high voltage) presents a special safety issue, and precaution should be exercised to prevent hazardous shock. Preformed sleeves of mu-metal are usually available from the PMT manufacturers.

[11] The name "mu-metal" comes from the Greek letter μ, the usual symbol for magnetic permeability.

14.1.9 Environmental Effects

Finally, a word or two regarding environmental effects on PMTs. Most manufacturers specify maximum storage and operating temperatures, which according to Engstrom [1980] is usually near 75°C. Apparently, higher temperatures can cause a chemical reaction at the photocathode which may compromise the PMT performance. On the other hand, rapid cooling may fracture the glass envelope. Differences in the thermal expansion coefficient between the glass and PMT socket/base may also cause cracking, and it is recommended that the PMT temperature not go below −50°C. Cooling may also produce condensation that may cause short circuits between the dynodes. Coating with a moisture-resistant insulator can help mitigate this problem.

Photomultiplier tubes can withstand reasonable pressures, but it is advised that the external pressure be kept below 3 atm to avoid possible implosion.[12] Recall that gas diffusion into the PMT from a high pressure environment may be a problem, especially with He gas. Also photomultiplier tubes generate heat; hence operating them in vacuum can be problematic if a heat sink is not employed.

Photomultiplier tubes are relatively fragile, but can survive some level of shock force (up to about 10 g). Special robust PMTs are designed to withstand high shock (some up to 1500 g), and are used for space applications, military applications, and oil well logging. However, careful handling is always recommended. Damage to the internal structure can cause shorting or loss of gain and other performance characteristics. Obviously, excessive shock may also crack the glass envelope.

Of course, photomultiplier tubes are widely used in a radiation environment. High radiation environments, however, can cause an increase in background current by the production of fluorescence in the glass envelope, particularly in the face plate adjacent to the photocathode [Johnson 1973]. Permanent damage occurs from high radiation exposures that cause browning of the PMT faceplate. Soda lime and LiF faceplates are very susceptible to such radiation damage. Borosilicate glass has only slightly more radiation hardness. Quartz and sapphire windows show much less degradation than borosilicate or soda lime glasses. For shorter wavelength UV photons beyond the range of quartz or sapphire, MgF_2 windows are recommended for use in high radiation environments.

14.2 Semiconductor Photodetectors

Semiconductor photodetectors are based upon physics discussed in Chapters 12, 15, and 16, which include solid state physics, semiconductor device physics, and semiconductor device configurations. However, for completeness, the authors decided that these important photosensitive devices should be covered, to some extent, in the present chapter. Hence, a general explanation of these photodetectors and their operation is provided here, whereas detailed explanations on how these devices are designed and operated are offered in Chapters 15 and 16.

Attractive features of semiconductor photodetectors include their compact size, relatively low operating voltage, and fast response times. Semiconductor photodetectors, unlike PMTs, are also insensitive to magnetic fields, thereby allowing them to be used in environments with high magnetic fields. The overall quantum efficiency can be remarkably high for specific ranges of photon wavelengths as determined by the semiconductor's band-gap energy and the photon absorption efficiency. The main types of photon detectors used with scintillators are photodiodes, avalanche photodiodes, and semiconductor photomultipliers.

[12] This eventuality occurred on a devastating scale on Nov. 12, 2001 in the Super-Kamiokande neutrino detector located 1000 m below ground in an old zinc mine in Japan. The detector was a cylinder (34 m in diameter and 36 m high) filled with ultra-pure water and lined with 11,146 PMTs. On the fateful day, as the chamber was being refilled, a PMT imploded setting off a chain reaction that caused 6,600 of the $3,000 PMTs to also implode.

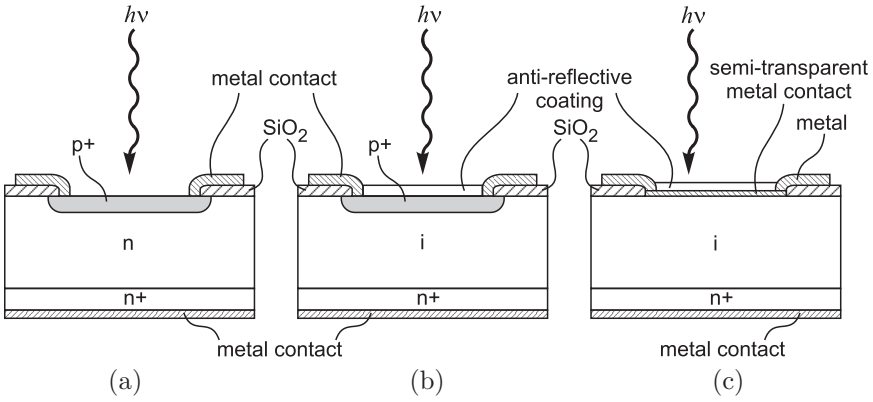

Figure 14.31. Semiconductor photodiodes of different designs, including (a) a common *pn* junction photodiode, (b) a *pin* photodiode and a (c) Schottky contact photodiode.

14.2.1 Photodiodes

Photodiodes are semiconductor devices formed into a *pn* or *pin* junction diode. The designation p refers to p-type impurity dopants that produce positive charge carriers, n refers to n-type impurity dopants that produce negative charge carriers, and i refers to the *intrinsic* material that is generally devoid of impurity dopants. Diodes formed from a simple *pn* junction offer an inexpensive method for detecting photons, yet have relatively thin active volumes. The reason for this thin volume, as explained in detail in Chapter 15, arises from buidup of space charge in the sensitive region that limits the electric field and, thus, narrows the photon active sensitive region or *depletion region*. The n and p doped regions are necessary for the device to function properly, yet this space charge appears as a consequence of the "impurity doping" in the semiconductor.

A configuration often used to increase the active region of a semiconductor photodiode is the *pin* junction diode. In general, the device has a p-type material adjacent to intrinsic material, with n-type material completing the diode opposite the intrinsic material. A simple *pin* device cross section is depicted in Fig. 14.31(b). The active region is increased by including an intrinsic, or low-doped (π or ν), region between the n and p region, thereby greatly reducing the space charge density and increasing the active region width.

A simple and common photodiode is based upon the Schottky effect (see Sec. 15.3), in which the application of an appropriate metal forms a rectifying blocking contact upon the semiconductor. Such a device functions similarly to a *pn* or *pin* junction photodiode, but generally has higher leakage current. The higher leakage current is fundamentally due to the physical process that suppresses the leakage current in reverse bias. The Schottky diode relies upon a barrier to reduce thermionic emission, whereas the *pn* junction relies upon the reduction in minority carriers available for leakage as explained in more detail in the next chapter.

When photons strike the semiconductor photodiode, usually fabricated from Si or GaAs based materials, electrons are excited into the conduction band of the material. A voltage bias across the diode causes the photoelectrons to drift across the device and induce charge in a similar fashion as that described for gas-filled ion chambers. The quantum efficiency of the semiconductor diode varies with the configuration and packaging of the diode. For instance, different commercial Si photodiodes have peak efficiencies at wavelengths ranging between 700 to 1000 nm. Regardless, they are typically more sensitive to longer wavelengths than commercial PMTs. For instance, CsI(Tl) scintillation emissions are better matched to Si photodiodes than to PMTs. Photodiodes operate with low voltage, are small, rugged and relatively inexpensive and, thus, they offer a compact method of sensing light emissions from scintillators.

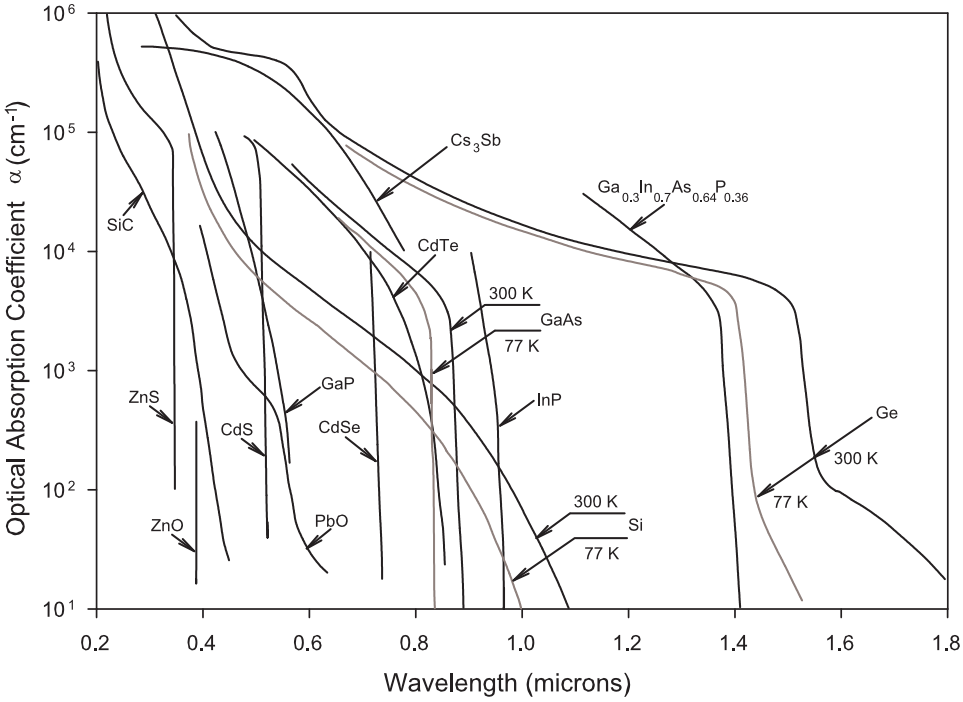

Figure 14.32. Optical absorption coefficients for various semiconductor photodetector materials. After [Melchior 1972; Sze 1981].

Performance Characteristics Quantum efficiency generally approaches a maximum as photon energies approach the band-gap energy. For photon energies below the band gap energy ($h\nu < E_g$), the material is generally transparent to the light, except for absorption by defect and impurity centers. For photon energies greater than the band gap ($h\nu > E_g$), absorption may occur with increasing likelihood as the photon energy increases. The increase in the absorption coefficient α occurs because electrons that are deeper in the valence band can be excited across the band gap into the conduction band as the energy of the absorbed photon increases. This property can be observed in Fig. 14.32 as the increase in absorption coefficient α as the light wavelength decreases.

For photons with wavelengths below the cutoff wavelength, determined by the semiconductor band-gap energy, optical absorption increases, as also shown in Fig. 14.32. However, the energy conversion efficiency[13] actually decreases as the photon energy increases, a consequence of excess energy being expended to excite a single electron-hole pair. For example, if an 800 nm photon (1.55 eV) is absorbed in GaAs ($E_g = 1.42$ eV), there is a likely chance that a single electron-hole pair is excited; hence $\eta_e = 0.916$. The same is true for a 700 nm photon (1.77 eV), but $\eta_e = 0.802$. Although the energy is higher for the second case, the photon has insufficient energy to excite two electron-hole pairs, causing η_e to decrease. Consequently, the energy conversion efficiency decreases even though the photon absorption efficiency increases.

The active region width of Si *pn* and *pin* photodiodes need only be about 1 to 4 microns to effectively absorb photons of wavelengths ranging between 450 nm to 650 nm [Melchior 1972]. For Ge photodiodes, these same active region widths correspond to photons of 950 nm to 1500 nm wavelengths. At shorter wavelengths,

[13] The energy conversion efficiency η_e is the band-gap energy divided by the energy expended to produce an electron-hole pair, i.e., $\eta_e = h\nu/E_g$.

absorption increases near the surface, consequently causing an increase in surface recombination and, thereby a decrease in the quantum efficiency. This behavior is apparent in Fig. 14.33 at the shorter wavelengths. Thus, the long wavelength cutoff is limited by the band-gape energy and the short wavelength cutoff is limited by high surface absorption and surface recombination. By contrast, Si Schottky contact photodiodes (also known as metal-semiconductor photodiodes), see Fig. 14.31(c), have thin metal contacts that allow photons to pass deeper into the active region of the photodiodes than do *pn* and *pin* diodes and, thereby extend the short wavelength range below 400 nm [Melchior 1972].

Both the energy conversion efficiency and the quantum efficiency determine the total charge excited by scintillation photons and, thereby affect the energy resolution of the detector. Silicon photodiodes can function at typical scintillation emissions with wavelengths near 400 nm, but excel in performance at longer wavelengths, generally in the 600 nm to 1000 nm range. Photodiodes generally do not have gain, and the charge signal is determined by the primary electron-hole pairs excited by the scintillation event. Consequently, the signals from photodiodes are small and need more amplification than signals from PMTs.

The quantum efficiency η_Q is defined as the average number of electron-hole pairs produced per scintillation photon. For light detection, a useful quantity used to determine the relative sensitivity of the diode to light is the *spectral responsivity* R, usually measured in amperes/watt [Donati 2000], and is defined as[14]

$$R = \frac{q_e \eta_Q \lambda}{hc} = \frac{q_e \eta_Q}{h\nu}. \tag{14.75}$$

From this result, R is seen to decrease with photon energy and to increase with quantum efficiency. Shown in Fig. 14.33 are spectral responses for several semiconductor photodiodes of interest for scintillation counting.

The details of semiconductor devices and operation are presented in Chapters 15 and 16. However, briefly stated, the number of charge carrier pairs produced is the average ionization energy w divided into the particle energy E, i.e., the number of electron-ion pairs is E/w. For high energy photons (x and gamma rays), most semiconductors have average ionization energies ranging between 2.5 and 5.5 eV/e-h pair. For low-energy photons emitted from scintillators, the average energy expended per electron-hole pair is a function of the absorption efficiency, the quantum efficiency, and the energy conversion efficiency. Consequently, without gain, the total number of charge pairs produced per scintillation event is considerably less than the number of charges produced by a PMT. Although the statistical spread in the number of electron-hole pairs produced is less than that predicted by Poisson statistics, the relatively low number of charge carriers per event compromises the overall energy resolution. Additionally, electronic noise from leakage and generation current can adversely affect the pulse height spectrum because of the relatively small signals produced by a common photodiode. This problem of poor energy resolution is particularly severe for low-energy scintillation photons.

Electronic Noise The electronic noise arising in common photodiodes is classified as either *series noise* or *parallel noise*. It is the fluctuation in these two current sources that produces a broad electromagnetic spectrum of frequencies in the noise, and, thus, it is usually referred to as *white noise*.

Parallel noise arises from dark current fluctuations within the diode, generally from thermionic leakage current and bulk generation current. Bulk generation current arises from charge carriers being thermally excited from the valence band into the conduction band, a process that increases with the active volume of the detector. Hence, bulk generation current is a function of both the contact area and the depth of the active region. Moreover, the dark current increases with applied voltage, mainly because the leakage current increases from non-ideal current saturation and the generation current increases as the active region increases with voltage. Parallel noise can be reduced by decreasing the leakage current of minority carriers

[14] This property is sometimes referred to as "spectral sensitivity" or "photosensitivity".

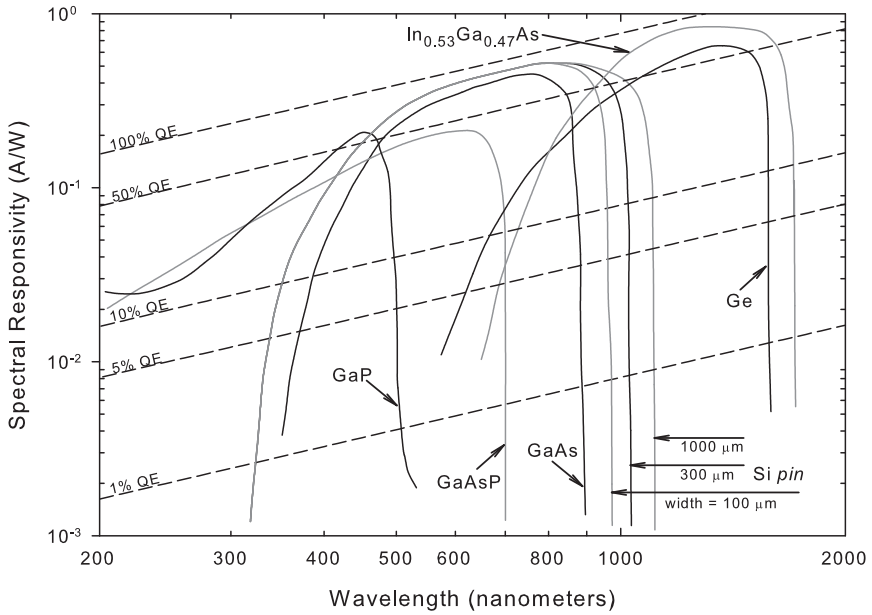

Figure 14.33. Spectral responsivity in amps/watt for various semiconductor photodetector materials of interest for scintillation counting. Quantum efficiency is also indicated. [after Donati 2000].

or by increasing the rectifying barrier height. Because the total leakage current increases as the total contact area increases, the practical size of photodiodes for scintillation spectroscopy is limited. For Si photodiodes, this area is usually restricted to approximately 1 cm^2.

Series noise arises from fluctuations in the series resistance and fluctuations in the current flowing into the input stages of the preamplifier circuitry, fluctuations that consequently produce short current bursts in the output of the preamplifier. This series noise is also referred to as *shot noise*. A large contribution to the series noise arises from the detector input capacitance C_{in} and is generally quantified as a function of C_{in}^2 [Iwanczyk and Patt 1985]. Hence, it is important to reduce the input capacitance as much as practically possible. This reduction can be accomplished by both reducing the detector contact area and increasing the active region, between the contacts. Note that both series and parallel noise can be decreased by selecting photodiodes with small contact areas; however, parallel noise decreases with the size of the active region whereas series noise increases with the size of the active region. Such counteracting trends in the two noise sources means there is an optimum operating voltage, which determines the size of the active region. Indeed, photodiodes are usually operated at active region depths well beyond those required to completely absorb the impinging scintillation light in order to optimize performance.

Photodiode Materials Silicon is of interest because of its good quantum efficiency in the extended red-wavelength range and because it couples well to common scintillators such as CsI(Tl) and even BGO, scintillators that typically are not optimized when coupled to PMTs. Although most photodiodes are manufactured from Si materials, there are many photodiodes manufactured from wide band-gap materials. These wide bandgap materials are almost all compound semiconductors, such as InP, GaAs, CdTe, GaP, CdS, and SiC, and generally have lower bulk generation current than that in Si. Further, because of their higher resistivity, wide band-gape semiconductors generally have lower leakage currents than Si diodes. Indeed, dark

current can be reduced, in concept, by wider band-gap materials, but this higher resistivity is usually accomplished by the purposeful introduction of compensating energy levels into the material. The fluctuations in generation current can be significant, mainly a result of the shorter generation-recombination lifetimes characteristic of compensated compound semiconductors, and it is the fluctuation in dark current that contributes to the electronic noise. Wide band-gap experimental photodiodes have also been investigated, such as HgI_2. Indeed, a rather sizeable CsI(Tl) crystal (about 16 cm^3) coupled to a HgI_2 photodiode held the energy resolution record for many years for a scintillator/semiconductor device operated at room temperature, namely 4.98% FWHM at 662 keV [Markakis 1988]. Competing processes between direct gamma-ray detection by the photodiode and the CsI(Tl) crystal were evident, a consequence of using compound semiconductor photodiodes composed of high Z elements. Some other binary compound semiconductors and complex ternary and quaternary compound semiconductors, such as PbS, PbSe, InSb, InGaAs, InAsSb, and InGaAsP, have extended IR sensitivity, but typically also have higher dark current densities than those expected for wide band-gap materials.

Overall, photodiodes offer a relatively compact and inexpensive method to detect radiation induced light from scintillators. They usually require only a modest bias voltage, compared to that required by PMTs, and are generally unaffected by magnetic fields. Further, semiconductor photodiodes are robust and less prone to shock damage. However, semiconductor photodiodes have much smaller output signals, thereby compromising energy resolution. Parallel and series noise further reduce energy resolution. Finally, the leakage current from semiconductor photodiodes increases with temperature, thereby reducing their use in high temperature environments. Compact Peltier coolers can be used to help remedy the noise problem, yet this added complication with its own power requirement still restricts the use of photodiodes in many circumstances.

14.2.2 Drift Diodes

One method to increase the active area of a photodiode, while still maintaining relatively low capacitance, is to use a *silicon drift diode* (SDD). Details of the structure and operation of the drift diode are given in Sec. 16.4 on silicon detectors. However, the basic device has a relatively small anode with structured cathodes guiding electrons by way of consecutively divided potentials. The capacitance is dominated by the low anode capacitance. Further, modern designs incorporate the first amplifier stage directly onto the diode, thereby reducing the coupling capacitance. These detectors can have relatively larger areas compared to common photodiodes, often greater than 25 mm^2 and up to 1 cm^2 area. Modest cooling (about 0°C) can be implemented to ameliorate the bulk generation current caused by the larger diode volume.

Although the charges drift for a longer time than that in common photodiodes (typically a few microseconds) the rise time is surprisingly fast, mainly because it is mostly dependent upon the drift distance between the anode and the closest cathode in the structure. However, diffusion of the charge cloud causes differences in rise times, a consequence of photon interactions occurring randomly over the entire diode volume. Hence, the diode integration time should be set high enough to allow complete charge collection, regardless of interaction location.

Drift diodes have demonstrated excellent results when coupled to scintillators. For instance, a cylindrical CsI(Tl) crystal, (3-mm diameter and 5-mm thickness) produced 4.34% FWHM energy resolution for 662-keV gamma rays when coupled with Nuclear Enterprises' 586 optical grease to a SDD [Fiorini et al. 1998]. Later, Fiorini et al. [2006] produced 2.7% FWHM energy resolution for 662-keV gamma rays with a cylindrical $LaBr_3$(Ce) crystal (5-mm diameter and 5-mm thickness) when coupled to a 5 mm^2 SDD. Although the scintillators were comparatively small, the excellent reported performance rivals the best performance for systems incorporating PMTs. To increase the overall detector area, an array of hexagonal SDDs is also reported by Fiorini et al. [2007] as a method to produce a compact Anger camera [Anger 1958].

14.2.3 Avalanche Diodes

Semiconductor photodiodes based upon avalanche gain provide a method to combine the high quantum efficiency of semiconductors with large output signals. Avalanche photodiodes (APDs) are operated at high reverse bias voltages and are designed such that an electric field capable of promoting avalanche multiplication is produced within the device. Those properties, important for common photodiodes used for scintillation detection, are also required for APDs: namely, high quantum efficiency, efficient photon absorption, good response speed and high energy conversion efficiency. Thus, properties mentioned earlier for common photodiodes also apply to APDs. Quantum efficiencies ranging from 50% to 80%, depending on the wavelengths of the scintillation photons, are typical for commercial Si APDs. Additionally, gain and electronic noise properties are important for APD applications. Typical gains exceeding 100 can be achieved; however, APDs are characteristically noisier than common *pn* and *pin* junction photodiodes.

Avalanche Gain

Electron-hole pair production from energetic electrons and holes are usually described by ionization coefficients $\alpha(\mathcal{E})$ for electrons and $\beta(\mathcal{E})$ for holes and are the probabilities, per unit differential path-length of travel, that the charge carrier undergoes an ionizing collision. Typically, for most semiconductors, $\alpha(\mathcal{E}) > \beta(\mathcal{E})$, although there are exceptions. For instance, in Ge $2\alpha \simeq \beta$, yet for Si $\alpha > \beta$ and for GaAs $\alpha \gg \beta$ [Melchior 1972].

Consider a *pin* APD with a depletion region $x \in (0, W)$ in which a current of holes $I_h(x)$ flows from holes injected at $x = 0$, which increases from $x = 0$ to $x = W$ as a result of impact ionizations. Likewise a current of electrons $I_e(x)$ is formed that increase from $x = W$ to $x = 0$. Under steady-state conditions the total current $I = I_h(x) + I_e(x)$ is constant, as is the electric field so that α and β are constant throughout the depletion region. In this case the following balance equation holds:

$$dI_h(x)/q_e \text{ (increase in holes at } x) = (I_h/q_e)(\beta\, dx) + (I_e/q_e)(\alpha\, dx) \text{ (no. e-h pairs produced in } dx \text{ per s)},$$

or, because $I_e(x) = I - I_h(x)$,

$$\frac{dI_h(x)}{dx} - (\beta - \alpha) I_h(x) = \alpha I. \tag{14.76}$$

The solution of this differential equation, subject to the initial condition $I = I_h(W) = M_h I_h(0)$ or $I_h(0) = I/M_p$ where M_p is the multiplication factor for holes,

$$I_h(x) = I \exp((\beta - \alpha)x) \left\{ \frac{1}{M_h} + \frac{\alpha}{\beta - \alpha} \left[1 - \exp(-(\beta - \alpha))x\right] \right\}. \tag{14.77}$$

Sze [1981] considered a more general model in which α and β are functions of position in the depletion region and obtained

$$I_h(x) = I \left\{ \frac{1}{M_h} + \int_0^x \alpha(x') \exp\left[- \int_0^{x'} [\beta(x'') - \alpha(x'')]\, dx'' \right] dx' \right\} \Bigg/ \exp\left[- \int_0^x [\beta(x') - \alpha(x')]\, dx' \right], \tag{14.78}$$

which reduces to Eq. (14.77) when α and β are constants.

The hole multiplication factor M_h (or rather its inverse) is readily found from Eq. (14.77) by setting $x = W$ and setting $I_h(W) = I$ and performing some algebraic manipulations to obtain

$$1 - \frac{1}{M_h} = \frac{\beta}{\beta - \alpha}[1 - e^{-(\beta - \alpha)W}]. \tag{14.79}$$

Because the avalanche breakdown voltage is the voltage at which M_h approaches infinity, the breakdown condition is found from Eq. (14.79) by setting $1/M_h$ to zero. This condition can be written as

$$1 = \frac{\beta}{\beta - \alpha}[1 - e^{-(\beta - \alpha)W}]. \tag{14.80}$$

If the avalanche process were initiated by electrons injected at $x = W$, the same breakdown condition is obtained [Sze 1981]. This is to be expected since breakdown depends only on what is happening in the depletion region and not on which charge carriers (or primary current) initiate the avalanche. In the limit as $\beta \to \alpha$ the multiplication factor of Eq. (14.79), which is the APD gain M_{APD}, has the limiting value

$$M_{APD} = \frac{1}{1 - \alpha W}. \tag{14.81}$$

Note that as the product αW approaches unity, the gain progresses towards ∞, a generally undesirable result for the operation of common APDs. This situation is referred to as avalanche breakdown. However, there is a practical limitation to M_{APD}, in which series resistance and space charges limit the overall gain. An empirical formulation for gain in the pre-breakdown region was reported as [Miller 1955],

$$M_{\text{APD}} = \frac{1}{1 - (V_R/V_B)^n}. \tag{14.82}$$

where V_B is the breakdown voltage, V_R is the reverse bias voltage, and n depends upon the semiconductor material and device structure. As V_R approaches V_B, Melchior and Lynch [1966] developed a description for gain under high light illumination,

$$M_{\text{APD}} = \left.\frac{1}{1 - (V_R - IR/V_B)^n}\right|_{V_R \to V_B} \simeq \frac{V_B}{nIR}, \tag{14.83}$$

where IR is the voltage drop due to series resistance. If the gain is defined as the total amplified (avalanche enhanced) current I_{av} divided by the total unamplified primary current I_h, then Eq. (14.83) reduces to [Sze 1981] $M_{\text{APD}} = \sqrt{V_B/(nI_hR)}$. Thus the amplified photocurrent is $I_{av} = I_h M_{\text{APD}} = \sqrt{I_h V_B/(nR)}$.

Overall, the APD is operated as a linear amplification device, in which the total current, or integrated charge, is taken to be a linear function of the energy of light absorbed. However, because the quantum efficiency for scintillation light is less than unity (less than one electron-hole pair per photon), the APD is actually measuring the number of photons that strike the diode and not the energy absorbed in the scintillation crystal. As with PMTs, it is assumed that the total number of photons striking the APD is a linear function of energy absorbed in the scintillation detector. This assumption is mostly true despite issues with non-linear light output for many scintillators. Hence, the magnitude of the output current gives a measure of the initial energy absorbed in the scintillation crystal.

APD Designs

Various configurations for avalanche photodiodes have been explored, of which three are shown in Fig. 14.34. Most commercial APDs are fabricated from Si, although APDs made from commercial low-noise InGaAs and designed for photon wavelengths between 1.0 and 1.6 μm are also available. The design of Fig. 14.34(a) is perhaps one of the simplest, relying upon a high electric field at the n^+p junction to produce the avalanching electric field. The guard ring reduces leakage current and early breakdown at the pn junction corners. The $p^+ - \pi - p - n^+$ "hi-lo" structure of Fig. 14.34(b) has a similar structure to that of a common IMPATT diode [Sze 1981]. The $p^+\pi$ region provides a lower field drift region, in which electrons drift towards the high electric field region defined at the pn^+ junction. The low doped π region allows the active depletion region to extend nearly completely across the diode. When electrons reach the high field region, an avalanche occurs and produces the device gain. The beveled sidewalls of the APD design in Fig. 14.34(c) reduce the surface electric field [Huth et al. 1966], thereby allowing a higher electric field within the semiconductor bulk to promote avalanche gain. Note that the high field region, defined by the $p^+\nu$ junction, is near the thin semiconductor window. The etched thin window reduces photon absorption losses in the "dead" surface region. Overall, there are a variety of other APD designs that can be used as sensors for scintillation detectors, some of which are described elsewhere [Melchior 1972; Sze 1981].

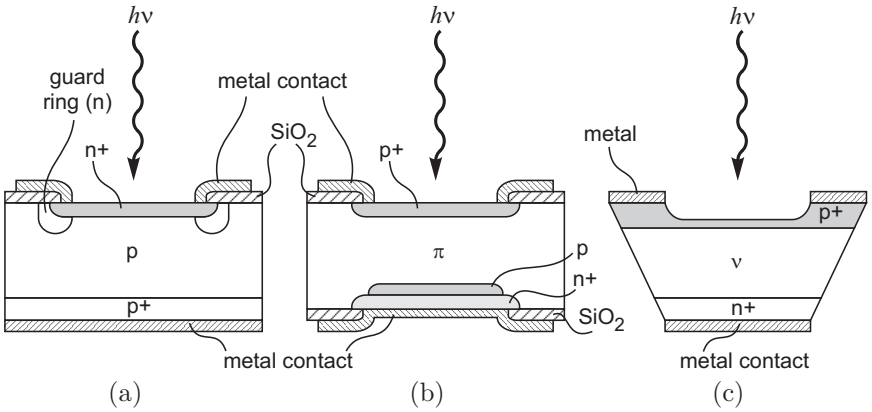

Figure 14.34. Avalanche photodiodes of three different designs: (a) a Si guard ring structure avalanche photodiode, (b) a $p^+ - \pi - p - n^+$ avalanche photodiode, and (c) a deep etched depletion avalanche photodiode with beveled sides.

Noise Factor

Ultimately, the desired feature of any photon detector is a proportional response to the total energy absorbed in the scintillation crystal attached to the detector. Hence, charge collected from an APD should be a linear measure of energy deposited in the scintillator, with an energy resolution defined by the variance of the output signal. Variations in the gain broaden the energy resolution of the scintillation light, and a non-linear output can make the energy calibration of the pulse height spectra difficult.

As developed in Sec. 10.5.4 for proportional counters, the avalanche process in an APD is statistical in nature. In other words, the amount of avalanching, and thus gain, for each electron is different, slight as it may be. Hence, the square of the average gain is not equal to the average gain squared but, rather the variance in the gain is

$$\sigma_M^2 = \langle M^2 \rangle - \langle M \rangle^2. \tag{14.84}$$

The "noise factor" is defined as

$$F = \frac{\langle M^2 \rangle}{\langle M \rangle^2}. \tag{14.85}$$

From Eqs. (14.84) and (14.85), the variance in the gain is

$$\sigma_M^2 = (F-1)\langle M \rangle^2. \tag{14.86}$$

Note that if the gain variance is zero, then $F = 1$.

The mean square shot noise current for a reverse biased pn junction is defined as

$$\langle i^2 \rangle = 2q_e I B, \tag{14.87}$$

where B is the bandwidth in Hz. If a uniform avalanche multiplication region exists, the differential mean square shot noise $\langle di^2 \rangle$ for the differential current dI generated within element dx at x is multiplied by the mean square gain at x, $\langle M^2(x) \rangle$, to yield

$$d\phi(x) = \frac{\langle di^2 \rangle}{B} = 2q_e \, d\, I(x) \langle M(x)^2 \rangle, \tag{14.88}$$

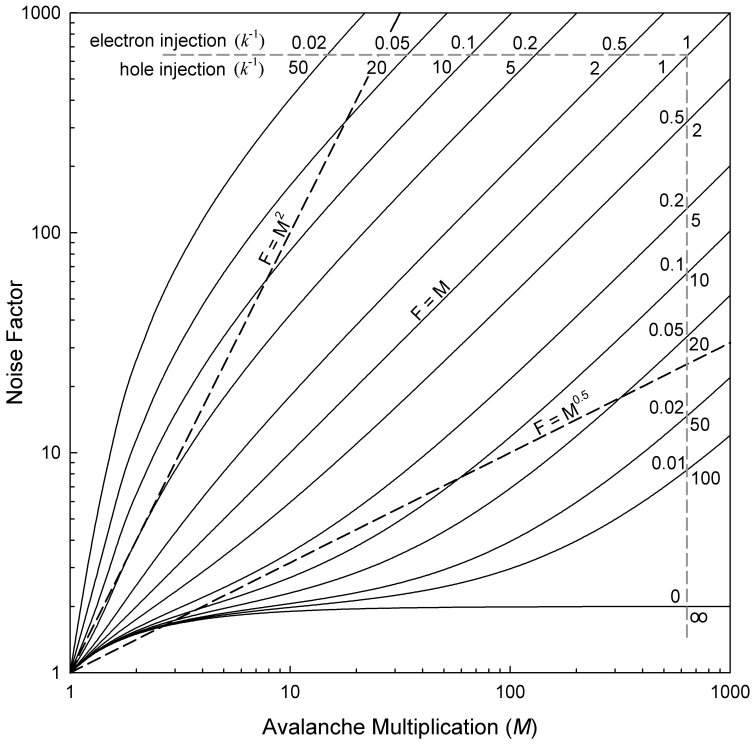

Figure 14.35. Noise factor as a function of gain M and the ratio α/β.

where ϕ is termed the "spectral density," and Eq. (14.87) represents a portion of the total mean square noise current. Integration of Eq. (14.87) yields the total noise contribution of the multiplication process. If $\beta = k\alpha$ (or $k^{-1} = \alpha/\beta$), where k is a scaling constant, and M is independent of x, McIntyre [1966] shows that the noise factors for electron and hole injection are

$$F_e = \frac{\phi}{2q_e I\langle M\rangle^2} = M\left[1-(1-k)\left(\frac{M-1}{M}\right)^2\right] \quad \text{and} \quad F_h = \frac{\phi}{2q_e I\langle M\rangle^2} = M\left[1+\frac{(1-k)}{k}\left(\frac{M-1}{M}\right)^2\right]. \tag{14.89}$$

The results from Eqs. 14.89 for several M and α/β are plotted in Fig. 14.35. In the case that $\alpha = \beta$, or $k = 1$, then both Eqs. 14.89 reduce to $F = \langle M\rangle$. For the case of electron injection, in which holes play no part in the avalanche process ($\beta = 0$), Eq. (14.89) reduces to,

$$F_e = \left(\frac{2M-1}{M}\right). \tag{14.90}$$

This result reduces to $F_e \simeq 2$ as $M \to \infty$. A similar result is achieved if holes play the major part in the avalanche current and electrons do not contribute to the avalanche.[15]

[15] Hence, $k^{-1} \to 0$, as shown in Fig. 14.35.

14.2.4 Semiconductor Photomultipliers

Junction breakdown of semiconductors can be used as another means of radiation counting and spectroscopy. For any *pn* junction operated with a reverse bias voltage, there is a voltage above which the junction "breaks down" and continues to conduct current across the semiconductor. This phenomenon is initiated by three different means, namely (1) thermal instabilities, (2) tunneling current, and (3) avalanche breakdown.

Here it is avalanche breakdown that is of interest. Avalanche breakdown occurs when Eq. (14.78) is satisfied. Should $\alpha = \beta$, then the breakdown condition is achieved when $\int_0^W \alpha(x)\,dx = 1$. The critical electric field required to sustain the avalanche condition is $\mathcal{E}_A = 2V_B/W$, where V_B is the breakdown voltage [Sze 1981].

The avalanche process is solely dependent upon what occurs within the depletion region W. Hence, an event that excites a charge carrier within the active depletion region may trigger an enormous, continuous avalanche from impact ionization with gains exceeding 10^6. This interesting mode of operation is usually not preferred for APD operation, the effects of which were studied by McIntyre [1961] and Haitz [1961].

However, there are particular applications in which the breakdown mode of operation is beneficial, mainly realized with the single-photon avalanche diode (SPAD), so-named because of its ability to detect low light levels, one photon at a time. The leading edge of an avalanche signal marks the arrival time of the interacting photon within the depletion region, and SPADs with 28 ps timing resolution at room temperature have been reported [Cova et al. 1989]. After the avalanche is triggered, the self-sustained current continues to flow unless quenched. Often a series resistance is included in the design that serves to quench the avalanche, much like an externally quenched GM counter. As a matter of fact, APDs designed and operated in this mode are often said to operate in "Geiger Mode" [Renker 2006]. As the avalanche current flows through the quenching resistance, it draws voltage from the source, thereby causing the voltage across the APD to drop below the breakdown voltage, causing the avalanche to cease. As a result, the output current and collected charge are nearly the same for each avalanche regardless of energy deposition in the device, statistical fluctuations notwithstanding. Consequently, if two or more photons interact in the device simultaneously, the total charge liberated from the quenched avalanche is roughly the same as if a single photon caused the avalanche, again much like a GM counter.

Silicon photomultipliers (SiPM)[16] use the breakdown condition with thousands of tiny silicon APDs arranged into a compact array, presently on the order of 6 mm × 6 mm area or less. The individual APDs in silicon photomultipliers (SiPM) have linear dimensions usually between 20 μm and 100 μm, a common size is 35 μm × 35 μm per APD pixel. Hence a single SiPM array may have more than 10^4 APD pixels. Each APD is electrically decoupled from adjacent APDs with polysilicon resistors fabricated on the same substrate. Typical operational bias voltage is 10% to 15% above the breakdown voltage. A scintillator may be fastened to the SiPM face, much like a conventional PMT, and light from radiation interactions within the scintillator triggers the APDs. Each APD provides information that is ultimately limited to recognizing the excitation of an electron-hole pair within the avalanche region. Because each pixel produces an avalanche of relatively the same magnitude per event, the total photon count can be determined by dividing the total measured charge by the avalanche gain. Hence, the device operates mainly as a photon counter, and the total measured current is proportional to the total number of photons. The enormous gain per pixel, when the pixel counts are added together, can produce more than 10^9 free electrons per event. Properties of commercially available SiPMs are given in Table 14.9.

General SiPM Characteristics

A particular advantage of SiPMs is the high quantum efficiency of Si for photons with wavelengths between 350 nm and 950 nm. The increased probability of absorption of scintillation photons, in the active volume of

[16] Also called multi-pixel photon counters (MPPC).

Table 14.9. Properties of some commercial silicon photomultipliers. The legend abbreviations are as follows: A manufacturer (H Hamamatsu, K Ketek, S SensL); B model; C SiPM chip size (x mm $\times$ x mm); D microcell pixel size (x μm $\times$ x μm); E number of microcells; F microcell fill factor (%); G gain at room temperature $\times 10^6$; H breakdown voltage, VBr (volts); I bias range above VBr (volts); J peak wavelength (nm); K maximum photon detection efficiency (%) at peak wavelength and max voltage; L dark count rate (kHz); M signal rise time (ns); N signal pulse width (FWHM in ns); O microcell recovery time (ns); P VBr temperature drift (mV/°C); and Q gain drift (%/°C). Non-reported table entries are indicated by NR.

the APD, is a clear advantage of the SiPM when compared to the smaller absorption probabilities in PMT semitransparent photocathodes or PMT reflective photocathodes. Hence, the photon detection efficiency of a SiPM can be much higher than that of a common PMT. However, many commercial SiPM units usually have a peak sensitivity near 420 nm, much like that of conventional bialkali PMTs. SiPMs are compact and rugged, which allows them to be fabricated as compact instruments and dosimeters. This compactness is perhaps one of the most useful features of SiPMs compared to vacuum tube PMTs. Further, they need only modest power, usually requiring no more than a few tens of volts for operation, which is substantially less than that needed for a PMT. SiPMs are also insensitive to magnetic fields, thereby making them an attractive choice for applications in areas where high magnetic fields may arise. Typically, the total array of APDs in the SiPM has an extremely fast rise time, between 0.3 and 1 ns. However, the actual recovery time

required for the SiPM is much longer and usually ranges from a few tens of ns up to 400 ns, depending on the pixel and array sizes. Hence, the rise times and count rates are comparable to conventional PMTs.

Presently the cost of a single SiPM array chip is modest, yet these devices range in area from only 1 mm $\times$ 1 mm up to 6 mm $\times$ 6 mm. Such small light detectors might be adequate for small projects and compact scintillation applications. However, to cover the same area as a 3-inch diameter bialkali PMT, typically used for scintillation spectroscopy, a minimum of 127 SiPM chips are needed, if the larger 6 mm $\times$ 6 mm chips are used. Commercially available SiPM arrays are available, presently with a maximum size of 6 mm $\times$ 6 mm chips arranged in an 8×8 array that has the equivalent area of a two-inch diameter PMT. At the time of writing, the cost of such an array is considerably higher than the PMT counterpart. However, commercial scintillation detector units have recently become available with a SiPM readout option.

Unlike a PMT photocathode, SiPMs have regions between the diodes that are insensitive to illumination. The ratio of the sensitive area to the total area is termed the "fill factor." Modern commercial units have fill factors ranging between about 30% to 70%. As fill factor increases, the possibility of cross talk between pixels also increases. Cross talk may manifest itself as photon emissions from de-exited electrons, and their subsequent absorption in adjacent pixel cells. Hence, a photon emitted in one pixel cell can trigger an avalanche in an adjacent cell. One method proposed to reduce this effect is the incorporation of etched trenches between the pixels. The trenches are then backfilled with an opaque material [Piemonte 2006]. However, if de-excitation photons are emitted from a pixel cell and towards the scintillator, it is also possible that they are subsequently reflected into a different pixel cell, thereby triggering an unwanted avalanche. Cross talk for commercial SiPMs ranges between $< 1\%$ to 35% and generally increases with the sizes of pixel cell and the array.

Another minor problem with APDs is the possibility of stray avalanches arising from the emission of charge carriers from trapping sites, an effect referred to as "afterpulsing". Electrons and holes flowing in the APD can become trapped in impurity and defect centers and are later emitted from the traps with a time constant, which strongly depends on the energy level of the trap. Whenever they are emitted, the detrapping of these charge carriers can trigger another avalanche, which may be included in the overall measurement of the initial scintillation event, thereby overestimating the light yield. Afterpulsing for commercial SiPMs ranges between 0.2% and 0.6%.

It is also possible that more than one photon strikes a pixel simultaneously (or at least within the pixel recovery time), so that only one of the photons is recorded. The compact pixel arrays are designed such that simultaneous interactions are relatively improbable, usually with negligible effect on performance. However, as the total light fluence from a scintillation event increases, and the decay time of the scintillator decreases, the probability of nearly simultaneous absorptions increases. Consequently, the measured current underestimates the measured light, producing non-linearity in the output spectrum. As the light intensity increases, the SiPM output becomes increasingly disproportionate to the number of scintillation photons produced.

A breakdown avalanche can also be triggered by thermally generated charge carriers and thus can cause problematic background count rates. The dark current, and count rate, from thermal excitation can be relatively large, ranging from 3×10^4 cps to 3×10^6 cps for commercial units and increases with pixel size and SiPM array size. This problem can be greatly mitigated by operating the device at reduced temperatures. Further, randomly triggered events ultimately produce an avalanche from a single pixel, which produces a substantially lower current than expected from a scintillation flash. Unless the device is being operated as a single photon detector for a low level light source, the use of a discriminator set at a reasonable threshold helps defeat this problem.

PROBLEMS

1. A NaI(Tl) crystal is coupled to a PMT having a Corning 7044 borosilicate window. The coupling compound Dow-Corning Q2-3067 has an index of refraction of 1.48. At the peak wavelength, determine the critical angle in the NaI(Tl) crystal for light passing through to the photocathode layer in the PMT.

2. Determine the value of $\tau(\lambda)$ for borosilicate glass and LiF at the wavelengths of 300 nm and 400 nm.

3. If there are no window absorption losses and the reflectance $R(\lambda)$ is small, show from Eqs. (14.10) and (14.11) that the total transmittance for a glass PMT window is described by

$$T(\lambda) = \frac{(1 - R(\lambda))^2}{1 - R^2(\lambda)} \simeq \frac{2n(\lambda)}{n(\lambda)^2 + 1}.$$

where one interface is surrounded by air and the other interface is at vacuum.

4. Determine the free electron concentration for Li, Na, K, Rb and Cs at absolute zero.

5. Determine the thermionic emission current density for a S-11 response PMT at a temperature of 32°C and compare it to that of a S-24 response PMT.

6. Determine the electron cutoff energy for the peak wavelength emission from a $LaBr_3$ detector coupled to a pure $CsSb_3$ photocathode. Repeat for a Na_2KSb photocathode.

7. Show that Eq. (14.37) can be cast into the form Eq. (14.38). Hint: Start with the substitution $y(x) \equiv E(x)$.

8. Given a 10-stage PMT with $\alpha = 0.72$ and a gain of 10^6 at 700 volts, find the value of k. What is the new gain if the voltage is increased to 800 volts?

9. The dark current from a PMT with an electron gain of 5×10^5 is measured to be 1.5 mA. What is the corresponding emission rate of electrons from the photodiode?

10. A $LaBr_3$:Ce detector is coupled to a PMT having a KCs photocathode in a borosilicate envelope. The detector is being used to detect gamma rays from a ^{137}Cs source. With 90% light impinging on the glass interface at all angles, determine the output charge from full energy absorption with a 10-stage PMT having the following properties: $\eta_i = 0.98$, $\eta_a = 0.98$, $\delta_i = 4$ for the first 5 stages, and $\delta_i = 3.8$ for the last five stages.

11. What are the advantages of using a microchannel PM tube compared to one of conventional design?

[17] Interestingly, there is no "Part I" by G.A. Morton. In the beginning of the article, Morton mentions this paper as being added to the story written by R.A. Hofstadter which was published directly before this work in *IEEE Trans. Nucl. Sci.*, NS-22, 13–25, (1975a). Hence, this reference is "Part II" to the story begun by Hofstadter.

Chapter 15

Basics of Semiconductor Detector Devices

It has today occurred to me that an amplifier using semiconductors rather than vacuum is in principle possible.

William Shockley

15.1 Introduction

Semiconductors are much better for energy spectroscopy than are gas-filled or scintillation detectors because semiconductors have vastly superior energy resolution. This improved resolution is largely due to the better statistics caused by the larger numbers of signal carriers (charges) produced by a radiation interaction. On average, it takes only 3 to 5 eV to produce an electron-hole pair in a semiconductor. By comparison, it takes between 25 and 40 eV to produce an electron-ion pair in a gas-filled detector and between 100 eV and 1 keV to produce a single photoelectron ejection from the photocathode of a photomultiplier tube (PMT) in a scintillation/PMT detector, a consequence of light reflections and poor quantum efficiency at the photocathode. Hence, a semiconductor produces considerably more charge carriers from the primary ionization event and, thereby reduces the statistical fluctuations in the energy resolution.

Semiconductor radiation detectors have many different shapes, sizes, and configurations, yet there are some basic designs that, in some form or another, can be attributed to practically all semiconductor radiation detectors. These basic designs include *pn*-junction diodes, *pin*-junction diodes, Schottky diodes, resistive detectors, and photoconductors. The vast field of semiconductor device physics is much too large to describe in a single book chapter. As a result, only those concepts needed to understand basic detector operations and characteristics are offered here.

The general purpose of this text is to familiarize the reader with various aspects of radiation detectors so that the skills to design, fabricate, characterize, and deploy such devices are acquired. Proficiency in detector design and fabrication requires an understanding of basic solid state and semiconductor physics, hence the reason for the preceding and present chapters. In this chapter, the basic physics used to make semiconductors into radiation detectors is summarized. In this chapter much of the notation introduced in Chapter 12 is used extensively without any further explanation. Finally, values of the many physical constants used here and in other chapters are tabulated in Appendix A.

15.2 Charge Carrier Collection

Charge carriers in the conduction band spontaneously drop back into empty states in the valence band, while, at the same time, other electrons gain energy to cross the band gap. Overall, a somewhat constant density of electrons and holes remains in the conduction and valence bands, respectively. The time over which a charge carrier remains in either band is altered by impurity and defect states that appear in the band gap.

These traps and defects increase the probability of electrons or holes moving from either band edge to an intermediate state before completing the recombination process. If a charge carrier falls into a defect state, it is referred to as "trapped"; whereas, if the charge carrier's journey is completed, e.g., an electron falls completely back into a hole in the valence band, it is referred to as having "recombined". The average time over which an excited electron remains in the conduction band before being trapped or recombining is the *electron lifetime* τ_e. Similarly, the average time in which a hole remains in the valence band before being trapped or recombining is the *hole lifetime* τ_h.

15.2.1 Charge Carrier Generation, Recombination and Injection

The concentration of charge carriers in the conduction and valence bands of a semiconductor is temperature dependent. As the population of electrons and holes increases, the probability that electrons return to the valence band and recombine with holes also increases. The overall process reaches a thermal equilibrium, in which $np = n_i^2$.

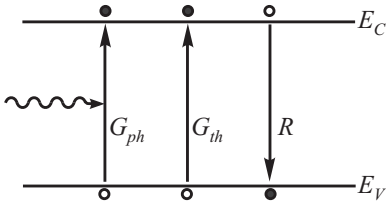

Figure 15.1. Thermal generation G_{th}, photo-generation G_{ph}, and recombination R of electron-hole pairs across the band gap of a semiconductor.

Other sources of energy deposition, such as the photoelectric effect, can excite charge carriers from the valence band into the conduction band (see Fig. 15.1). The introduction of these extra charge carriers is commonly referred to as charge carrier *injection*, and produces a non-equilibrium condition in the semiconductor. The continuous constant injection of charge may reach a steady-state, but the semiconductor cannot reach its equilibrium until the source of the charge injection is stopped. Semiconductor radiation detectors rely upon the charge injection process to excite electron-hole pairs, in which the deposition of radiation energy in the semiconductor produce excess electron and hole populations, Δn and Δp, thereby producing the condition $np > n_i^2$. These excess charge carriers can be measured to indicate the presence, and often energy, of the radiation particles interacting in the semiconductor.

15.2.2 Radiative Recombination

Consider a semiconductor material, initially at equilibrium, that has a package of charge Δn injected into the bulk material. Because these charges are excited from the valence band, an equal package of excess holes Δp appears in the valence band. Let the recombination rate with an excess of electrons be $r_n(n, p)$ and the equilibrium recombination rate be $r_n(n_o, p_o)$, in which the notation n_o and p_o are used for the equilibrium electron and hole concentrations. The change in electron recombination rate from the equilibrium case after charge injection is

$$R_n = r_n(n, p) - r_n(n_o, p_o). \tag{15.1}$$

Likewise, for hole recombination,

$$R_p = r_p(n, p) - r_p(n_o, p_o). \tag{15.2}$$

The electron lifetime is defined as the excess electron concentration divided by the change in recombination rate, i.e.,

$$\tau_n = \frac{n - n_o}{R_n} = \frac{\Delta n}{R_n} \tag{15.3}$$

and the hole lifetime is

$$\tau_p = \frac{p - p_o}{R_p} = \frac{\Delta p}{R_p}. \tag{15.4}$$

Radiative electron recombination refers to a direct transition from the conduction band to the valence band, during which a photon is released by the de-excitation of the electron. This process can occur only

if a hole is available to complete the recombination process. Hence, the recombination rate is proportional to the product of electron and hole concentrations, i.e., $r_n = r_p = \beta np$, where β is an empirical, radiative-recombination, proportionality constant. From Eq. (15.1), the change in electron recombination after carrier injection becomes

$$R_n = R_p = \beta(np - n_i^2). \tag{15.5}$$

Because $\Delta n = \Delta p$, τ_n must equal τ_p. Substitution of Eq. (15.5) into Eq. (15.3) yields

$$\tau_n = \tau_p = \frac{n - n_o}{\beta(np - n_i^2)} = \frac{\Delta n}{\beta([n_o + \Delta n][p_o + \Delta n] - n_i^2)} = \frac{1}{\beta(n_o + p_o + \Delta n)}. \tag{15.6}$$

Here the equilibrium condition $n_o p_o = n_i^2$ has been invoked. This result shows that radiative recombination is inversely proportional, in all circumstances, to the total concentration of charge carriers.

15.2.3 Shockley-Read-Hall Recombination

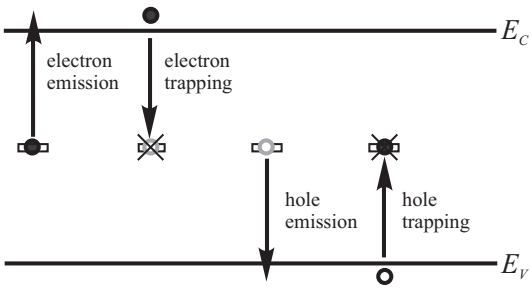

Figure 15.2. Shockley-Read-Hall recombination depicting electrons and holes emitted and trapped in energy states arising from material imperfections.

Material imperfections often introduce energy states or traps in the band gap that, in turn, can participate in the recombination process. Typically, this trap-assisted recombination, known as *Shockley-Read-Hall* (SRH) recombination, is more likely to occur than are direct radiative transitions (see arguments in Shockley and Read [1952], Hall [1952, 1959] and Varshni [1967]). The processes of SRH trapping are illustrated in Fig. 15.2.

Consider a concentration of imperfections in a semiconductor with trapping states at energy E_T. These trapping sites may arise from native defects, such as anti-sites, voids and interstitials, or may result from impurities in the material. The probability that an electron is captured by an electron trap at energy E_T is a function of the *unfilled* trap density N_T and the electron population n, with capture rate

$$R_{cn} = n\beta_{cn}N_T[1 - f_{\mathcal{FD}}(E_T)] = \frac{n\beta_{cn}N_T}{1 + \exp\left[\dfrac{E_F - E_T}{kT}\right]}, \tag{15.7}$$

where β_{cn} is a proportionality constant for electron capture. For those traps that are occupied by an electron, the rate at which electrons are emitted into the conduction band is

$$R_{en} = \beta_{en}N_T f_{\mathcal{FD}}(E_T) = \frac{\beta_{en}N_T}{1 + \exp\left[\dfrac{E_T - E_F}{kT}\right]}, \tag{15.8}$$

where β_{en} is a proportionality constant for electron emission.

At equilibrium, the rate at which electrons arrive in the conduction band must be equal to the rate at which they are captured from the conduction band, i.e.,

$$\beta_{en} = \beta_{cn}n_o\frac{[1 - f_{\mathcal{FD}}(E_T)]}{f_{\mathcal{FD}}(E_T)} = \beta_{cn}n_o \exp\left[\frac{E_T - E_F}{kT}\right]. \tag{15.9}$$

where n_o is the equilibrium electron concentration. For a non-degenerate semiconductor, n_o is described by Eq. (12.126), which when substituted into Eq. (15.9) gives

$$\beta_{en} = \beta_{cn} N_C \exp\left[\frac{E_T - E_C}{kT}\right]. \tag{15.10}$$

In the case that the trap energy E_T is equal to E_F

$$\beta_{en} = \beta_{cn} N_C \exp\left[\frac{E_F - E_C}{kT}\right] = \beta_{cn} n_1, \tag{15.11}$$

where n_1 is the electron concentration in the conduction band *if* $E_F = E_T$. The net rate R_n at which electrons are captured from the conduction band is the difference between Eq. (15.7) and Eq. (15.8), so that with Eq. (15.10) one obtains

$$R_n = R_{cn} - R_{en} = \beta_{cn} N_T \{n[1 - f_{\mathcal{FD}}(E_T)] - n_1 f_{\mathcal{FD}}(E_T)\}. \tag{15.12}$$

In the same manner used above for electrons, the rate at which holes are captured from the valence band into traps or, equivalently the rate at which traps are filled with electrons is

$$R_{cp} = p\beta_{cp} N_T f_{\mathcal{FD}}(E_T) = \frac{p\beta_{cp} N_T}{1 + \exp\left[\dfrac{E_T - E_F}{kT}\right]}, \tag{15.13}$$

where β_{cp} is the proportionality constant for hole capture. The rate at which holes are emitted from the trap as electrons move from the valence band into the traps is

$$R_{ep} = \beta_{ep} N_T [1 - f_{\mathcal{FD}}(E_T)] = \frac{\beta_{ep} N_T}{1 + \exp\left[\dfrac{E_F - E_T}{kT}\right]}, \tag{15.14}$$

where β_{ep} is the proportionality constant for hole emission. Making the emission and capture rates equal yields,

$$\beta_{ep} = \beta_{cp} p_o \frac{f_{\mathcal{FD}}(E_T)}{[1 - f_{\mathcal{FD}}(E_T)]} = \beta_{cp} p_o \exp\left[\frac{E_F - E_T}{kT}\right]. \tag{15.15}$$

At equilibrium, the hole capture and emission rates must be equal and the hole concentration in the conduction band is p_o. Substitution of Eq. (12.128) for p_o into Eq. (15.15), the emission rate for holes is found to be

$$\beta_{ep} = \beta_{cp} N_V \exp\left[\frac{E_V - E_T}{kT}\right]. \tag{15.16}$$

If the trap energy E_T is equal to E_F

$$\beta_{ep} = \beta_{cp} N_V \exp\left[\frac{E_V - E_F}{kT}\right] = \beta_{cp} p_1. \tag{15.17}$$

where p_1 is the hole concentration in the valence band at $E_F = E_T$. The net rate at which holes are captured from the valence band is the difference between Eq. (15.13) and Eq. (15.14), and with $\beta_{ep} = \beta_{cp} p_1$ from Eq. (15.17),

$$R_p = R_{cp} - R_{ep} = \beta_{cp} N_T \{p f_{\mathcal{FD}}(E_T) - p_1[1 - f_{\mathcal{FD}}(E_T)]\}. \tag{15.18}$$

Unlike pure radiative recombination, with carrier injection, it is quite possible that $\Delta n \neq \Delta p$, mainly because the carrier capture coefficients for electrons and holes may be quite different. This issue becomes more important as the trap density in a semiconductor increases. For the following derivation, however, it is assumed that the trap density is relatively low so that, even in the non-equilibrium condition, $\Delta n \simeq \Delta p$. Hence, Eq. (15.12) and Eq. (15.18) are equal. Equating the right-hand sides of Eq. (15.12) and Eq. (15.18) and solving for $f_{\mathcal{FD}}(E_T)$ one obtains

$$f_{\mathcal{FD}}(E_T) = \frac{\beta_{cp} p_1 + \beta_{cn} n}{\beta_{cn}(n + n_1) + \beta_{cp}(p + p_1)}. \tag{15.19}$$

Substitute this result into either Eq. (15.12) or Eq. (15.18) to find

$$R_n = R_p = \frac{\beta_{cn}\beta_{cp} N_T (pn - n_i^2)}{\beta_{cn}(n + n_1) + \beta_{cp}(p + p_1)}, \tag{15.20}$$
