in which it is recognized that $n_1 p_1 = n_i^2$. Division of the numerator and denominator of Eq. (15.20) by $\beta_{cn}\beta_{ce}N_T$ gives

$$R_n = R_p = \frac{pn - n_i^2}{\dfrac{1}{\beta_{cp}N_T}(n + n_1) + \dfrac{1}{\beta_{cn}N_T}(p + p_1)}. \tag{15.21}$$

Finally, define the trapping time for electrons as $\tau_n = 1/(\beta_{cn}N_T)$ and the trapping time for holes as $\tau_p = 1/(\beta_{cp}N_T)$, and substitute these definitions into Eq. (15.22) to obtain the general expression for SRH recombination rates, namely

$$\boxed{R_n = R_p = \frac{pn - n_i^2}{\tau_p(n + n_1) + \tau_n(p + p_1)}.} \tag{15.22}$$

Note that at equilibrium $np = n_i^2$ and Eq. (15.22) at the net recombination rate is zero.

15.2.4 Equations of Continuity

In a semiconductor, even in non-steady-state conditions, the hole generation rate must always equal the electron generation rate, i.e., $g_n = g_p$. Similarly, the hole and electron recombination rates must always be equal, i.e., $n/\tau_n = p/\tau_p$. The generation rates, carrier concentrations and lifetimes are, generally, functions of position $\mathbf{r}$ in the crystal and time.

In this section the continuity equations that determine the free electron concentration $n(\mathbf{r}, t)$ and the hole concentration $p(\mathbf{r}, t)$ are developed. Begin by first considering the free electrons in a small but arbitrary volume V of a semiconductor. In this volume, the following balance relation must apply:

$$\left\{\begin{array}{l}\text{the net}\\ \text{rate of}\\ \text{increase in}\\ V \text{ of free}\\ \text{electrons}\end{array}\right\} = \left\{\begin{array}{l}\text{generation}\\ \text{rate in } V\\ \text{of free}\\ \text{electrons}\end{array}\right\} - \left\{\begin{array}{l}\text{rate of recom-}\\ \text{bination of}\\ \text{electrons with}\\ \text{holes in } V\end{array}\right\} - \left\{\begin{array}{l}\text{rate at which}\\ \text{free electrons}\\ \text{flow out of } V\\ \text{through the}\\ \text{surrounding}\\ \text{surface } S\end{array}\right\}. \tag{15.23}$$

In symbols, this balance relation is written as

$$\int_V dV\, \frac{\partial n}{\partial t} = \int_V dV\, g_n - \int_V dV\, \frac{n}{\tau_n} - \int_S dS\, \mathbf{J}_n \bullet \hat{\mathbf{n}}, \tag{15.24}$$

where dS is a differential element of the surface with outward normal $\hat{\mathbf{n}}$ and $\mathbf{J}_n(\mathbf{r},t)$ is the current vector, i.e., the flow rate of free electrons across a unit area perpendicular to $\mathbf{J}_n$.

The last term in Eq. (15.24) can be written as a volume integral by use of Gauss's theorem, namely

$$\int_S dS\, \mathbf{J}_n \bullet \hat{\mathbf{n}} = \int_V dV\, \boldsymbol{\nabla} \bullet \mathbf{J}_n. \tag{15.25}$$

With this result, all the terms in Eq. (15.24) can be combined into a single integral, namely

$$\int_V dV \left\{ \frac{\partial n}{\partial t} - g_n + \frac{n}{\tau_n} + \boldsymbol{\nabla} \bullet \mathbf{J}_n \right\} = 0. \tag{15.26}$$

But V is arbitrary, and the only integrand that integrates to zero for arbitrary integration limits is the zero integrand. Hence the balance condition is

$$\frac{\partial n}{\partial t} = -\boldsymbol{\nabla} \bullet \mathbf{J}_n + g_n - \frac{n}{\tau_n}. \tag{15.27}$$

A similar derivation can be made to derive a balance relation for the hole concentration $p(\mathbf{r},t)$. The result is

$$\frac{\partial p}{\partial t} = -\boldsymbol{\nabla} \bullet \mathbf{J}_p + g_p - \frac{p}{\tau_n}. \tag{15.28}$$

Equations (15.27) and (15.28) are often referred to as the *continuity* equations.

Before these equations can be used to find $n(\mathbf{r},t)$ and $p(\mathbf{r},t)$, the hole and electron current vectors must be written in terms of the concentrations. This can be done by writing $\mathbf{J}_n$ and $\mathbf{J}_p$ as a sum of a current from a diffusion process and a drift current caused by an electric field $\boldsymbol{\mathcal{E}}$.[1] In the diffusion process, charge carriers are assumed to flow away from regions of higher concentration according to Fick's law.[2] The currents of the free electrons and holes are written as

$$\mathbf{J}_n = -D_n \boldsymbol{\nabla} n - n\mu_n \boldsymbol{\mathcal{E}}, \tag{15.29}$$

$$\mathbf{J}_p = -D_p \boldsymbol{\nabla} p + p\mu_p \boldsymbol{\mathcal{E}}, \tag{15.30}$$

where μ_n is the electron mobility and μ_p is the hole mobility. The diffusion coefficients can be evaluated in terms of mobilities as [McKelvey 1966]

$$D_n = \frac{\mu_n kT}{q_e} \qquad \text{and} \qquad D_p = \frac{\mu_p kT}{q_e}, \tag{15.31}$$

which are often called the Einstein relationships.

Substitution of Eqs. (15.29) and (15.30) into Eqs. (15.27) and (15.28) gives

$$\frac{\partial n}{\partial t} = D_n \nabla^2 n + \mu_n \boldsymbol{\nabla} \bullet (n\boldsymbol{\mathcal{E}}) + g_n - \frac{n}{\tau_n}, \tag{15.32}$$

$$\frac{\partial p}{\partial t} = D_p \nabla^2 p - \mu_p \boldsymbol{\nabla} \bullet (p\boldsymbol{\mathcal{E}}) + g_p - \frac{p}{\tau_p}. \tag{15.33}$$

[1] It is assumed here that there are negligible magnetic fields.

[2] This is analogous to Fourier's law of heat conduction, in which heat energy flows away from regions at higher temperature into regions of lower temperature. Thus, free electrons flow, as a result of their random thermal motion, in the opposite direction of the electron density's greatest rate of increase, i.e., $\mathbf{J}_n = -D_n \boldsymbol{\nabla} n$, where D_n is the *diffusion coefficient*.

The drift terms in these continuity equations can be put into a more tractable form by use of the vector identity

$$\boldsymbol{\nabla}\bullet(n\boldsymbol{\mathcal{E}}) = \boldsymbol{\mathcal{E}}\bullet\boldsymbol{\nabla}n + n\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}}. \tag{15.34}$$

Finally, it is convenient to express the generation rate (g_n or g_p) as the sum of the thermal generation rate (g_{on} or g_{op}) plus the rate at which the carriers are produced in excess of the thermal generation rate (g'_n or g'_p), i.e.,

$$g_n = g_{on} + g'_n \qquad \text{and} \qquad g_p = g_{op} + g'_p. \tag{15.35}$$

With these alterations, the continuity equations assume the form

$$\boxed{\begin{aligned} \frac{\partial n}{\partial t} &= D_n\nabla^2 n + \mu_n(\boldsymbol{\mathcal{E}}\bullet\boldsymbol{\nabla}n + n\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}}) + g'_n - \left(\frac{n}{\tau_n} - \frac{n_o}{\tau_n}\right) \\ \frac{\partial p}{\partial t} &= D_p\nabla^2 p - \mu_p(\boldsymbol{\mathcal{E}}\bullet\boldsymbol{\nabla}p + p\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{E}}) + g'_p - \left(\frac{p}{\tau_p} - \frac{p_o}{\tau_p}\right) \end{aligned}} \tag{15.36}$$

An Example of the Use of the Continuity Equation: Consider the case in which charge is injected, continuously at a constant rate, into the end of a semiconductor block without an electric field present, as depicted in Fig. 15.3. Eventually, the distribution of free electrons assumes a steady-state distribution along the length of the semiconductor. The one-dimensional, steady-state form of Eq. (15.36), with $\boldsymbol{\mathcal{E}} = 0$, gives the following equation for the right-hand portion of the semiconductor in which no charge is injected ($g'_n = 0$).

$$D_n\frac{d^2n(x)}{dx^2} - \frac{n(x) - n_o}{\tau_n} = 0. \tag{15.37}$$

The general solution for $n(x) - n_o$ is

$$n(x) - n_o = \Delta n(x) = C_1\exp\left[\frac{x}{\sqrt{D_n\tau_n}}\right] + C_2\exp\left[\frac{-x}{\sqrt{D_n\tau_n}}\right], \tag{15.38}$$

where C_1 and C_2 are arbitrary constants and $\sqrt{D_n\tau_n}$ is the electron diffusion length L_n. Application of the boundary conditions that as $x \to \infty$ $n(x,t)$ must remain finite implies C_1 must be zero. So in the right-hand portion of the semiconductor the electron density must vary as

$$n(x) = n_o + C_2\exp\left[\frac{-x}{\sqrt{D_n\tau_n}}\right], \tag{15.39}$$

where C_2 depends on $n(x)$ in the injection region. At the location $x = 0$, the injected charge is Δn, so that

$$n(x) = n_o + \Delta n\exp\left[\frac{-x}{\sqrt{D_n\tau_n}}\right], \tag{15.40}$$

from which the injected electron population is seen to exponentially decrease with x.

In a similar fashion, if holes are injected into the left-hand end of the semiconductor. The steady-state hole density $p(x)$ in the right portion of the semiconductor where there is no charge injection is the solution of

$$D_p\frac{d^2p(x)}{dx^2} - \frac{p(x) - p_o}{\tau_p} = 0. \tag{15.41}$$

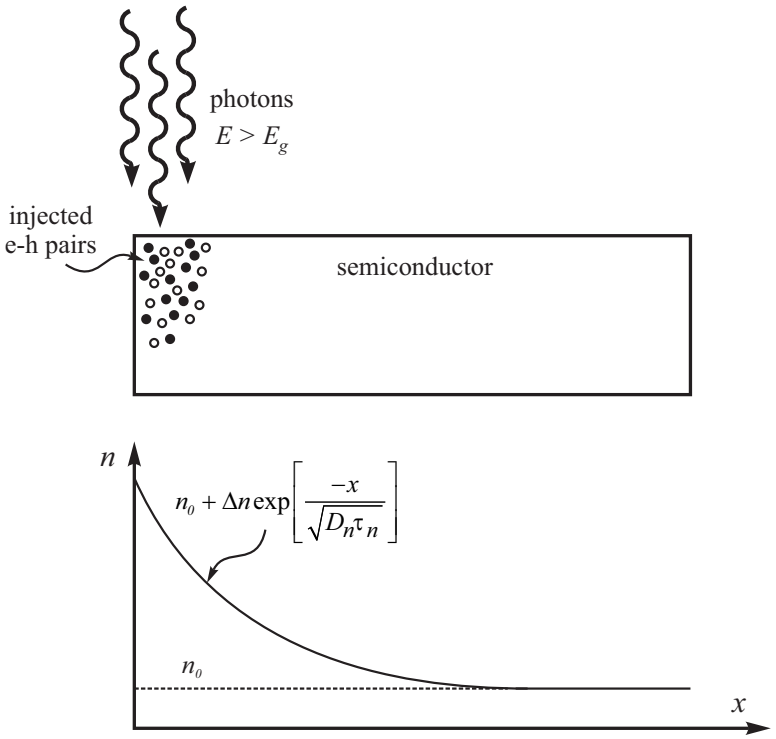

Figure 15.3. Electron-hole pairs can be injected through the photoelectric effect. Their population decreases through recombination as they diffuse through the semiconductor.

The general solution for $p(x) - p_o$ is

$$p - p_o = \Delta p(x) = C_3 \exp\left[\frac{x}{\sqrt{D_p \tau_p}}\right] + C_4 \exp\left[\frac{-x}{\sqrt{D_p \tau_p}}\right], \tag{15.42}$$

where again C_3 and C_4 are arbitrary constants and $\sqrt{D_p \tau_p}$ is the hole diffusion length L_p. Because p must remain finite as $x \to \infty$, C_3 must vanish so the solution to the present problem is

$$p(x) = p_o + C_4 \exp\left[\frac{-x}{\sqrt{D_p \tau_p}}\right]. \tag{15.43}$$

At the location $x = 0$, the injected charge is Δp so the above result becomes

$$p(x) = p_o + \Delta p \exp\left[\frac{-x}{\sqrt{D_n \tau_n}}\right], \tag{15.44}$$

from which the injected hole population is seen to exponentially decrease with increasing x.

15.3 Basic Semiconductor Detector Configurations

Semiconductor detectors can be fashioned into many different configurations, including junction diodes, Schottky barrier diodes, photoconductors, and photoresistors. To select the most appropriate configuration,

one must consider the semiconductor material and the radiation detection application. Some semiconductor materials are composed of substances that are not easily converted into junction diodes, such as HgI_2 and PbI_2, whereas other semiconductors, such as Si and Ge, are easily fashioned into junction devices. Some materials, such as GaAs, can be fabricated easily into either photoconductors or Schottky barrier devices. Limited doping selection and other chemical constraints prevent some materials to be configured easily as either reverse biased diodes or photoconductors. The following section introduces the reader to basic semiconductor configurations.

15.3.1 The *pn* Junction

If two blocks of semiconductor material, one doped with concentration N_D donors and the other doped with concentration N_A acceptors, are brought into contact, then the p-type side of the junction boundary has an excess of free hole charge carriers and the n-type side of the junction has an excess of free electron charge carriers (see Fig. 15.4). The concentration gradient across the junction boundary causes holes to diffuse across the boundary into the n-type side, and electrons to diffuse to the p-type side (see Fig. 15.5). The free carriers leave behind the immobile host ions, which produce a region of *space charge* of opposite polarity, as depicted in Fig. 15.6. The result is the production of an internal electric field with an applied force in the opposite direction of the diffusion current. The presence of space charge distorts the band energy levels and causes the bands to bend across the junction boundary. The bands distort and bend until the diffusion current is equal to the electric-field current, thereby producing a state of equilibrium. In other words, the concentration gradient force that causes diffusion current matches the electric field force that causes the drift current in the opposite direction, such that a state of equilibrium is reached, as depicted in Fig. 15.6.

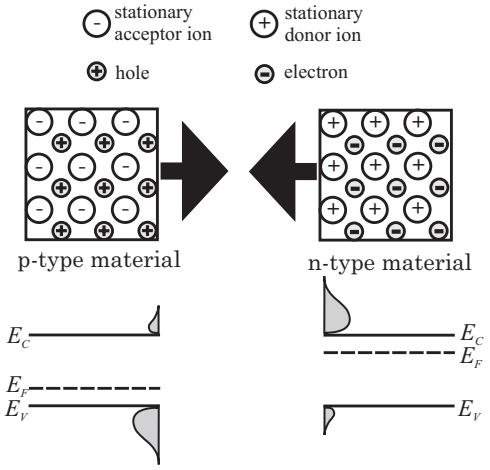

Figure 15.4. Depiction of two semiconductor materials and their energy band diagrams, one of which is p-type material and the other n-type material, suspended in vacuum before coming into contact.

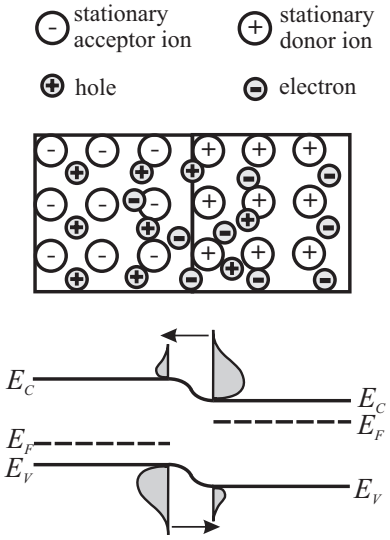

Figure 15.5. When the p-type and n-type materials come into contact, holes from the p side diffuse over to the n side, and electrons from the n side diffuse over to the p side. As they do, they leave the host ions behind, which behave as stationary space charge. Further, the Fermi energy level must be constant across the interface at equilibrium, hence the energy bands distort and bend as the system changes to the equilibrium condition.

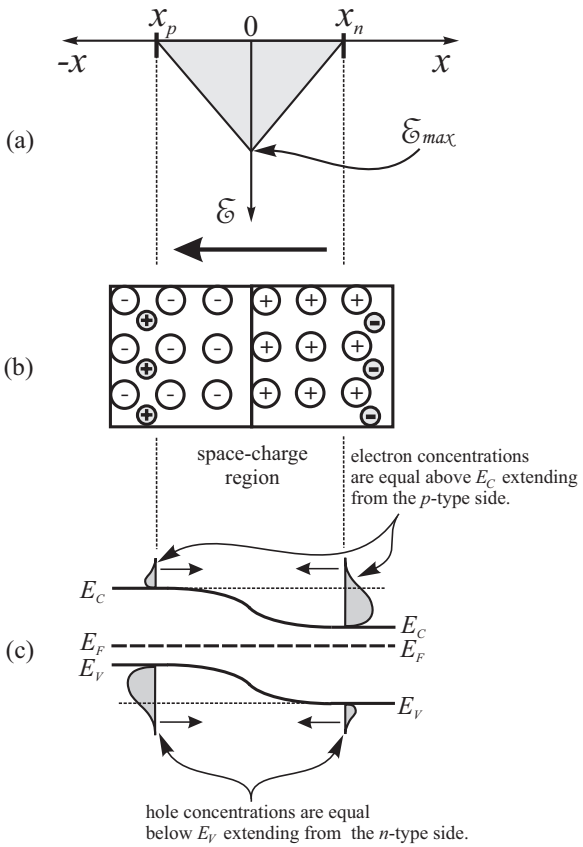

Figure 15.6. At equilibrium, the free carriers are swept from the space-charge or *depletion* region, leaving behind a polarized zone that produces an internal electric field. Hence diffusion of charges in one direction is balanced by electric field drift in the other. Depicted in the diagram are (a) the electric field, (b) the space-charge region, and (c) the energy band diagram.

Width of the Space-Charge Region

To determine the width of the space-charge region, begin with Poisson's equation and a few simplifying assumptions. The general Poisson equation is

$$\boldsymbol{\nabla}\bullet\boldsymbol{\mathcal{D}} = \boldsymbol{\nabla}\bullet[\epsilon_0\kappa\boldsymbol{\mathcal{E}}] = \boldsymbol{\nabla}\bullet[\epsilon_0\kappa\boldsymbol{\nabla}V(\mathbf{r})] = \rho_c(\mathbf{r}), \tag{15.45}$$

$\boldsymbol{\mathcal{D}}$ is the electrical displacement, ϵ_0 is the permittivity of free space, κ is the dielectric constant, $\boldsymbol{\mathcal{E}}$ is the electric field, V is the electric potential, and ρ_c is the volumetric charge density. For the one-dimensional case with a constant permittivity, Eq. (15.45) reduces to

$$\frac{\partial^2\psi(x)}{\partial x^2} = -\frac{\rho(x)}{\epsilon_0\kappa} = \frac{q_e}{\epsilon_s}(N_A^- - N_D^+ - p + n) \tag{15.46}$$

where q_e is the unit electron charge, $\psi(x)$ is the scalar voltage component in the x direction (the y and z voltage components are zero in the present example). Here n, p, N_D^+, and N_A^- are the concentrations of the

free electrons, free holes, ionized donors, and ionized acceptors, respectively. Also the relation $\epsilon_s = \epsilon_0\kappa$ has been used. To simplify the problem further, the following approximations are made.

1. Assume that the junction is abrupt at the interface between the p-type side and the n-type side and that all dopants in the materials are uniformly distributed.
2. Assume $N_D^+ \gg n$, p, or N_A for the n-type side and that $N_D^+ \simeq N_D$ at 300 K.
3. Assume $N_A^- \gg n$, p, or N_D for the p-type side and that $N_A^- \simeq N_A$ at 300 K.

Equation (15.46) then reduces to the following:

$$\frac{\partial^2\psi(x)}{\partial x^2} \simeq \frac{-q_e N_D^+}{\epsilon_s}, \quad 0 \le x \le x_n, \qquad \text{and} \qquad \frac{\partial^2\psi(x)}{\partial x^2} \simeq \frac{q_e N_A^-}{\epsilon_s}, \quad x_p \le x \le 0, \tag{15.47}$$

and outside the space-charge region $\partial^2\psi(x)/\partial x^2 = 0$, $x \notin (x_p, x_n)$.

The electric field on the n-type side of the junction is found by integration of Eq. (15.47) as

$$-\frac{\partial\psi(x)}{\partial x} = \mathcal{E}(x) = \int \frac{q_e N_D}{\epsilon_s}\,dx = \frac{q_e N_D}{\epsilon_s}x + C_1, \quad 0 \le x \le x_n, \tag{15.48}$$

and the electric field on the p-type side is

$$-\frac{\partial\psi(x)}{\partial x} = \mathcal{E}(x) = -\int \frac{q_e N_A}{\epsilon_s}\,dx = -\frac{q_e N_A}{\epsilon_s}x + C_2, \quad x_p \le x \le 0. \tag{15.49}$$

With the boundary conditions $\mathcal{E}(x_p) = \mathcal{E}(x_n) = 0$ the arbitrary constants C_1 and C_2 can be evaluated and the electric field is found to be

$$\mathcal{E}(x) = \begin{cases} \dfrac{q_e N_D}{\epsilon_s}(x - x_n), & 0 \le x \le x_n \\ -\dfrac{q_e N_A}{\epsilon_s}(x - x_p), & x_p \le x \le 0 \end{cases}. \tag{15.50}$$

Notice that the slope of the electric field magnitude is a linear function of the doping concentrations, N_D and N_A. The electric field must also be continuous across the junction, hence at $x = 0$ one has

$$-\frac{q_e N_D}{\epsilon_s}x_n = \frac{q_e N_A}{\epsilon_s}x_p \qquad \text{so that} \qquad N_D x_n = -N_A x_p. \tag{15.51}$$

These are important relations because they show that the relative width of the space charge region increases as the doping concentration decreases. For instance, if N_D is 10 times greater than N_A, then for any given applied voltage, x_p must be 10 times greater than x_n. Notice also that the largest magnitude of the electric field must be at $x = 0$ (the pn junction interface), i.e.,

$$\mathcal{E}_{max} = -\frac{q_e N_D}{\epsilon_s}x_n = \frac{q_e N_A}{\epsilon_s}x_p. \tag{15.52}$$

The change in voltage across the space-charge region can be found by integration of electric field,

$$\begin{aligned} \Delta V &= -\int_{x_p}^{x_n} \mathcal{E}(x)\,dx = \int_{x_p}^{0} \frac{q_e N_A}{\epsilon_s}(x - x_p)\,dx - \int_{0}^{x_n} \frac{q_e N_D}{\epsilon_s}(x - x_n)\,dx \\ &= \frac{q_e}{2\epsilon_s}\left(N_A x_p^2 + N_D x_n^2\right). \end{aligned} \tag{15.53}$$

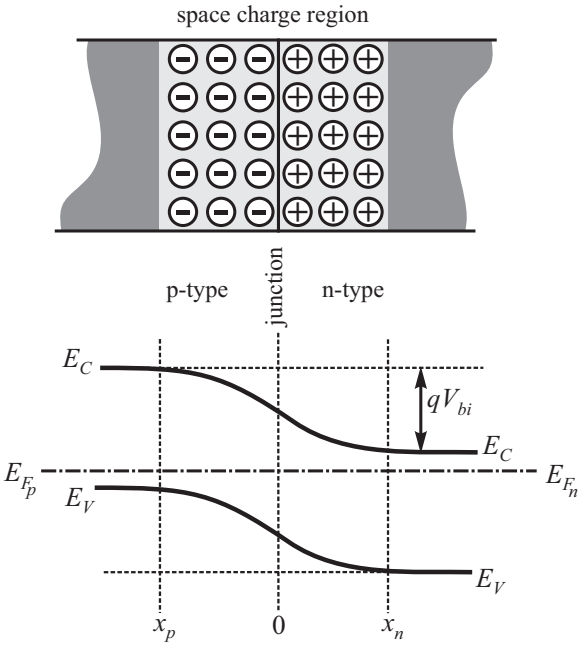

Figure 15.7. At equilibrium in a *pn* junction, the free charge carriers are swept from the space-charge or *depletion* region, leaving behind a polarized zone that produces an internal electric field. Diffusion of charges in one direction is balanced by electric field drift in the other. At equilibrium, the Fermi level is constant across the junction. At the *pn* junction, the energy bands bend and produce the built-in potential V_{bi}.

Hence, there is an electric field and a *built-in* voltage potential V_{bi} at the *pn* junction without the need of any externally applied voltage. Some semiconductor detectors operate well on this built-in potential alone. The built-in potential can be rewritten as

$$\begin{aligned} V_{bi} &= \frac{q_e}{2\epsilon_s}\left(N_A x_p^2 + N_D x_n^2\right) \\ &= -\frac{\mathcal{E}_{max}}{2}\left(x_n - x_p\right) = -\frac{\mathcal{E}_{max} W}{2}, \end{aligned} \tag{15.54}$$

where $W = x_n - x_p$ is the total space-charge region width as shown in Fig. 15.7. Typically, *pn* junction diode detectors have a voltage applied in the reverse direction to increase the width of the space-charge or *active region*.

With the second result of Eq. (15.51), Eq. (15.53) can be rewritten as

$$V_{bi} = \frac{q_e}{2\epsilon_s}\left(\frac{N_D^2 x_n^2}{N_A} + N_D x_n^2\right),$$

which, upon solving for x_n, gives

$$x_n = \left\{\frac{2\epsilon_s V_{bi}}{q_e}\left(\frac{N_A}{N_D(N_D + N_A)}\right)\right\}^{1/2}. \tag{15.55}$$

In the same way, Eq. (15.53) can be rewritten as

$$V_{bi} = \frac{q_e}{2\epsilon_s}\left(N_A x_p^2 + \frac{N_A^2 x_p^2}{N_D}\right),$$

whose solution for x_p is

$$x_p = -\left\{\frac{2\epsilon_s V_{bi}}{q_e}\left(\frac{N_D}{N_A(N_D + N_A)}\right)\right\}^{1/2}. \tag{15.56}$$

Equation (15.55) and Eq. (15.56) can be combined to yield the active region width W, without a bias, as

$$\begin{aligned} W = x_n - x_p &= \left\{\frac{2\epsilon_s V_{bi}}{q_e}\left(\frac{N_A}{N_D(N_D + N_A)}\right)\right\}^{1/2} + \left\{\frac{2\epsilon_s V_{bi}}{q_e}\left(\frac{N_D}{N_A(N_D + N_A)}\right)\right\}^{1/2}, \\ &= \left\{\frac{2\epsilon_s V_{bi}}{q_e(N_D + N_A)}\right\}^{1/2}\left\{\sqrt{\frac{N_A}{N_D}} + \sqrt{\frac{N_D}{N_A}}\right\} = \left\{\frac{2\epsilon_s V_{bi}}{q_e}\left(\frac{N_A + N_D}{N_A N_D}\right)\right\}^{1/2}. \end{aligned} \tag{15.57}$$

When an external bias is applied, the active region width is

$$W = \left\{\frac{2\epsilon_s (V_{bi} - V)}{q_e}\left(\frac{N_A + N_D}{N_A N_D}\right)\right\}^{1/2}. \tag{15.58}$$

In the case that one side of the junction is doped much higher than the other side, by at least an order of magnitude, Eq. (15.58) can be approximated by

$$W \simeq \left\{ \frac{2\epsilon_s (V_{bi} - V)}{q_e N_b} \right\}^{1/2}, \tag{15.59}$$

where N_b is the doping concentration of the *lighter* doped side, commonly named the one-sided abrupt junction approximation.

One can also calculate V_{bi} as a function of the extrinsic and intrinsic Fermi energies. From Fig. 15.7, it is seen that $q_e V_{bi}$ equals the energy difference in the conduction band levels on the p-type side and on the n-type side. Thus, V_{bi} can be calculated as

$$\begin{aligned} q_e V_{bi} &= (E_i - E_{Fp})\,\big|_{p-type} + (E_{Fn} - E_i)\,\big|_{n-type}, \\ &= kT \ln\left(\frac{p_p}{n_i}\right) + kT \ln\left(\frac{n_n}{n_i}\right) = kT \ln\left(\frac{n_n p_n}{{n_i}^2}\right). \end{aligned}$$

At room temperature $p_p \simeq N_A$ and $n_n \simeq N_D$ so that

$$V_{bi} \simeq \frac{kT}{q_e} \ln\left(\frac{N_D N_A}{{n_i}^2}\right). \tag{15.60}$$

Example 15.1: Consider a Si diode structure with a p-type dopant of concentration $N_A = 10^{17}$ cm^{-3} diffused into the surface of lightly doped n-type material that has a background concentration of $N_D = 10^{14}$ cm^{-3}. What is the built-in potential and total active region width at room temperature (300 K)?

Solution:

For Si $\epsilon_s = 11.9\epsilon_o$, and $n_i(300\text{K}) = 1.45 \times 10^{10}$ cm^{-3}. Substitution into Eq. (15.60) gives

$$V_{bi} = \frac{kT}{q_e} \ln\left(\frac{N_D N_A}{{n_i}^2}\right) = \frac{(1.38 \times 10^{-23}\ \text{J/K})\,(300\ \text{K})}{1.6 \times 10^{-19}\ \text{C}} \ln\left(\frac{(10^{14}\ \text{cm}^{-3})\,(10^{17}\ \text{cm}^{-3})}{(1.45 \times 10^{10}\ \text{cm}^{-3})^2}\right) = 0.636 \text{ volts.}$$

From Eq. (15.58) the active region (or depletion region) width is

$$\begin{aligned} W &= \left\{ \frac{2\epsilon_s (V_{bi} - V)}{q_e} \left(\frac{N_A + N_D}{N_A N_D}\right) \right\}^{1/2}, \\ &= \left\{ \left(\frac{(2)(11.9)(8.854 \times 10^{-14}\ \text{F/cm})(0.636\ \text{V} - 0\ \text{V})}{1.6 \times 10^{-19}\text{C}}\right) \left(\frac{10^{17}\text{cm}^{-3} + 10^{14}\text{cm}^{-3}}{(10^{14}\text{cm}^{-3})\,(10^{17}\text{cm}^{-3})}\right) \right\}^{1/2} = 2.895 \times 10^{-4}\ \text{cm}. \end{aligned}$$

Because the n-type side has a significantly lower doping concentration than the p-type side, one can also use the approximation of Eq. (15.59) with $N_b = N_D$ to give

$$W \simeq \left\{ \frac{2\epsilon_s (V_{bi} - V)}{q_e N_b} \right\}^{1/2} = \left\{ \frac{(2)(11.9)(8.854 \times 10^{-14}\ \text{F/cm})(0.636\ \text{V} - 0\ \text{V})}{(1.6 \times 10^{-19}\text{C})(10^{14}\ \text{cm}^{-3})} \right\}^{1/2} = 2.894 \times 10^{-4}\ \text{cm}.$$

This result is essentially the same as the first solution.

At room temperature, the material resistivity ρ_s can be expressed as $\rho_s = 1/(q_e \mu_s N_s)$, where N_s and μ_s are the background dopant concentration and mobility for the lighter doped side of the junction, and Eq. (15.59) can be rewritten as

$$W \simeq \{2\epsilon_s \mu_s \rho_s (V_{bi} - V)\}^{1/2}. \tag{15.61}$$

The magnitude of the electric field across the device is

$$|\mathcal{E}(x)| \simeq \frac{q_e N_s}{\epsilon_s}(W - x), \quad 0 \le x \le W. \tag{15.62}$$

Device Capacitance

The capacitance of a parallel contact *pn* junction detector is given by

$$C_{det} = \frac{\epsilon_s A}{W}, \tag{15.63}$$

where A is the device active contact area. Substitution of Eq. (15.61) into Eq. (15.63) yields

$$C_{det} \simeq A \left[\frac{\epsilon_s}{2\mu_s \rho_s (V_{bi} - V)} \right]^{1/2}. \tag{15.64}$$

Detector capacitance affects the input voltage pulse height, with a large capacitance diminishing the input voltage from the detector that is measured by the amplification circuit such that

$$V_{in} \simeq \frac{Q}{C_{tot}}, \tag{15.65}$$

where C_{tot} is the total capacitance (detector and coupling) and Q is the total charge collected from the radiation detector after a radiation event. Hence, it is important to reduce detector capacitance and coupling capacitance between the detector and the shaping electronics. From Eq. (15.64), it is seen that increasing the reverse bias voltage decreases the detector capacitance, but at the expense of increasing the leakage current.

Fermi Level and Current at Equilibrium

The general equations describing current density for electrons and holes are given by Eqs. (15.29) and (15.30). The total conduction current density is $\mathbf{J}_c = \mathbf{J}_p + \mathbf{J}_n$. Under a condition of no applied external voltage and equilibrium conditions, these currents must all vanish. Thus, in one dimension,

$$J_p(x) = q_e \mu_p p(x)\, \mathcal{E}(x) - q_e D_p \frac{dp(x)}{dx} = 0, \tag{15.66}$$

in which μ_p is the hole mobility, p is the hole concentration, and

$$J_n(x) = q_e \mu_n n(x)\, \mathcal{E}(x) + q_e D_n \frac{dn(x)}{dx} = 0. \tag{15.67}$$

where μ_n is the electron mobility, n is the hole concentration. There is a relative change in the *intrinsic* Fermi level $E_i(x)$ location, with respect to the band edges, across a *pn* junction. From the definitions of $q_e V(x) = E(x)$ and D_n given by Eq. (15.31), Eqs. (15.66) and (15.67) can be written as

$$J_p(x) = \mu_p p(x) \frac{dE_i(x)}{dx} - kT\mu_p \frac{dp(x)}{dx} = 0, \tag{15.68}$$

and

$$J_n(x) = \mu_n n(x) \frac{dE_i(x)}{dx} + kT\mu_n \frac{dn(x)}{dx} = 0. \tag{15.69}$$

Eq. (12.130) can be divided by Eq. (12.128) to yield

$$\frac{p(x)}{n_i} = \frac{N_V \exp\left[\dfrac{E_V - E_F(x)}{kT}\right]}{N_V \exp\left[\dfrac{E_V - E_i(x)}{kT}\right]} = \exp\left[\frac{E_i(x) - E_F(x)}{kT}\right], \tag{15.70}$$

which is an expression for $p(x)$. The resulting derivative for dp/dx is then found to be

$$\begin{aligned}\frac{dp(x)}{dx} &= \frac{n_i}{kT} \exp\left[\frac{(E_i(x) - E_F(x))}{kT}\right] \left[\frac{dE_i(x)}{dx} - \frac{dE_F(x)}{dx}\right], \\ &= \left(\frac{p(x)}{kT}\right) \left[\frac{dE_i}{dx} - \frac{dE_F}{dx}\right]. \end{aligned} \tag{15.71}$$

Substitution of Eq. (15.71) into Eq. (15.68) gives

$$J_p(x) = \mu_p p(x) \frac{dE_i(x)}{dx} - kT\mu_p \left(\frac{p(x)}{kT}\right) \left[\frac{dE_i}{dx} - \frac{dE_F}{dx}\right] = \mu_p p(x) \frac{dE_F}{dx} = 0. \tag{15.72}$$

A similar result can be derived for the n-type side, namely

$$J_n(x) = \mu_n n(x) \frac{dE_F}{dx} = 0. \tag{15.73}$$

so that the total current density is

$$J(x) = J_p(x) + J_n(x) = \mu_p p(x) \frac{dE_F}{dx} + \mu_n n(x) \frac{dE_F}{dx} = 0. \tag{15.74}$$

Recall that the Fermi level at equilibrium is continuous across a boundary. The interpretation of Eq. (15.74) is that the Fermi level at equilibrium is constant on the p and n sides of the junction, and must also be constant across the junction, as shown in Fig. 15.8(e). Hence, at equilibrium, the net current must be zero.

Current Under Forward Bias

The current density of a pn junction diode is described by [Sze 1981]

$$J = J_s \left\{ \exp\left[\frac{q_e V}{\breve{n} kT}\right] - 1 \right\}, \tag{15.75}$$

where $\breve{n}$ is an *ideality factor* to correct for non-ideal behavior, and saturation current density J_s is

$$J_s = \frac{q_e D_p p_{no}}{L_p} + \frac{q_e D_n n_{po}}{L_n}, \tag{15.76}$$

D_p is the diffusion coefficient for holes, D_n is the diffusion coefficient for electrons, p_{no} is the minority hole concentration in the n-type material, n_{po} is the minority hole concentration in the p-type material, and the diffusion lengths L_p and L_n are defined as

$$L_{p,n} = \sqrt{D_{p,n} \tau_{p,n}}. \tag{15.77}$$

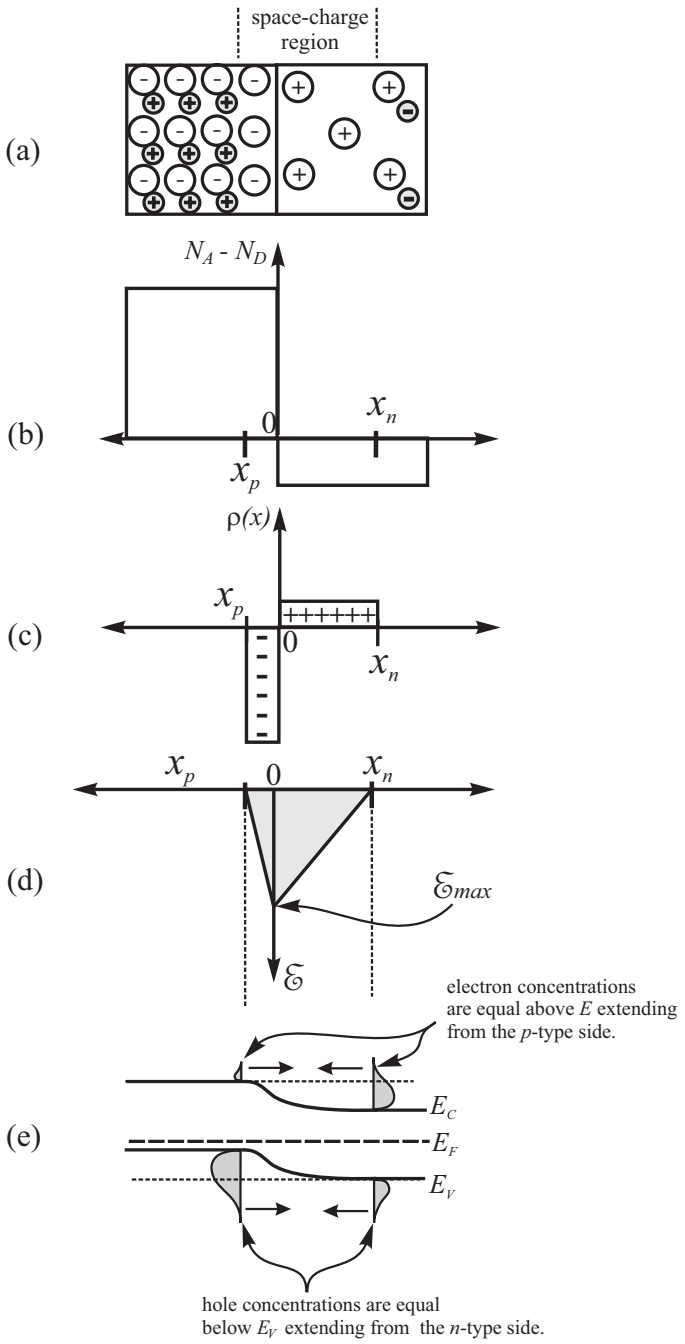

Figure 15.8. The depleted region extends furthest into the junction region of lowest doping. For the case in which the p-type region is of higher doping levels than the n-type region, shown are (a) the device space-charge region, (b) the dopant density, (c) the space-charge density (d) the electric field, and (e) the energy band diagram.

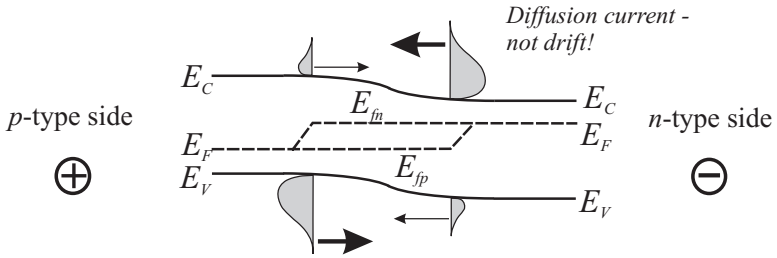

Figure 15.9. Diffusion current dominates in forward bias and, because of the non-linear distribution of free carriers in the conduction and valence bands, the observed current increases exponentially with increasing forward bias.

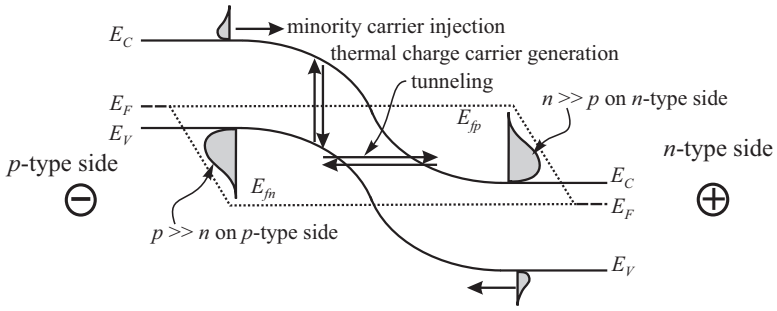

Figure 15.10. In reverse bias, the density of available carriers, dominated by the *minority* carrier concentration, determines the leakage current. At higher voltages, bulk generation and tunneling may increase the observed leakage currents.

Here $\tau_{p,n}$ is the corresponding charge carrier lifetime. With a forward bias (see Fig. 15.9), the electron distribution on the n-type side is raised in energy above the barrier on the p-type side, thereby allowing diffusion of charge carriers to flow into the p-type side. According to the integrand of Eq. (12.120), the electron distribution in the conduction band as a function of energy is non-linear, and the amount of current increases exponentially as more forward voltage is applied. From the integrand of Eq. (12.123), the same can be shown for holes diffusing from the p-type side over into the n-type side.

Also depicted in Fig. 15.9 are the quasi-Fermi levels E_{fn} for electrons and E_{fp} for holes.[3] A quasi-Fermi level describes the population of electrons and holes separately in the conduction band and valence band when no longer in equilibrium, such as the case with applied voltage (forward or reverse) or other cases of charge injection, such as photoexcitation.

Leakage Current Under Reverse Bias

There are three main sources of leakage current, as depicted in Fig. 15.10. Although the *majority* carriers on the p-type side are holes, according to Eq. (12.131) a small concentration of electrons is still present. These *minority* charge carriers (electrons) can diffuse into the depletion region, where they are swept across by the electric field and contribute to the leakage current. A similar case is true for holes diffusing from the n-type side into the depletion region. Leakage current can also occur from thermal generation of electrons directly across the band gap into the conduction band, producing electron and hole free carriers. Thermal generation of such charge carriers can be suppressed by cooling the detector while it is operating. Under high

[3] A quasi-Fermi level is also called an 'imref', the word 'fermi' spelled backwards [Hannay 1959].

voltage bias conditions, charge carriers can also tunnel directly across the band gap, again contributing to the leakage current. Variations about the leakage current can be a significant source of electronic noise (shot noise), which broadens the overall energy resolution of the detector. Basically, *pn* junctions are employed to minimize leakage currents in semiconductor detectors.

Example 15.2: Given a silicon *pn* junction with $N_A = 10^{15}$ cm^{-3} and $N_D = 10^{13}$ cm^{-3}, what is the minority carrier saturation leakage current density under reverse bias at 300 K? The electrons and hole mobilities are and 1320 cm^{2}V^{-1}s^{-1} and 470 cm^{2}V^{-1}s^{-1}, respectively (see Fig. 16.3), with $\tau_{n,p} = 10^{-3}$ s.

Solution:
From Eq. (15.31)

$$D = \frac{\mu kT}{q_e}$$

we have

$$D_p = \frac{(470 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1})(1.38 \times 10^{-23} \text{ J K}^{-1})(300 \text{ K})}{1.6 \times 10^{-19}\text{C}} = 12.16 \text{ cm}^2 \text{ s}^{-1}.$$

and

$$D_n = \frac{(1320 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1})(1.38 \times 10^{-23} \text{ J K}^{-1})(300 \text{ K})}{1.6 \times 10^{-19}\text{C}} = 34.16 \text{ cm}^2 \text{ s}^{-1}.$$

Because $np = n_i^2$, one has

$$J_s = q_e \left(\frac{D_p p_{n0}}{L_p} + \frac{D_n n_{p0}}{L_n} \right) = q_e n_i^2 \left(\sqrt{\frac{D_p}{n^2 \tau_p}} + \sqrt{\frac{D_n}{p^2 \tau_n}} \right),$$

which gives

$$J_s = (1.6 \times 10^{-19} \text{ C})(1.5 \times 10^{10} \text{ cm}^{-3})^2 \left(\sqrt{\frac{12.16 \text{ cm}^2 \text{ s}^{-1}}{(10^{13} \text{ cm}^{-3})^2 (10^{-3} \text{ s})}} + \sqrt{\frac{34.16 \text{ cm}^2 \text{ s}^{-1}}{(10^{15} \text{ cm}^{-3})^2 (10^{-3} \text{ s})}} \right),$$

$$= 4.04 \times 10^{-14} \text{ amperes}$$

Use of Reverse Bias

The active radiation-sensitive volume of the *pn*-junction detector is defined by the space-charge region (or depletion region), and the undepleted regions act as series resistances. Detectors based on *pn* junction diodes are typically operated under *reverse bias*, which is regarded as a negative voltage, but is actually a positive voltage applied to the *n*-type material with respect to the *p*-type material. Shown in Fig. 15.10 is the band diagram of a reverse biased *pn* junction. The large energy band barriers prevent electrons on the *n*-type side from diffusing over to the *p*-type side and prevent holes on the *p*-type side from diffusing into the *n*-type side. There remains the possibility of electrons on the *p*-type side diffusing to the *n*-type side, and holes on the *n*-type side diffusing into the *p*-type side, both of which produce current. However, from Eq. (12.131), the density of minority carrier holes and minority carrier electrons is small (depicted in Fig. 15.10), and consequently the leakage current is small. As a result, the *pn* junction suppresses leakage current that would be present if the semiconductor were operated as a resistor. This necessary condition reduces the electron current such that minute charge packets excited in the depletion region by radiation interactions can be measured.

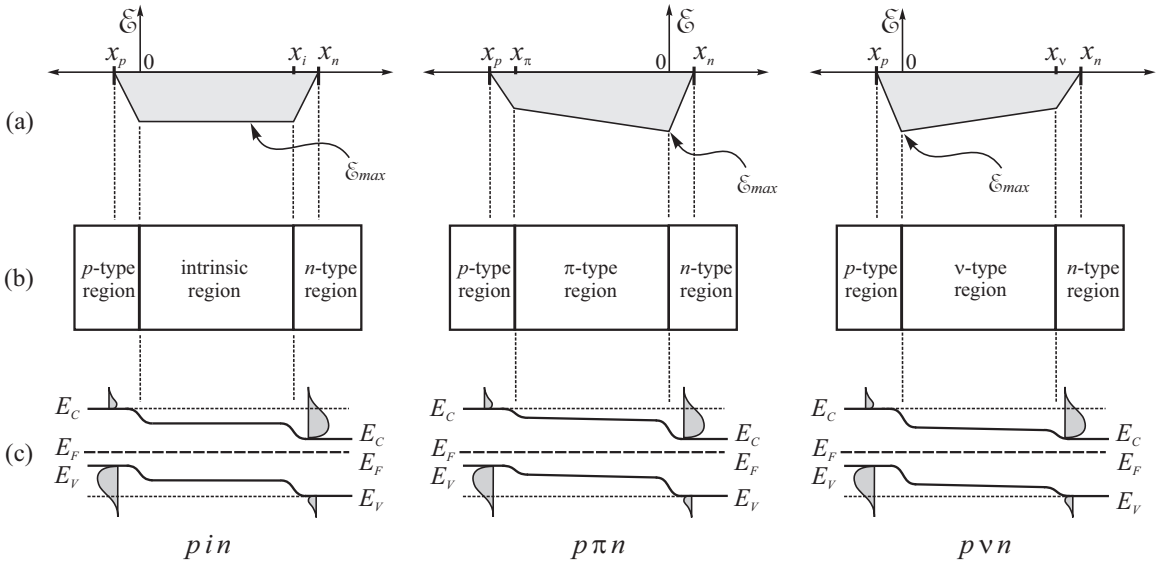

Figure 15.11. Electric field (a), material regiobs (b), and band diagrams (c) of *pin*, $p\pi n$ and $p\nu n$ devices. Note that the electric field across the intrinsic region of the *pin* diode is constant, but the lightly doped $p\pi n$ and $p\nu n$ have a definite slopes to their electric fields.

15.3.2 *pin* Junction Devices

Reverse biased diode detectors need a large depletion region to maximize radiation absorption. As found in Eq. (15.58), the depletion region width is proportional to the square root of the applied reverse voltage. This relationship indicates large voltages are required to produce large depletion regions in a common *pn* junction diode. The usual remedy to avoid high voltages is to construct a *pin* diode that has an intrinsic, or high purity region, between the *p*-type and *n*-type contacts. The *p* and *n* type contacts can be used as either blocking barriers or electrical *ohmic* contacts to the material. The application of *p*-type contacts to *p*-type material, or *n*-type contacts to *n*-type material, generally produce non-rectifying electrical contacts that follow Ohm's law.

A *pin* device may have a truly intrinsic region between the *p* and *n* type contacts, in which the electron and hole populations are identical, or the high purity region may be a lightly doped material. Lightly doped *p*-type material is commonly denoted π-type, and lightly doped *n*-type material is commonly denoted ν-type. Analysis of the diode construction should take into account the "punch-through" voltage, in which the depletion region extends completely across the high purity region, whether the material is i, ν, or π type. Semiconductor *pin* diode radiation detectors are commonly operated at biases above the punch-through voltage.

Intrinsic material either has dopant concentrations below the intrinsic concentration or has compensation dopants that cause the residual free carrier concentration to be below the intrinsic concentration. In either case, the residual space charge is practically zero ($\rho_c \simeq 0$), and from Eq. (15.46) the resulting electric field is constant across the *pin* diode under reverse bias. Many detectors are fashioned from high-purity semiconductor materials, yet such detectors may not behave intrinsically, because of a small concentration of residual dopants that is still above the intrinsic concentration. As a result, ρ_c is non-zero, even if very small, and the depletion region width is determined by V_{bi} and the applied voltage. If the lightly doped π or ν regions are relatively thin, the detector might become "fully depleted" without an applied voltage, as depicted in Fig. 15.11. However, complete depletion is usually not the case, and a reverse bias must then be

applied to extend the depletion region and the electric field across the device, as determined from Eq. (15.58) and Eq. (15.59), respectively.

Example 15.3: Given a silicon $p\nu n$ diode with $N_A = 10^{15}$ cm^{-3}, $N_d = 10^{13}$ cm^{-3}, and $N_D = 10^{15}$ cm^{-3}, what is the depletion width for a 450 micron thick ν region with a bias of 200 volts reverse bias? With N_d reduced to 10^{12} cm^{-3}, what is the depletion width at 100 volts reverse bias?

Solution:

The one-sided abrupt junction approximation is used in the first case.

$$W \simeq \sqrt{\frac{2\kappa\epsilon_o V}{q_e N_d}} = \sqrt{\frac{(2)(11.9)(8.854 \times 10^{-14}\text{F cm}^{-1})(200 \text{ volts})}{(1.6 \times 10^{-19} \text{ C})(10^{13} \text{ cm}^{-3})}} = 162.3 \text{ microns.}$$

The ν region dopant concentration is now reduced to 10^{12} cm^{-3}, yielding,

$$W \simeq \sqrt{\frac{2\kappa\epsilon_o V}{q_e N_d}} = \sqrt{\frac{(2)(11.9)(8.854 \times 10^{-14}\text{F cm}^{-1})(200 \text{ volts})}{(1.6 \times 10^{-19} \text{ C})(10^{12} \text{ cm}^{-3})}} = 513.2 \text{ microns,}$$

which is wider than the ν region. Hence, in the second case the diode is fully depleted with $W = 450$ microns.

15.3.3 Metal-Semiconductor Contacts

Consider a situation in which a metal block and a semiconductor block are both suspended in free space, and that somehow they are spontaneously fused together. What then would happen? Entire books have been published on the physics of metal-semiconductor contacts. Such depth of coverage is not possible here; however, those major concepts, important to the design and fabrication of semiconductor detectors, are briefly presented.

Schottky Devices

Earlier it was shown that the Fermi energy level must be constant at equilibrium. Further, if the derivative of the Fermi level with respect to position were to change, it would imply the presence of current flow. However, it can be readily assumed that a free floating semiconductor substance onto which a metal is attached does not have current flowing through the structure. Hence, the Fermi level must remain constant. As a metal and semiconductor are brought together, the energy bands must deform to (1) ensure that the vacuum level is continuous and (2) ensure that the Fermi level is constant.

The application of a metal to a semiconductor surface acts to bend the semiconductor bands to form an energy barrier $q_e\phi_{bn}$, much like the pn junction diode, as shown in Fig. 15.12. The Fermi energies, defined by the metal and semiconductor work functions (ϕ_m and ϕ_s) must align when the two materials are brought into contact.

Shown in Fig. 15.12(a) are depictions of the energy bands for a metal and a semiconductor. The vacuum levels of both materials are continuous. The work functions of both materials are defined as the difference between the vacuum level and Fermi levels. Given a temperature and pressure, the work function of the metal, $q_e\phi_m$, may be regarded as a constant. However, the Fermi level of a semiconductor, $q_e\phi_s$, is a function of doping concentration, and, hence, is not considered a constant reference point. Instead, the electron affinity, $q_e\chi_s$, defined as the difference between the vacuum level and the conduction band edge, is generally used as a constant of reference. As the junction reaches equilibrium, the Fermi level on the metal

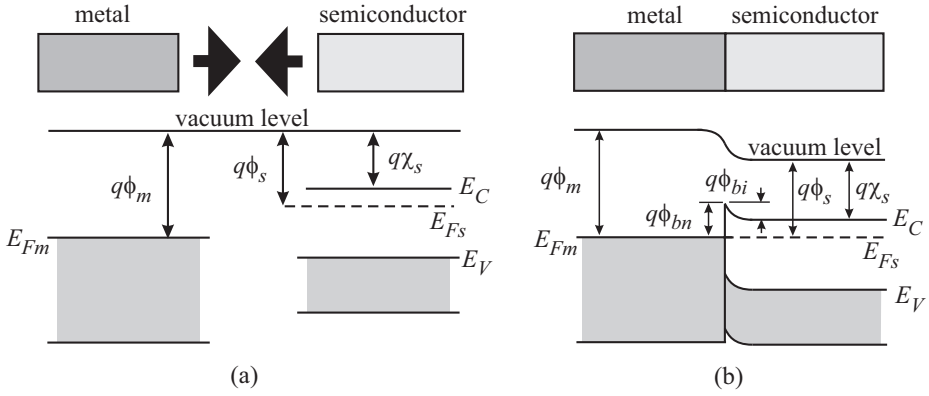

Figure 15.12. The band configuration depicted for a metal and semiconductor (a) before and (b) after contact, according to the Schottky-Mott model.

and semiconductor sides must align. As a result of the junction formation, a built-in potential $q_e\phi_{bi}$ forms and a potential barrier $q_e\phi_{bn}$ forms. The final barrier height is given by

$$q_e\phi_{bn} = q_e(\phi_m - \chi_s), \tag{15.78}$$

and the built in potential is

$$q_e\phi_{bi} = q_e(\phi_m - \phi_s). \tag{15.79}$$

This result is called the *simple* Schottky model. Under a reverse bias, this energy barrier serves to reduce leakage current. Typically the barrier height is lower than that for *pn* or *pin* junction diodes, hence detectors based on the Schottky barrier diode typically have higher leakage currents than *pn* or *pin* diodes.

Schottky Effect

Consider a single point charge in vacuum, an electron for instance, placed near the surface of a conductor at distance x, as shown in Fig. 15.13. The point charge repels similar charges in the metal, leaving a net positive charge on the surface, thereby giving the appearance of a positive charge of equal magnitude in the metal at the distance $-x$ from the metal surface. The forces exerted upon the point and image charges are equal and opposite, namely

$$F = \left.\frac{q_e^2}{4\pi\epsilon_s(2x)^2}\right|_{point} = \left.\frac{-q_e^2}{4\pi\epsilon_s(2x)^2}\right|_{image}. \tag{15.80}$$

The potential due to the *image force* is found as

$$V_1(x) = \int_\infty^x F\,dx = \frac{-q_e^2}{16\pi\epsilon_s x}, \tag{15.81}$$

and the electric field potential is $V_2(x) = -q_e xE$. Therefore, the total energy is

$$V_{tot} = V_1 + V_2 = \frac{-q_e^2}{16\pi\epsilon_s x} - q_e xE. \tag{15.82}$$

The situation is depicted in Fig. 15.14, in which the total potential of the image charge has a maximum value at $q_e\Delta\phi$ located at x_m from the metal/vacuum interface.

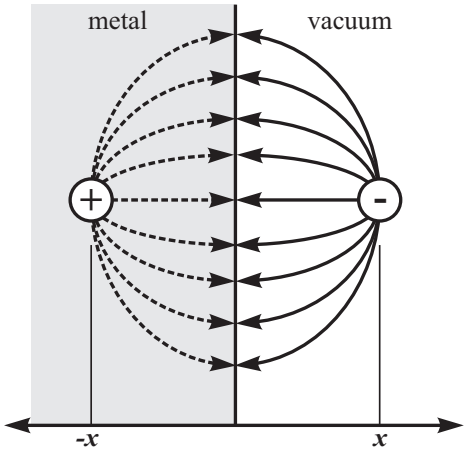

Figure 15.13. A single point charge in vacuum, such as an electron, near a conductive surface effectively produces an *image charge* of opposite magnitude to appear in the conductor.

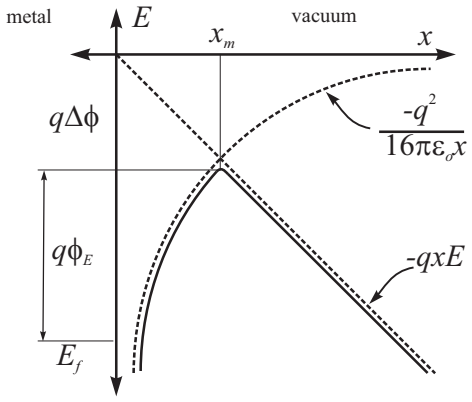

Figure 15.14. Schottky barrier lowering results from the combined effects of the image and electric field potentials.

The Schottky barrier effect thus lowers the Schottky barrier by an amount $q_e\Delta\phi$. This barrier lowering occurs at x_m, where the electric field has a maximum E_m. The distance x_m can be found by setting the derivative of Eq. (15.82) to zero, i.e.,

$$\frac{d}{dx}\left(\frac{-q_e^2}{16\pi\epsilon_s x} - q_e x E_m\right)\Bigg|_{x_m} = \frac{q_e^2}{16\pi\epsilon_s x_m^2} - q_e E_m = 0. \tag{15.83}$$

Solution of Eq. (15.83) for x_m gives

$$x_m = \sqrt{\frac{q_e}{16\pi\epsilon_s E_m}}, \tag{15.84}$$

from which the maximum field strength is

$$E_m = \frac{q_e}{16\pi\epsilon_s x_m^2}. \tag{15.85}$$

The change in the Schottky barrier height is

$$\Delta\phi_{bi} = x_m E_m + \frac{q_e}{16\pi\epsilon_s x_m} = 2x_m E_m = 2E_m\sqrt{\frac{q_e}{16\pi\epsilon_s E_m}} = \sqrt{\frac{q_e E_m}{4\pi\epsilon_s}}, \tag{15.86}$$

which is also the potential of Schottky barrier lowering. What this result means is that the actual Schottky barrier for the diode is lower than expected from the simple Schottky model. The end result is a barrier height of

$$q_e\phi_{bn} = q_e(\phi_m - \chi_s - \Delta\phi_{bi}). \tag{15.87}$$

Bardeen Model: Surface State Effects

It should be noted that measured Schottky barrier heights typically do not match the theoretical values, even after considering the Schottky lowering effect. In fact, quite often the actual barrier height ϕ_{bn} is only modestly affected by ϕ_m, or in some cases the final barrier height ϕ_{bn} appears to be completely independent of the metal.

Because the surfaces of semiconductors have defects, interface states, and possible contaminants, the actual barrier height depends not only upon the choice of metal but also on how the surface is prepared. These surface states can effectively "pin" the detector barrier height, thereby predetermining the actual value of $q_e\phi_{bn}$ before the metal is applied. Bardeen offered an explanation to the difference by taking into account the effect of interface states on the Schottky barrier.

Assume that there is an unspecified density D_s (in units of $\text{eV}^{-1}\ \text{cm}^{-2}$) of unbonded states upon the surface of a semiconductor material. These unbonded states can arise from a combination of open bonds from the semiconductor host atoms, referred to as Tamm-Shockley states, and also from contaminate atoms attached to the surface. The surface states are classified donor states if they are neutral when occupied, and these states are classified as acceptor states if they are neutral when empty. Fast surface states are close to the bulk material and reach equilibrium quickly with a rapid change in potential. Slow surface states are further from the bulk material and take a relatively longer time to reach equilibrium with a potential change.

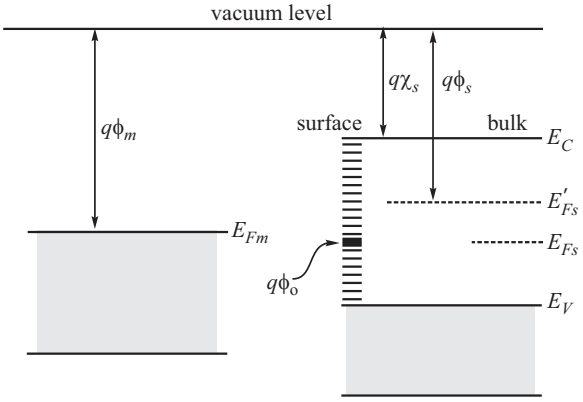

Figure 15.15. Band conditions for an n-type semiconductor with a high density of surface states, showing the neutral level $q_e\phi_o$. States below $q_e\phi_o$ are donors and states above $q_e\phi_o$ are acceptors.

Now assume that there is a thin interfacial insulator region δ between the metal and the semiconductor that is capable of supporting a potential. Also assume that the surface states are a property of the semiconductor alone and are independent of the metal. The states must be either filled or empty, and the filled surface states produce image charges of the opposite polarity in the semiconductor. In other words, for n-type material, a space-charge (depletion) region forms from the repulsion of electrons at the surface, and the bands bend to accommodate the potential formed at the surface. Overall, a specific density of these states is filled up to a neutral level $q_e\phi_o = E_o$, as depicted in Fig. 15.15. The states below the neutral level are filled donor states and hence are neutral, and the states above the neutral level are empty acceptors and are also neutral. If the Fermi level is raised to E'_f, then some of the surface acceptor states become filled and produce a net negative surface charge.

The surface charge Q_{ss} density, in units of C cm^{-2}, is

$$Q_{ss} = -q_e D_s \left[E_g - q_e\Delta\phi_{bi} - q_e\phi_{bn} - q_e\phi_0\right], \tag{15.88}$$

in which ϕ_{bn} is the energy barrier height at the metal-semiconductor interface. According to Gauss' law, the semiconductor and metal cannot support an electric field, hence

$$\epsilon_i\mathcal{E}_i = Q_{ss} = -Q'_m, \tag{15.89}$$

where ϵ_i is the permittivity of the thin interface insulator, and Q_m is the mirror charge formed on the metal. The voltage across the thin insulator is

$$V_i = \delta\mathcal{E}_i = \frac{\delta Q_{ss}}{\epsilon_i}. \tag{15.90}$$

As depicted in Fig. 15.16, the metal work function is,

$$q_e\phi_m = q_eV_i + q_e\chi_s + q_e\phi_{bo}, \tag{15.91}$$

and therefore the barrier height is

$$q_e\phi_{bo} = q_e\phi_m - q_e\chi_s - q_e\frac{\delta Q_{ss}}{\epsilon_i}. \tag{15.92}$$

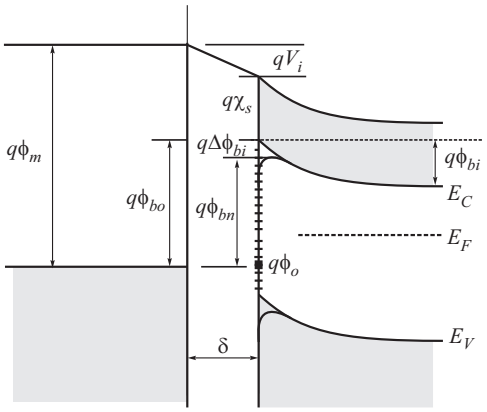

Figure 15.16. Band conditions for an n-type pinned Schottky barrier, showing the neutral level $q_e\phi_o$, below which states are filled and above which states are empty. The shaded regions indicate energy bands with allowed states.

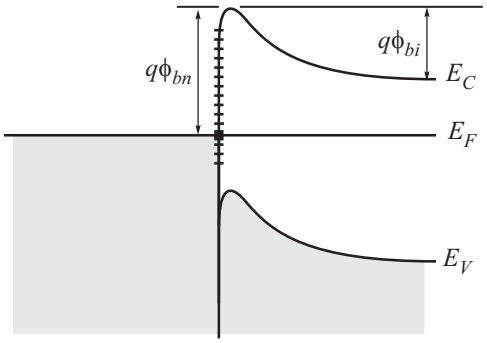

Figure 15.17. Band conditions for an n-type pinned Schottky barrier, showing the Fermi energy pinned at the neutral level $q_e\phi_o$.

Substitution for Q_{ss} from Eq. (15.88) gives

$$q_e\phi_{bo} = q_e\phi_m - q_e\chi_s + \frac{q_e\delta D_s\left[E_g - q_e\Delta\phi_{bi} - q_e\phi_{bn} - q_e\phi_0\right]}{\epsilon_i}. \tag{15.93}$$

Define $\zeta \equiv \epsilon_i/(\epsilon_i + q_e\delta_i D_s)$, and substitute it into Eq. (15.93) to obtain

$$\phi_{bo} = q_e\phi_{bn} + \Delta\phi_{bi} = \zeta(\phi_m - \chi_s) + (1-\zeta)\left(\frac{E_g}{q_e} - \phi_o\right). \tag{15.94}$$

As the width δ of the thin interface insulator decreases to zero, $\zeta \to 1$ and Eq. (15.94) reduces to

$$\phi_{bn} = \phi_m - \chi_s - \Delta\phi_{bi}, \tag{15.95}$$

which is the expected result of Eq. (15.87) found earlier. If the surface state density becomes large, then $\zeta \to 0$ and Eq. (15.94) becomes

$$\phi_{bn} = \frac{E_g}{q_e} - \phi_o - \Delta\phi_{bi}. \tag{15.96}$$

The barrier height is no longer a function of the Fermi energy, but is instead a function of the neutral surface state energy. Note that the neutral level may not be at the same energy as the bulk Fermi energy. The Fermi level in the semiconductor bulk must remain constant under equilibrium conditions, hence, if E_o is below E_{Fs}, the bands must bend up (as shown in Fig. 15.17) until the Fermi level is aligned with E_o. If the neutral level E_o is above E_{Fs}, then the energy bands must move downwards. In Fig. 15.18 the interface states and band conditions are shown for n-type and p-type Schottky barriers.

Depletion Region

The electric field and the depletion region width can be calculated from the one-dimensional Poisson's equation

$$\frac{d^2\psi}{dx^2} = -\frac{d\mathcal{E}(x)}{dx} = -\frac{\rho_c(x)}{\epsilon_s}, \tag{15.97}$$

where $\psi(x)$ is the voltage or potential in the device. Thus, Eq. (15.97) for n-type material becomes

$$\frac{d^2\psi(x)}{dx^2} = -\frac{d\mathcal{E}(x)}{dx} = -\frac{q_eN_D^+}{\epsilon_s}, \tag{15.98}$$

and for p-type material

$$\frac{d^2\psi(x)}{dx^2} = -\frac{d\mathcal{E}(x)}{dx} = \frac{q_eN_A^-}{\epsilon_s}. \tag{15.99}$$

At room temperature, it is reasonable to assume that the shallow dopants are fully ionized, i.e., $N_A^- \simeq N_A$ and $N_D^+ \simeq N_D$. For an n-type Schottky contact, the electric field is

$$\mathcal{E}(x) = \int \frac{d\mathcal{E}(x)}{dx}\,dx = \int \frac{q_eN_D}{\epsilon_s}dx = \frac{q_eN_D}{\epsilon_s}x + C. \tag{15.100}$$

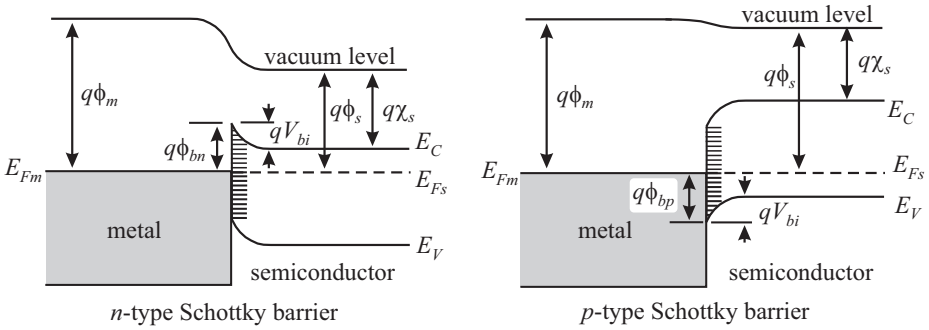

Figure 15.18. Interface states and band conditions for n-type and p-type "pinned" Schottky barriers.

With the boundary condition $\mathcal{E}(x_n) = 0$, the integration constant C in the above result is found to be $C = -(q_e N_D x_n)/\epsilon_s$, and the electric field is thus

$$\mathcal{E}(x) = \frac{q_e N_D}{\epsilon_s}(x - x_n). \tag{15.101}$$

The built-in potential is then evaluated as

$$V_{bi} = -\int_0^{x_n} \mathcal{E}(x)dx = -\int_0^{x_n} \frac{q_e N_D}{\epsilon_s}(x - x_n)dx = \frac{q_e N_D x_n^2}{2\epsilon_s}. \tag{15.102}$$

Rearrangement of terms and inclusion of a reverse bias voltage yield the width of the depletion region as

$$W = \left\{\frac{2\epsilon_s(V_{bi} - V)}{q_e N_D}\right\}^{1/2}, \tag{15.103}$$

a result similar to that for a one-sided abrupt pn junction.

For p-type Schottky junctions, it can be shown in a similar fashion

$$\mathcal{E}(x) = \frac{q_e N_A}{\epsilon_s}(x_p - x), \tag{15.104}$$

and

$$W = \left\{\frac{2\epsilon_s(V_{bi} - V)}{q_e N_A}\right\}^{1/2}. \tag{15.105}$$

Just as Eq. (15.59) can be rewritten as Eq. (15.61), Eqs. (15.103) and (15.105) can be rewritten as

$$W \simeq \{2\epsilon_s \mu_s \rho_s (V_{bi} - V)\}^{1/2}. \tag{15.106}$$

The value of V_{bi} for common Schottky diodes is 0.3 volts. Note that Schottky contacts can be formed on n-type or p-type semiconductors, as depicted in Fig. 15.19. Besides being simple to construct, Schottky barrier detectors have a thin entrance region at the contact, unlike most pn and pin diodes, and energy attenuation in this "dead region" is kept to a minimum. As a result, Schottky barrier detectors (sometimes called "surface barrier detectors") are useful as charged-particle spectrometers.

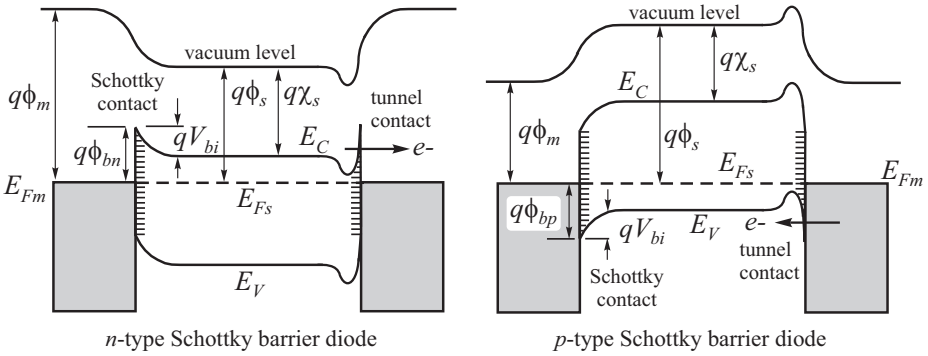

Figure 15.19. Interface states alter the interface potentials and effectively "pin" the Schottky barrier. Shown are n-type and p-type Schottky barriers, along with n-type and p-type tunneling ohmic contacts.

Current Under Forward Bias

The current density of a Schottky barrier rectifying junction can be written as [Rhoderick and Williams 1988]

$$J = J_s \left(\exp\left[\frac{q_e V}{kT} \right] - 1 \right), \tag{15.107}$$

and

$$J_s = A^* T^2 \exp\left[-\frac{q_e \phi_{bn}}{kT} \right]. \tag{15.108}$$

and A^* is the effective Richardson constant. Under forward bias, the majority carrier concentration is elevated in energy above the semiconductor barrier ϕ_{bi}, thereby allowing a non-linear supply of electrons to diffuse across the junction.

In the case that the Schottky barrier height is affected by a bias voltage, an additional change must be included

$$\phi'_{bn} = \phi_m - \chi_s - \Delta\phi_{bi} + \beta V = \phi_{bn} + \beta V, \tag{15.109}$$

where the coefficient β is positive for forward bias [Rhoderick and Williams 1988]. Substituting ϕ'_{bn} for ϕ_{bn} into Eq. (15.107) yields

$$J = J_s \exp\left[\frac{-\beta q_e V}{kT} \right] \left(\exp\left[\frac{q_e V}{kT} \right] - 1 \right), \tag{15.110}$$

The *ideality factor* is defined as

$$\breve{n} = \frac{1}{1-\beta}, \tag{15.111}$$

which, upon substitution into Eq. (15.110), yields

$$J = J_s \exp\left[\frac{q_e V}{\breve{n} kT} \right] \left(1 - \exp\left[\frac{-q_e V}{kT} \right] \right). \tag{15.112}$$

For large values of V ($> 3kT/q_e$), Eq. (15.112) can be approximated by

$$J \approx J_s \exp\left[\frac{q_e V}{\breve{n} kT} \right]. \tag{15.113}$$

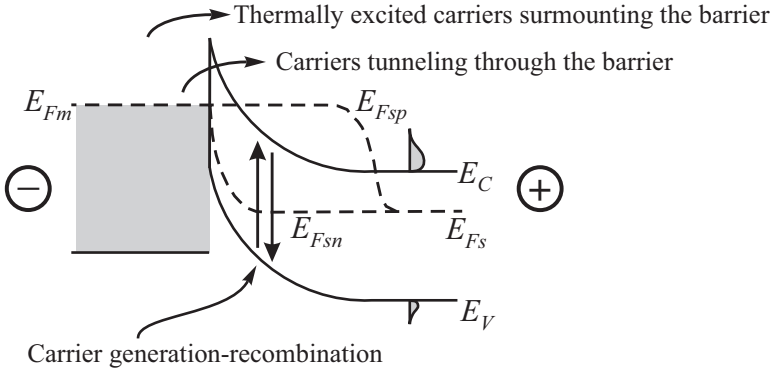

Figure 15.20. Energy band diagram for an n-type Schottky contact under reverse bias.

Reverse Leakage Current Under Reverse Bias

Sources of leakage current are shown in Fig. 15.20. Unlike the *pn* junction device, there is no supply of "minority" carriers at the junction boundary. Instead, there is a reservoir of free electrons from the metal, which must surmount the energy barrier before they can enter the semiconductor. Hence, the reverse bias for a Schottky barrier is a function of the barrier height ϕ_{bn}. Under reverse bias, these charge carriers (electrons) can be elevated by thermionic emission over barrier and contribute to the leakage current. A similar situation occurs for holes with a p-type Schottky contact. Leakage current can also occur from thermal generation of electrons directly across the band gap into the conduction band, producing electron and hole free carriers. Similar to the *pn* junction device, thermal generation can be suppressed by cooling the device while under operation. Finally, under high voltage bias conditions, charge carriers can tunnel quantum mechanically directly through the energy barrier, thereby also contributing to the leakage current.

Junction Breakdown

In Sec. 14.2.3, the concept of diode breakdown was briefly discussed as an introduction to SPAD and SiPM light detection devices. The phenomenon of breakdown can also be observed in semiconductor diodes such as *pn*, *pin*, and Schottky devices. Breakdown can be recognized as a tremendous increase in leakage current at bias voltages past a specific threshold. Two mechanisms can describe this junction breakdown, namely, *tunneling* and *avalanche* breakdown.

Tunneling Breakdown Under high reverse bias conditions, it is possible to cause such band bending across a *pn* junction that electrons can tunnel directly from the valence band into the conduction band. Such a condition is shown in Fig. 15.10 as a potential source of leakage current. In some circumstances, *pn* junction diodes are fabricated with relatively high dopant concentrations with the intentional purpose of causing this kind of breakdown. Such devices are called *Zener diodes*,[4] and are commonly used for overvoltage circuit protection. Typically, electric fields exceeding 10^6 V cm^{-1} are needed to achieve the band bending required for Zener breakdown in specially designed highly doped *pn* junctions [Grove 1967]. Radiation detectors are usually fabricated from high purity materials, and Zener breakdown is usually not reached before other breakdown mechanisms are reached. Other breakdown mechanisms are usually of more concern.

Avalanche Breakdown The topic of avalanche breakdown was discussed earlier in Sec. 14.2.3. Indeed, some light detection devices were seen to rely upon this effect for gain. However, avalanche breakdown can become a source of unwanted noise and can also cause irreparable damage to semiconductor detectors. The

[4]Named after Clarence M. Zener who discovered the effect.

breakdown occurs when electrons gain enough kinetic energy from an applied electric field such that some of their energy can be transferred to the lattice and excite more electrons into the conduction band.

Consider a uniformly doped semiconductor upon which is formed an abrupt one-sided rectifying junction. From Eqs. (15.50) and (15.52), the general expression for the applied voltage is

$$V = \int_0^W \mathcal{E}(x)dx = \int_0^W \frac{q_e N_b W}{\kappa\epsilon_o}\left(\frac{x}{W} - 1\right)dx = -\mathcal{E}_{max}\frac{W}{2}, \tag{15.114}$$

where N_b is the doping concentration of the lower doped side and W is the depletion width. Suppose that $\mathcal{E}_{max}$ is the critical field required for avalanche breakdown. Then the magnitude of the breakdown electric field is

$$|\mathcal{E}_{crit}| = \frac{2V_B}{W} = \frac{2(V_{bi} - V_{rev})}{W}, \tag{15.115}$$

where V_B is the breakdown voltage and V_{rev} is the applied reverse voltage. Substitution of the one-sided depletion approximation into Eq. (15.115) yields

$$V_B = V_{bi} - V_{rev} = \frac{\mathcal{E}_{crit}^2 \kappa\epsilon_o}{2q_e N_b}. \tag{15.116}$$

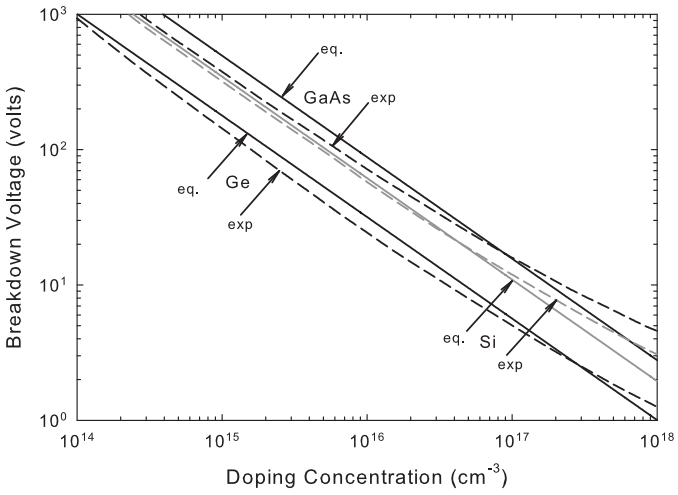

Figure 15.21. Avalanche breakdown voltage as a function of doping concentration for an abrupt one-sided *pn* junction diode. A comparison is made between the data of Sze and Gibbons [1966a] and the empirical formula of Eq. (15.116).

The breakdown voltage of Si, Ge, and GaAs as a function of background doping concentration was studied by Sze and Gibbons [1966a] and the experimental measurement results shown in Fig. 15.21. Sze and Gibbons [1966a] offer the following empirical relation to estimate the breakdown voltage

$$V_B \simeq 60\left(\frac{E_g}{1.1}\right)^{3/2}\left(\frac{N_b}{10^{16}}\right)^{-3/4} \text{ in volts}, \tag{15.117}$$

where N_b is the background impurity concentration and E_g is the band-gap energy in electron volts. A comparison of Eq. (15.117) with the measured data is also shown in Fig. 15.21. It appears that Eq. (15.117) yields acceptable results for background doping concentrations below 10^{17} cm^{-3}, but is less accurate at higher doping levels. It is shown in Fig. 15.21 and also Eq. (15.117) that the breakdown voltage increases with band-gap energy. Intuitively, this observation makes sense, because wider band-gap materials require more energy, on average, to produce an electron-hole pair than do narrow band-gap materials.

Another breakdown mechanism is a lowering of the breakdown voltage from rounded junction interfaces. When dopants are introduced into substrates, the contact pattern is often defined by photolithography methods. Doped patterns of specific size and shape are defined by windows etched through diffusion masks, commonly a layer of SiO_2 or other high-temperature insulator. Dopants are introduced by various methods, including diffusion and implantation (for details, see Sze [VLSI 1985 and others]). These dopants are heated to high temperatures to drive them into the substrate, and in doing so, they diffuse from high to low concentrations. Consequently, at the pattern edges, it is usually the case that the junction interface becomes

rounded in a semi-cylindrical volume, with radius r_j, as the dopants diffuse laterally from the point of introduction. At the pattern corners, the combined edges form a hemispherical interface. Recall from Sec. 8.7 and Sec. 8.8 that the electric field is higher at the smaller terminal than the larger terminal for cylindrical and hemispherical geometries. Hence, the electric field formed around the pattern edges is higher than expected with a simple planar *pn* junction. The overall effect is to lower the breakdown voltage of the *pn* junction [Armstrong 1957]. Reported results by Sze and Gibbons [1966b] on Si diodes with different junction curvatures are shown in Fig. 15.22.

Ghandhi [1977] offers an empirical relation to determine the breakdown voltages V_{JB} of curved junctions in Si abrupt one-sided *pn* junctions. For cylindrical junctions

$$\frac{V_{JB}}{V_B} = 0.5(\eta^2 + 2\eta^{6/7}) \ln(1 + 2\eta^{-8/7}) - \eta^{6/7}, \tag{15.118}$$

and for spherical junctions

$$\frac{V_{JB}}{V_B} = \eta^2 + 2.14\eta^{6/7} - (\eta^3 + 3\eta^{13/7})^{2/3}, \tag{15.119}$$

where V_B is the breakdown voltage for the dopant concentration and

$$\eta = \frac{r_j}{W} \tag{15.120}$$

where W is the depletion width of the material at V_B and r_j is the radius of curvature. The results from Eqs. (15.118) and (15.119) are shown in Fig. 15.23.

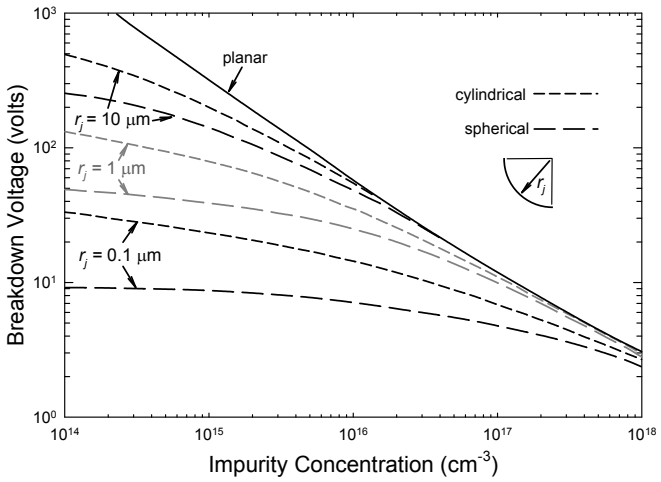

Figure 15.22. Breakdown voltage versus impurity concentration for one-sided abrupt junction Si diodes with different cylindrical and spherical curvatures. Data from Sze and Gibbons [1966b].

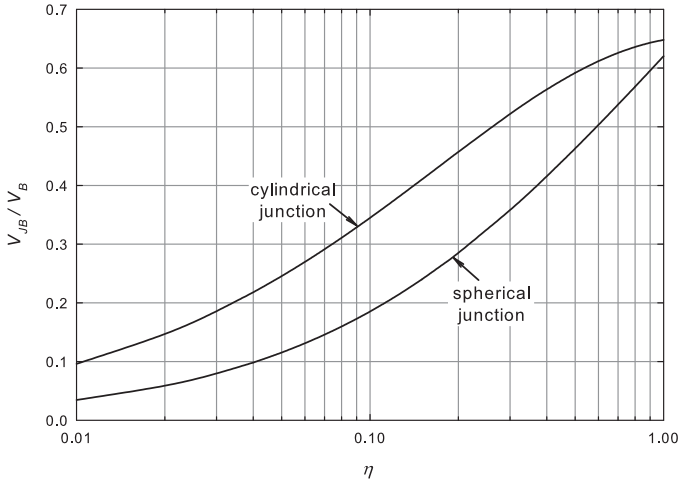

Figure 15.23. Normalized junction breakdown (V_{JB}/V_B) as a function of $\eta = r_j/W$ for cylindrical and hemispherical junctions in Si. After Ghandhi [1977].

Example 15.4: An abrupt p-type junction is diffused into a silicon substrate having an n-type background concentration of 10^{15} cm^{-3}. The edges are cylindrical with a radius of curvature equal to 1 micron. What is the junction breakdown voltage?

Solution:

First find the breakdown voltage from Eq. (15.117).

$$V_B \simeq 60\left(\frac{E_g}{1.1}\right)^{3/2}\left(\frac{N_B}{10^{16}}\right)^{-3/4} = 60\left(\frac{1.12\text{ eV}}{1.1}\right)^{3/2}\left(\frac{10^{15}}{10^{16}}\right)^{-3/4} = 346.65\text{V}.$$

Next find the depletion width at V_B.

$$W = \sqrt{\frac{2\kappa\epsilon_o V_B}{q_e N_b}} = \sqrt{\frac{2(11.9)(8.854\times10^{-14}\text{ F/cm})(346.65\text{ V})}{(1.6\times10^{-19}\text{ C})(10^{15}\text{ cm}^{-3})}} = 0.00214\text{ cm}.$$

Determine the value of η from Eq. (15.118),

$$\frac{V_{JB}}{V_B} = 0.5(\eta^2+2\eta^{6/7})\ln(1+2\eta^{-8/7}) - \eta^{6/7}$$

$$= 0.5\left[\left(\frac{1\ \mu\text{m}}{21.4\ \mu\text{m}}\right)^2 + 2\left(\frac{1\ \mu\text{m}}{21.4\ \mu\text{m}}\right)^{6/7}\right]\ln\left[1+2\left(\frac{1\ \mu\text{m}}{21.4\ \mu\text{m}}\right)^{-8/7}\right] - \left(\frac{1\ \mu\text{m}}{21.4\ \mu\text{m}}\right)^{6/7} = 0.2369.$$

The junction breakdown voltage is thus determined to be $V_{JB} = 0.2369(346.65\text{ volts}) = 82.12$ volts.

Punch Through Breakdown Semiconductor radiation detectors are usually fabricated from relatively pure materials with low background impurity concentrations. Consequently, it is possible to fully deplete a pn, $p\nu n$, or $p\pi n$ diode, a condition called *punch through*. As the voltage is increased, the maximum electric field also increases at the pn junction. At high enough voltages, the electric field reaches the critical field required for avalanching and reach a condition named *punch through breakdown*.

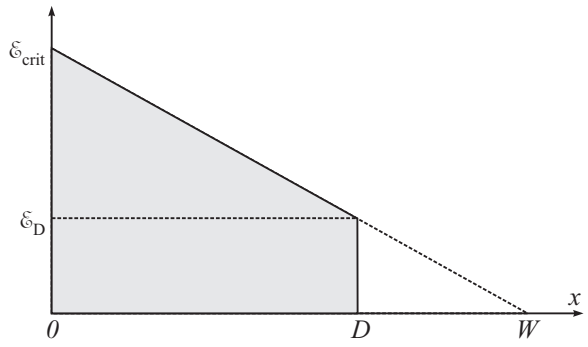

Figure 15.24. The breakdown electric field is a function of the background doping and space charge. The integral of the electric field as a function of x yields the resulting breakdown voltage, which is also a function of the substrate width.

Consider Fig. 15.24, in which an ideal electric field is depicted for an abrupt one-sided junction for a uniformly doped substrate. For a relatively thick substrate, a depletion width W is reached at the required breakdown electric field $\mathcal{E}_{crit}$, where W can be found with Eq. (15.115). The breakdown voltage V_B is described by Eq. (15.116) and can be estimated by Eq. (15.117); hence $\mathcal{E}_{crit}$ can be determined.

If instead the width of the substrate is less than W, labeled D in Fig. 15.24, the integral of the electric field yields the applied voltage, depicted by the shaded area of Fig. 15.24,

$$V = \int_0^D \mathcal{E}(x)dx.$$

Recall that the solution for the electric field in a uniformly doped pn junction yields a simple linear equation, shown in Eq. (15.50) with slope $(q_e N_b)/(\kappa\epsilon_o)$. Using simple geometric analysis with Fig. 15.24, the punch through breakdown voltage V_{BP} is

$$V_{BP} = V_B \frac{(\mathcal{E}_{crit}+\mathcal{E}_D)D}{2}\frac{2}{\mathcal{E}_{crit}W} = V_B\frac{D}{W}\left[2-\frac{D}{W}\right]. \tag{15.121}$$

Insertion of Eq. (15.59) and the relation $V_{bi}-V = V_B$ yields

$$V_{BP} = V_B D\sqrt{\frac{q_e N_b}{2\kappa\epsilon_o V_B}}\left[2 - D\sqrt{\frac{q_e N_b}{2\kappa\epsilon_o V_B}}\right]. \tag{15.122}$$

Shown in Fig. 15.25 are the dependences of V_{BP} on doping concentration for several values of D for silicon diodes.

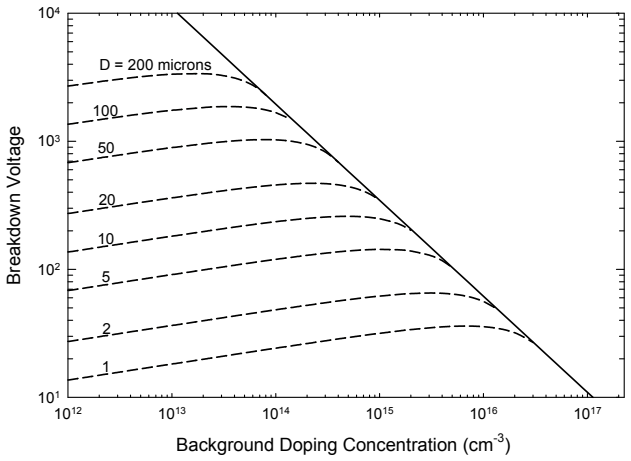

Figure 15.25. Breakdown voltage for Si $p\nu n$ and $p\pi n$ diodes as a function of background doping concentration and substrate thickness determined from Eq. (15.117) and Eq. (15.122).

Example 15.5: Given a 100-micron thick silicon $p\nu n$ diode with $N_A = 10^{15}$ cm^{-3}, $N_d = 10^{14}$ cm^{-3}, and $N_D = 10^{15}$ cm^{-3}, what is the punch through breakdown voltage?

Solution:

First find V_B by estimating the value with Eq. (15.117) or reading from the graph in Fig. 15.21.

$$V_B \simeq 60\left(\frac{E_g}{1.1}\right)^{3/2}\left(\frac{N_B}{10^{16}}\right)^{-3/4} = 60\left(\frac{1.12\text{ eV}}{1.1}\right)^{3/2}\left(\frac{10^{14}}{10^{16}}\right)^{-3/4} = 1949\text{V}.$$

At a voltage bias of 1949 volts, the expected depletion width is,

$$W = \sqrt{\frac{2\kappa\epsilon_o V_B}{q_e N_b}} = \sqrt{\frac{2(11.9)(8.854\times10^{-14}\text{ F/cm})(1949\text{ V})}{(1.6\times10^{-19}\text{ C})(10^{14}\text{ cm}^{-3})}} = 0.016\text{ cm}.$$

Consequently, at V_B, the diode is fully depleted and punched through. The punch through breakdown voltage is found with Eq. (15.121),

$$\begin{aligned} V_{BP} &= V_B\frac{D}{W}\left[2-\frac{D}{W}\right], \\ &= (1949\text{ V})\frac{0.01\text{ cm}}{0.016\text{ cm}}\left[2-\frac{0.01\text{ cm}}{0.016\text{ cm}}\right], \\ &= 1674.9\text{ V}. \end{aligned}$$

The punch through breakdown voltage V_{BP} is 85.94% of the breakdown voltage V_B.

15.3.4 The MOS Structure

Another common semiconductor device structure is the metal-oxide-semiconductor (MOS) capacitor. Radiation detectors usually do not have these structures, but there are some special radiation detection devices that operate with MOS capacitors. For that reason, this design and the operating physics are briefly discussed here. A MOS structure has three basic components, the semiconductor, the insulating oxide layer and a metallic gate upon the oxide as shown in Fig. 15.26. The MOS field effect transistor, or MOS-FET, also has an injecting source contact and a receiving drain contact.

An ideal MOS capacitor can be described as a structure in which both the metal work function ϕ_m and the semiconductor work function ϕ_s are equal, i.e.,

$$q_e\phi_m - q_e\phi_s = q_e\phi_m - q_e\chi_s - \frac{E_g}{2} - |q_e\psi_B| = 0, \quad \text{for } p\text{-type}, \tag{15.123}$$

and

$$q_e\phi_m - q_e\phi_s = q_e\phi_m - q_e\chi_s - \frac{E_g}{2} + |q_e\psi_B| = 0, \quad \text{for } n\text{-type}. \tag{15.124}$$

The MOS band structures for p-type and n-type substrates are depicted in Fig. 15.27. Hence, at zero voltage, the band structures have constant energy so they are flat. Further, the insulating oxide region of an ideal MOS device has no space charge imperfections and so there is no trapped charge at the oxide-semiconductor interface. Finally, the oxide acts as a perfect insulating barrier and no leakage current penetrates the oxide during operation. These conditions define an *ideal* MOS capacitor.

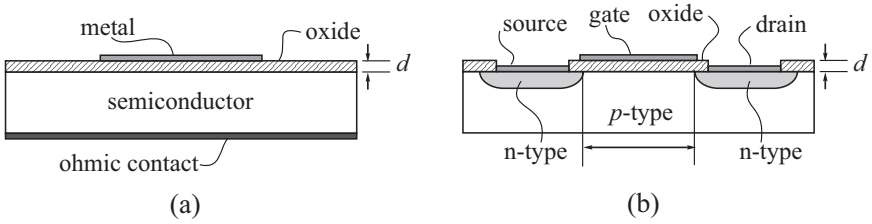

Figure 15.26. Cross section depiction of the main structural components of a (a) MOS capacitor and a (b) MOS field effect transistor.

The band structure of an ideal p-substrate MOS capacitor under bias is depicted in Fig. 15.28. Note that, because the oxide is a "perfect" insulator, no current can flow across the barrier, hence the Fermi energy level remains flat even under bias. If a net negative bias is applied to the gate metal, then the energy bands bend upwards, as shown in Fig. 15.28(a), and a potential well forms at the interface. The concentration of the majority carrier holes is

$$p_p = n_i \exp\left[\frac{E_i - E_{F_s}}{kT}\right], \tag{15.125}$$

and at the oxide-semiconductor interface $E_i - E_F$ becomes relatively large. Consequently, holes gather at the interface, a condition termed *accumulation*. A similar case occurs on a n-type substrate under positive bias in which the majority carriers are electrons which accumulate at the interface so that

$$n_n = n_i \exp\left[\frac{E_{F_s} - E_i}{kT}\right]. \tag{15.126}$$

Likewise the application of a small positive bias on the gate of a p-type MOS capacitor causes the energy bands to bend downwards, ultimately reducing the number of holes at the interface, thereby causing

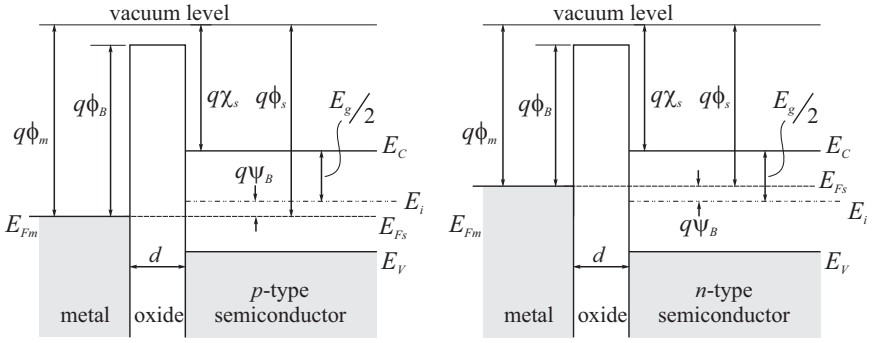

Figure 15.27. Energy band diagrams of *ideal* p-type and n-type MOS structures.

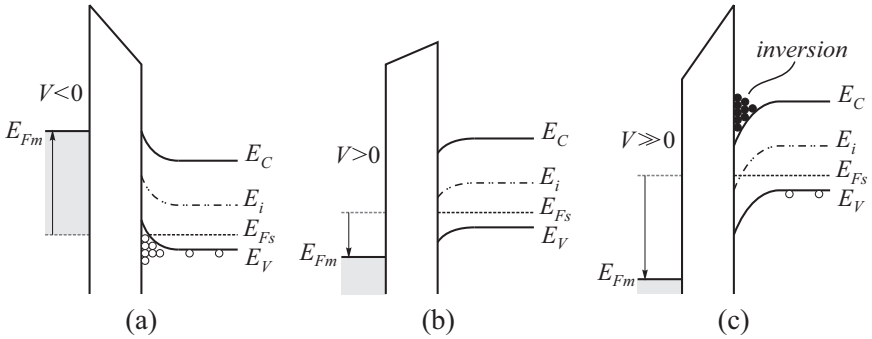

Figure 15.28. Energy band diagrams for an ideal p-type MOS structure under bias. (a) The band structure with the gate at negative voltage, termed *accumulation*. (b) The band structure with the gate at positive voltage, termed *depletion*. (c) The band structure with the gate at a large positive voltage, termed *inversion*.

a depletion region to form at the oxide-semiconductor interface. The depletion depth W is a function of the voltage and also the background doping concentration of the semiconductor substrate, where the space charge per unit area is approximated by

$$Q_{sc} = -q_e N_A W, \tag{15.127}$$

for a p-type substrate. A similar situation occurs if a negative voltage is applied to an n-type substrate so that

$$Q_{sc} = q_e N_D W. \tag{15.128}$$

If a radiation event produces electron-hole pairs in the semiconductor, the electrons accumulate in the potential well at the interface. With a readout contact adjacent to the oxide layer, this charge can be removed and measured, an ability that underlies the operation of the charge-coupled device discussed in the next chapter.

As the positive voltage is increased further, the depletion region continues to increase until the intrinsic Fermi energy E_i is bent down at the interface to the same value of the Fermi energy E_{F_s} in the semiconductor. Increasing the voltage even more causes E_i to cross over E_{F_s} and the Fermi energy approaches the conduction band. The minority electron concentration increases at the interface as

$$n_p = n_i \exp\left[\frac{E_{F_s} - E_i}{kT}\right], \tag{15.129}$$

and causes the p-type material to act as n-type material, an operating condition termed *inversion*. As the bias is increased further, the conduction band E_C eventually comes close to E_{F_s}, and the electron population near the interface increases rapidly. Hence, the charge density confined to a narrow inversion region of width x_i directly under the oxide becomes dominated by the electron population, and not the semiconductor space charge. Consequently, after the inversion layer is formed, additional voltage does not increase the depletion width, but instead tends to increase the electron density that opposes the additional applied voltage. In other words, with strong inversion, the depletion region no longer increases in width with higher voltage. With strong inversion, the total charge per unit area becomes

$$Q_s = -q_e n_p x_i - q_e N_A W_{max}. \tag{15.130}$$

The opposite situation occurs for an n-type substrate, namely

$$Q_s = q_e p_n x_i + q_e N_D W_{max}. \tag{15.131}$$

Consider the diagram of Fig. 15.26(b) under inversion. A electron rich population appears under the oxide connecting the source and drain. Hence, charge can flow across the device while under the inversion condition. Reduction of the voltage on the gate causes the device to return to the depletion condition, effectively stopping the charge flow. This behavior is fundamentally how the MOS-FET operates as a current switch.[5]

The maximum depletion width determines the potential at which the concentration of electrons at the surface is equal to the space charge density of the depleted volume. Here the electrostatic potential ψ is defined as the difference between the intrinsic Fermi energy in the semiconductor bulk (beyond the depletion region) to that near the surface region where the bands are bent so that

$$q_e \psi = E_{i_{bulk}} - E_{i_{bent}}. \tag{15.132}$$

Hence, ψ is zero in the semiconductor bulk. The surface potential is defined as

$$q_e \psi_s = E_{i_{bulk}} - E_{i_{sur}}. \tag{15.133}$$

The surface electron concentration can then be represented as

$$n_{sur} = n_i \exp\left[\frac{q_e(\psi_s - \psi_B)}{kT}\right], \tag{15.134}$$

and the surface hole population as

$$p_{sur} = n_i \exp\left[\frac{q_e(\psi_B - \psi_s)}{kT}\right], \tag{15.135}$$

in which $\psi_B = E_i - E_{F_s}$ in the bulk (see Fig. 15.27). The opposite conditions exist for the n-type substrate.

The potential distribution under the oxide can be calculated from Poisson's equation as [Sze 1981]

$$\psi(x) = \psi_s \left[1 - \frac{x}{W}\right]^2, \tag{15.136}$$

[5] Because the inversion layer behaves as an n-type channel, this type of device is called NMOS, after the type of inversion channel and not the substrate dopant. Similarly, a MOS device formed on an n-type substrate produces a hole-filled p-type inversion channel, and is thus called PMOS. Transistor circuits with complementary pairs of NMOS and PMOS transistors are called CMOS.

where the surface potential is

$$\psi_s = \frac{q_e N_A W^2}{2\kappa_s \epsilon_0}. \tag{15.137}$$

The surface potential at which strong inversion appears is generally accepted as approximately equal to $2\psi_B$ or

$$\psi_{inv} \simeq 2\psi_B = \frac{2kT}{q_e} \ln\left[\frac{N_A}{n_i}\right], \tag{15.138}$$

for p-type substrates, and

$$\psi_{inv} \simeq 2\psi_B = \frac{2kT}{q_e} \ln\left[\frac{N_D}{n_i}\right], \tag{15.139}$$

for n-type substrates. Substitution of Eq. (15.138) into Eq. (15.136) yields

$$W_{max} = \left[\frac{4\kappa_s \epsilon_0 kT}{q_e^2 N_A} \ln\left(\frac{N_A}{n_i}\right)\right]^{1/2}, \tag{15.140}$$

for p-type substrates where, from Eq. (15.127),

$$Q_{sc} = -q_e N_A W = -\left[4N_A \kappa_s \epsilon_0 kT \ln\left(\frac{N_A}{n_i}\right)\right]^{1/2} = -\left[4q_e N_A \kappa_s \epsilon_0 \psi_B\right]^{1/2}. \tag{15.141}$$

Similarly, for n-type substrates

$$W_{max} = \left[\frac{4\kappa_s \epsilon_0 kT}{q_e^2 N_D} \ln\left(\frac{N_D}{n_i}\right)\right]^{1/2}, \tag{15.142}$$

and

$$Q_{sc} = q_e N_D W = \left[4N_A \kappa_s \epsilon_0 kT \ln\left(\frac{N_D}{n_i}\right)\right]^{1/2} = \left[4q_e N_D \kappa_s \epsilon_0 \psi_B\right]^{1/2}. \tag{15.143}$$

Another important measure is the threshold voltage at deep inversion. Note that the potential applied to the gate drops partially through the oxide layer. Hence, the total voltage required to reach deep inversion includes both the voltage across the oxide V_o and the depletion region ψ_s, i.e., $V_G = V_o + \psi_s$. The capacitance per unit area across the oxide is defined as

$$C_o = \frac{\kappa_o \epsilon_0}{d}, \tag{15.144}$$

where d is the oxide thickness. Hence, the threshold voltage V_T becomes

$$V_T = \frac{-Q_{sc}}{C_o} + 2\psi_B = \left[\frac{4d^2 q_e N_A \kappa_s \psi_B}{\kappa_o^2 \epsilon_0}\right]^{1/2} + 2\psi_B. \tag{15.145}$$

or for n-type substrates

$$V_T = -\left[\frac{4d^2 q_e N_D \kappa_s \psi_B}{\kappa_o^2 \epsilon_0}\right]^{1/2} - 2\psi_B. \tag{15.146}$$

There are a few important features that can be gleaned from this simple ideal example. First, the maximum depletion region possible for a MOS structure is approximately proportional to the inverse of $\sqrt{N_{A,D}}$. Second, the threshold voltage for deep inversion increases with substrate background dopant concentration and oxide thickness. Third, the capacitance per unit area increases as the oxide thickness d is decreased.

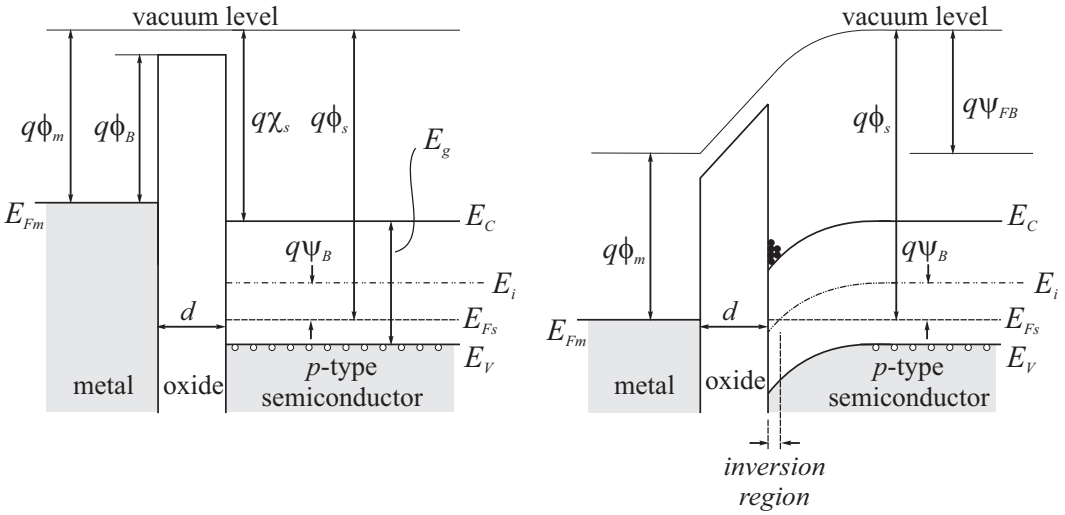

Figure 15.29. Energy band diagram for a more realistic p-type MOS structure. (left) The structure before equilibrium and (right) after equilibrium with a constant Fermi energy level.

However, there are additional properties of a common MOS device that are important to understand in order to use a MOS device in radiation detection applications. First, seldom are the work functions of both the metal and semiconductor equal. Second, impurities and defects in the oxide and at the oxide-semiconductor interface can produce space charge, which, in turn, affects the operating potentials of the device. Consider the diagram of Fig. 15.29 for a p-type substrate MOS structure. The work function of the metal is somewhat less than the semiconductor. As the materials are brought into contact, the bands bend to produce a flat Fermi energy, as shown in Fig. 15.29(right). Hence, to flatten the bands, a negative voltage must be applied to straighten the bands. This voltage is termed the *flat-band voltage* V_{FB}. The flat-band voltage must adjust for the difference in the work function $(\phi_m - \phi_s)$ and the oxide space charge (Q_{sc}), i.e.,

$$V_{FB} = q_e(\phi_m - \phi_s) + \frac{Q_{sc}}{C_o}. \tag{15.147}$$

The operating gate voltage must be adjusted to account for the flat-band voltage as

$$V_G' = V_G - V_{FB}, \tag{15.148}$$

and the threshold for the onset of deep inversion becomes

$$V_T' = V_T - V_{FB}. \tag{15.149}$$

Hence, it is possible that the device is in an inversion condition at zero voltage. It should be noted that the operating potential V_G changes as Q_{sc} changes, which is a major concern for MOS devices operated in a radiation environment. This space charge can arise from many sources, including interface trapped charge, fixed oxide charges, mobile ions, and trapped charges. Interface charge is a function of the semiconductor surface type and preparation. The $\langle 100 \rangle$ Si surface generally has the lowest density of surface states and is preferred over a $\langle 111 \rangle$ Si surface for MOS devices [Sze 1981]. Contamination of the oxide can produce a strong electric field which moves any mobile charges. Contamination from alkali metals, such as Na^+ ions, is often a source of mobile charges. Fixed charge, usually positive, is caused by oxide defects near the oxide-semiconductor surface and cannot be eliminated once formed. Finally, trapped charge is produced as a result

of radiation damage, usually from charged particles and x-ray irradiation. As the trapped charge increases, the voltage required to operate the device increases, ultimately causing catastrophic failure. Dopant type inversion can also occur in the semiconductor, especially under neutron irradiation, where transmutation activation can change the semiconductor work function over time.

15.3.5 Ohmic Contacts

Efficient charge carrier extraction from a semiconductor detector requires ohmic-like contacts; hence, it can be important that the metal/semiconductor interface *not* form a rectifying potential barrier. For instance, metal contacts to the n and p regions of pn and pin detectors are constructed so as to be non-rectifying or *ohmic*, i.e., they have a current-voltage relationship that satisfies Ohm's Law. For "ideal" ohmic contacts, a careful choice of metals upon a selected semiconductor can produce a non-rectifying junction. Unfortunately, because of interface state pinning, a potential barrier is formed when almost any metal is applied to the surface of semiconductors. To remedy this problem, degenerate doping is applied with the metal and diffused, typically through thermal treatment, into the semiconductor. The process causes the Schottky barrier to become extremely thin such that electrons can tunnel directly through the barrier, thereby producing a contact with ohmic behavior.

Schottky diodes are typically constructed with one (or more) Schottky contact used as a rectifying barrier to reduce leakage current and one (or more) opposing ohmic contact to allow more efficient carrier extraction, thereby reducing electronic noise (see depiction in Fig. 15.19).

Ideal Ohmic Contacts

Consider the case in which the work function of the metal is smaller than the work function of an n-type semiconductor, as is shown in the left-hand part of Fig. 15.30. In order for the Fermi energies in the metal and semiconductor to align, the semiconductor energy bands bend downward, as shown in Fig. 15.31. For p-type material, the metal work function must be larger than the semiconductor work function, in which case the bands bend upwards, as is depicted in the right-hand portion of Fig. 15.31.

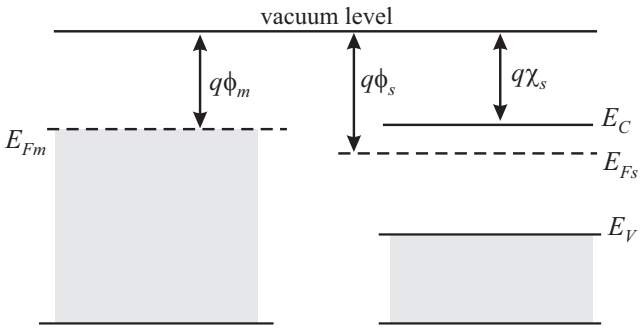

Figure 15.30. Energy band conditions for an ideal n-type ohmic contact.

For the n-type ohmic contact, electrons in the conduction band no longer encounter an energy barrier when drifting into the metal contact. Similarly, the holes no longer encounter and energy barrier at the metal-semiconductor interface. In both cases, the contact and resulting device have a linear current-voltage (IV) relationship that follows Ohm's law.

Tunneling Ohmic Contacts

As mentioned before, semiconductor surfaces typically have defects and impurity contamination. These imperfections may arise from the cutting and polishing processes that are usually incorporated during detector fabrication. Although subsequent liberal surface etching can remove much of the damage, sufficient surface damage usually remains that "pins" the energy barrier at the metal/semiconductor interface. Hence, the above ideal model of the ohmic contacts rarely applies.

Ohmic contacts can be made, however, by introducing degenerate doping at the semiconductor surface before or during the metal contact application, with degenerate n-type dopant levels introduced to n-type material and degenerate p-type dopant levels introduced to p-type material. The dopant is diffused into the surface, causing the bands to bend strongly at the interface. Although an energy barrier still appears, the

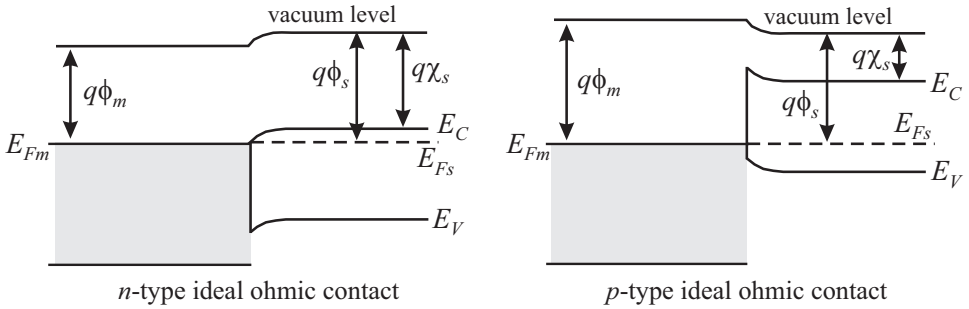

Figure 15.31. Energy band diagrams for ideal n-type and p-type ohmic contacts.

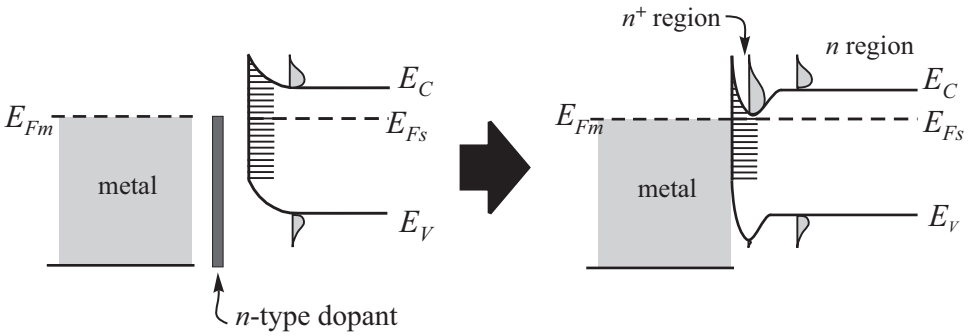

Figure 15.32. Interface states and band conditions for a tunneling n-type ohmic contact.

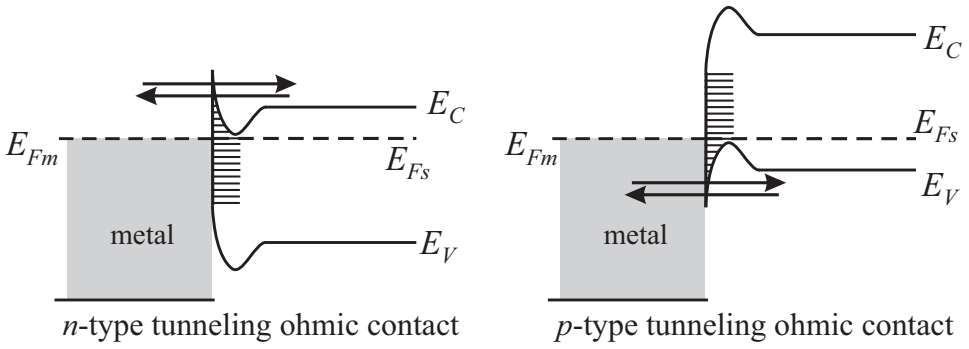

Figure 15.33. Energy band diagrams for n-type and p-type tunneling ohmic contacts.

actual barrier width is relatively small such that the charge carriers can tunnel directly through the barrier. The result is a linear IV relationship that follows Ohm's law. The interface states and energy bands for tunneling ohmic contacts are shown in Fig. 15.32 and Fig. 15.33, respectively.

The degenerate doping may be applied by traditional methods, such as ion implantation or thermal diffusion. Often a metal eutectic, partially composed of an element that is a dopant in the semiconductor, is applied to the surface and annealed so that the dopants become active in the semiconductor surface. Examples include AuGeNi annealed into n-type GaAs and AuZn annealed into p-type GaAs. Here Ge is an

n-type dopant and Zn is a p-type dopant. Often a chemical reaction may produce the desired effects, such as occurs in the application of $AuCl_3$ to p-type CdTe or CdZnTe. The $AuCl_3$ reacts with the Cd, displacing it, and deposits Au in the material, which acts as a p-type dopant.

15.3.6 Series Resistance and Space Charge Effects

Wide band-gap semiconductors are of interest because many can be operated at room temperature without the complications of cryogenic or mechanical cooling. Unfortunately, all of these room temperature semiconductors are compound materials,[6] and consequently, these semiconductors typically have low electrical resistivity from residual background impurities that are difficult to remove, or possess high concentrations of native defects that act as charge carrier donors or acceptors. The resistivity of these interesting materials can be significantly increased by clever additions of deep energy levels. These energy levels can be added through the purposeful introduction of deep dopant impurities or native defect states. The unintentional introduction of impurities and trapping centers and the purposeful introduction of compensating centers, work together to reduce the free charge carrier concentration, and thereby increase the resistivity of the semiconductor (as demonstrated in Chapter 12). These traps and compensating centers can produce space charge in the semiconductor when filled (or emptied, depending on type). The combined effect of series resistance and space charge alters the forward bias current characteristic in a semiconductor device.

However, the traps can cause issues with the internal electric field within the device, under either forward or reverse bias. Under forward bias, the high series resistance of the detector causes a reduction in the observed current, namely

$$J = J_s \left\{ \exp\left[\frac{q_e(V - JRA)}{kT} \right] - 1 \right\}, \tag{15.150}$$

where J_s is the saturation current density, V is the applied voltage, J is the current density, R is the diode forward resistance, and A is the diode effective area. As the resistance R in Eq. (15.150) is increased, the amount of voltage at the rectifying junction decreases, which causes a decrease in the observed current (Fig. 15.34). The result is a gradually rising forward current characteristic, often modeled with a corrective "ideality factor" $\breve{n}$ as

$$J \approx J_s \left\{ \exp\left[\frac{q_e V}{\breve{n} kT} \right] - 1 \right\}, \tag{15.151}$$

and the subsequent results are shown in Fig. 15.35. Rhoderick and Williams [1988] point out that the oft-used Eq. (15.151) in the literature is an incorrect form, and that the more correct form should actually be Eq. (15.112), mainly because of changes in the rectifying barrier physics. However, additional problems from series resistance and space charge limitations render that argument less effective, mainly because forward bias currents are controlled by other mechanisms than just the contact barrier height. Regardless, Eq. (15.151) is an approximation of the observed case.

The general case for electron current flow in an ideal insulating medium is approached with the current density Eq. (15.67). Consider the case in which electrical contacts are applied to an insulating slab, across which is applied a voltage V_0. For general conditions, drift current is substantially higher than the diffusion current. Hence, Eq. (15.67) reduces to

$$J \simeq q_e \mu_n n(x) \mathcal{E}(x). \tag{15.152}$$

If $n(x)$ is uniform, then from Poisson's equation

$$\int \mathcal{E}(x) d\mathcal{E} = \int \frac{J}{\mu_n \epsilon_s} dx, \tag{15.153}$$

[6] Diamond is an exception, but is inadequate as a gamma-ray detector because of the low Z number.

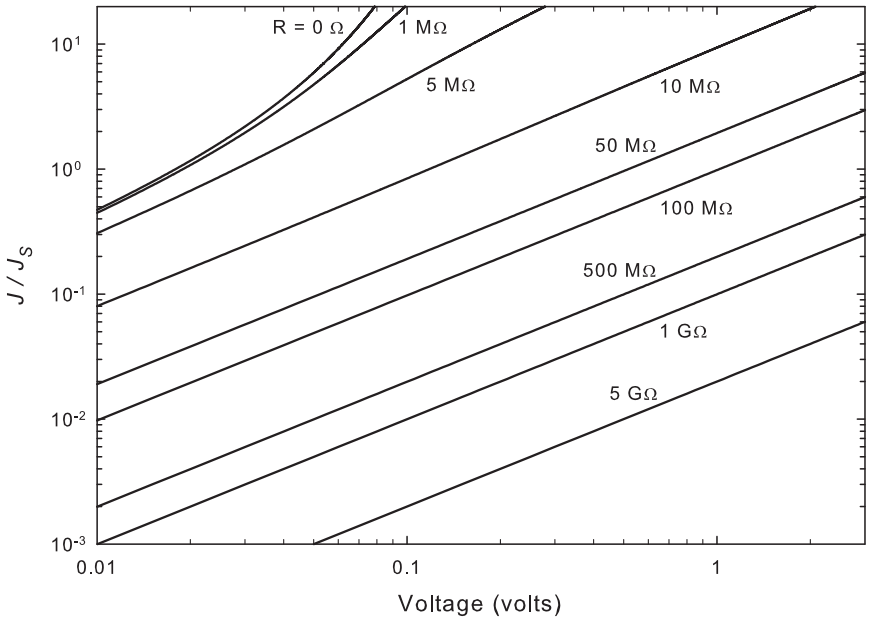

Figure 15.34. The ratio J/J_s plotted as a function of series resistance for the case $J_s = 1$ nA cm^{-2}.

or

$$\mathcal{E}(x) = \left[\frac{2Jx}{\mu_n \epsilon_s} + C\right]^{1/2}, \tag{15.154}$$

where C is an integration constant. For the simplified case, it is assumed that the electric field is zero at the cathode ($x = 0$) [Wright 1959], hence $C = 0$. The voltage drop across the insulating slab is

$$V = \int_0^W \mathcal{E}(x)dx = \int_0^W \left[\frac{2Jx}{\mu_n \epsilon_s}\right]^{1/2} dx = \frac{2}{3}\left[\frac{2J}{\mu_n \epsilon_s}\right]^{1/2} W^{3/2}, \tag{15.155}$$

where W is the slab thickness. Substitution of $i = JA$ and rearrangement of the terms in Eq. (15.155) yields the current

$$i = \frac{9}{8}\frac{\mu_n \epsilon_s A V^2}{W^3}, \tag{15.156}$$

where A is the effective contact area. Eq. (15.156) is known as Child's Law for solids, as developed by Mott and Gurney [1948].[7]

The forward current characteristic can also be affected by space charge buildup from the injected current. As the injected current is increased by the applied bias, the traps in the semiconductor material become filled at a rate high enough to produce a net space charge at steady state. More traps are filled as the forward voltage is increased, a case studied in detail by Rose [1963], Tredgold [1966], Lampert [1956], and Lampert and Mark [1970]. Consider that case in which a semiconductor has a trap density N_T. The voltage at which all traps are filled is similar to the one-sided depletion approximation, i.e., the trap-filled-limit

[7] Eq. (15.156) is also known as the "trap-free square law" or the "Mott-Gurney square law".

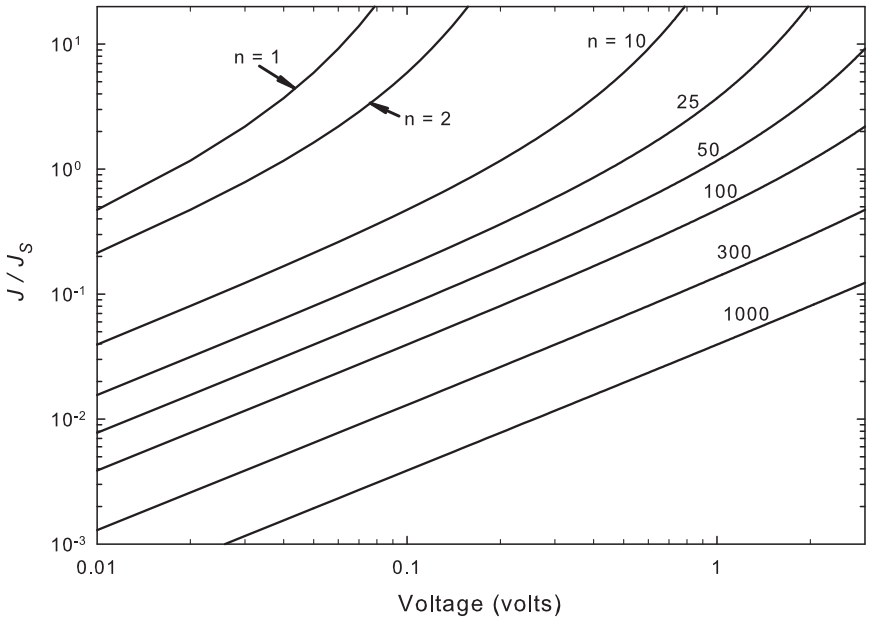

Figure 15.35. The ratio J/J_s plotted as a function of the ideality factor n.

voltage (V_{TFL}) is [Wright 1959]

$$V_{TFL} = \frac{q_e N_T W^2}{2\epsilon_s}. \tag{15.157}$$

Below V_{TFL}, the current is reduced by the trapping effect, which can be shown to be an alteration of Eq. (15.156) [Lampert and Mark 1970]

$$i = \frac{9}{8}\frac{\mu_n \epsilon_s \theta A V^2}{W^3} \tag{15.158}$$

where θ is the fraction of injected charge that is untrapped and remains available for current flow. Eq. (15.158) is referred to as the modified Child's Law. Three regions can usually be observed for space charge limited solids, namely, the ohmic region at very low voltages, the modified Child's Law region (Eq. (15.158)), and the Child's Law region (Eq. (15.156)). At low voltages, the current appears to have an ohmic response, i.e. $i \propto V$. As the voltage is increased, traps begin to fill and produce a space charge region, which affects the electric field and increases current flow ($i \propto V^2$). At V_{TFL} the traps are filled and an abrupt increase appears in the current characteristic from Eq. (15.158) to Eq. (15.156), above which is the full Child's Law region (see Fig. 15.36). This rectifying behavior is due to the overall trap density of the semiconductor (or semi-insulator) rather than a contact barrier or junction chemical potential.

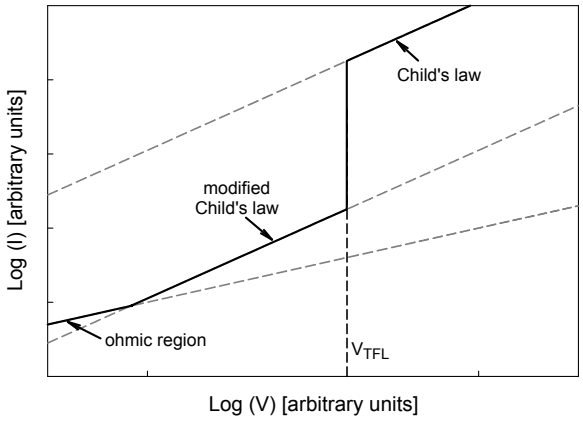

Figure 15.36. Rectifying behavior of space charge limited conduction through a solid.

Note that one of the assumptions with Eq. (15.156) and Eq. (15.158) is that the charge carrier speed is proportional to $\mu\mathcal{E}$, thus yielding one of the voltage terms. At high electric fields the charge carrier speeds saturate and it becomes possible that $i \propto V$ rather than V^2.

15.3.7 Resistive and Photoconductive Devices

There are detectors that operate without rectifying contacts, namely resistive and photoconductive detectors. Resistive detectors have such high resistivity that rectifying barriers are not needed to reduce the leakage current, and photoconductive devices use efficient charge injection to produce photoconductive gain.

Resistive Devices

Semiconductor detectors fabricated from wide band-gap materials (generally > 1.6 eV) have material resistivities high enough to reduce leakage currents to low levels, and, as a result, do not require rectifying contacts to suppress leakage currents. The devices typically have ohmic contacts as electrodes to prevent rectification and the formation of space-charge regions (which limits the active region volume). Radiation interactions in the detectors create electron-hole pairs that are swept out of the detectors by an applied electric field. The high resistivity of the device ensures that the leakage current is significantly lower than the current produced by radiation interactions in the device. For example, the current from a common 5-mm (width) $\times$ 10-mm $\times$ 10-mm CdZnTe detector, with a 1.62-eV band gap and electron mobility of 1350 $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$, has a resistivity of 10^{11} Ω cm, so that the detector has a resistance of 5×10^{10} Ω. At a bias of 500 volts, the electric field is 10^3 V cm^{-1} with a leakage current of 10^{-8} amps. The electron population is found from Eq. (15.152), from which the steady-state charge population is found to be 4.6×10^4 cm^{-3}. Given the volume, the steady-state electron charge population in motion for the detector is 2.3×10^4 cm^{-3}. The average ionization energy of CdZnTe is 5 eV; hence, a 662-keV gamma ray produces approximately 1.32×10^5 electron-hole pairs, thereby increasing the total electron population in the device, momentarily, by 5.74 times. Should the resistivity decrease, the leakage current would add more to the output, whereas an increase in resistivity would decrease the influence of leakage current. Notably, energy resolution degrades from *fluctuations* in the leakage current, which generally increases as the leakage current increases.

Photoconductive Devices

There is a unique class of semiconductor detectors known as photoconductors. To understand how these devices work, consider a semiconductor to which ohmic contacts are affixed that prevent the creation of a blocking barrier and a space-charge region. Such a device is in essence an ohmic resistor. From Eq. (12.90) it is seen that the resistivity of a semiconducting material is inversely proportional to the free carrier concentration. Further, the free carrier concentrations are affected by thermal changes and impurity atoms.

Free carriers are also produced in the semiconductor by gamma-ray interactions. For example, fast electrons are produced as photoelectrons, Compton recoil electrons and, for photons of sufficient energy, as pair production electrons. These fast electrons create many electron-hole pairs as they slow down, producing a small localized charge cloud. Thus, for a single radiation event in a conventional diode detector, the local conductivity is changed spontaneously; however, the small charge cloud is surrounded by higher resistivity material on all sides. Further, the charge cloud is dissipated rapidly by the applied voltage.

Suppose, however, the semiconductor block is saturated with a *radiation pulse*, consisting of a huge number of radiation quanta, such that electron-hole pairs are evenly distributed throughout the crystal bulk. Now, the conductivity of the entire semiconductor block increases because of the large and uniform injection of free carriers throughout the semiconductor crystal. Thus, with a constant applied voltage, the current flowing through the device must increase. After the pulse, the current continues to flow, if the ohmic contacts are well-fabricated, because every electron exiting the device at the anode is replaced by another electron injected at the cathode. This *photocurrent* continues to flow, decaying away as a function of the free charge carriers lifetimes.

A photoconductor consists of a semiconductor material upon which ohmic contacts have been applied. For pure (intrinsic) semiconductors, the conductivity can be described by

$$\sigma = \rho^{-1} = q_e(n\mu_n + p\mu_p), \tag{15.159}$$

where q_e is the unit electronic charge, n is the negative electron population, p is the positive "hole" population, and μ is the mobility of either electrons or holes. Photons interacting with the semiconductor excite electrons into the conduction band and, thus, serve to increase n, p, and the conductivity. The resistance of the material is described by

$$R = \frac{\rho L}{A} = \frac{L}{\sigma A}, \tag{15.160}$$

where L is the effective device length and A is the effective cross sectional area of the device. Hence, the observed current is

$$I = \frac{\sigma A V}{L} = \sigma A \mathcal{E} = q_e A \mathcal{E}(n\mu_n + p\mu_p), \tag{15.161}$$

where V is the applied voltage and $\mathcal{E}$ is the electric field. Note that the photocurrent is a direct function of the charge carrier densities n and p. Suppose that Δn the increase in the electron charge carriers produced by an impulse of light. Hence, $n(t) = n_o + \Delta n \exp(-t/\tau)$, where n_0 is the electron charge carrier population without light, i.e., the dark current. These charge carriers recombine or become trapped, so that charge carriers have a mean lifetime of τ. Under steady-state irradiation, free charge carriers that recombine are regenerated at the same rate, hence the generation rate per unit volume becomes $G = n/\tau$ or

$$\frac{n}{\tau} = \frac{1}{AL}\frac{q_e \eta_Q P_o}{h\nu}, \tag{15.162}$$

where P_o is the optical power density and η_Q is the quantum efficiency.[8] The electron current contribution is found by substituting Eq. (15.161) into Eq. (15.160) to obtain

$$I = I_n + I_p = \frac{(\mu_n \tau_n + \mu_p \tau_p)\mathcal{E}}{L}\frac{q_e \eta_Q P_o}{h\nu}. \tag{15.163}$$

The primary photocurrent is described by

$$I_{prim} = \frac{q_e \eta_Q P_o}{h\nu}, \tag{15.164}$$

which is the contribution to the current from the initial photoelectric excitation. However, because the resistivity changes with irradiation, charge carriers are injected into one contact as they exit the opposite contact, as required by Ohm's law. Hence, the photocurrent gain is [Bube 1960]

$$M_{\rm PC} = \frac{I}{I_{prim}} = \frac{(\mu_n \tau_n + \mu_p \tau_p)\mathcal{E}}{L} = \frac{(v_n \tau_n + v_p \tau_p)}{L} = \frac{\tau_n}{t_n} + \frac{\tau_p}{t_p}, \tag{15.165}$$

where t_n and t_p are the transit times across the device for electrons and holes, respectively. For a single flash of light, from a scintillator for instance, the current is described by

$$I = q_e A \mathcal{E}(\mu_n(n_o + \Delta n e^{-t/\tau_n}) + \mu_p(p_o + \Delta p e^{-t/\tau_p})). \tag{15.166}$$

[8] Here η_Q is defined as the number of electron-hole pairs excited per photon.

The current is largely affected by the excited charge carrier populations Δn and Δp, which eventually return to the dark current density of n_0 and p_0. If the photocurrent is primarily from band to band transitions with $n_0 = p_0$, then Eq. (15.166) reduces to

$$I = q_e A\mathcal{E}(n_o + \Delta n e^{-t/\tau_n})(\mu_n + \mu_p). \tag{15.167}$$

The gain for such a device is dominated by the charge carrier lifetimes. Hence, high speed devices require short lifetimes, whereas high gain devices require long lifetimes. Further, the fluctuation in current can be problematic and leads to poor energy resolution. Consequently, photoconductors are usually not the light sensing device of choice for scintillation detector spectroscopy.

For a planar device, Eq. (15.167) can be rewritten as

$$I(t) = \frac{q_e V A}{L}(n_o + \Delta n e^{-t/\tau_n})(\mu_n + \mu_p). \tag{15.168}$$

This result is important. First, the current decays away as a function of the free charge carrier lifetime, so that the current can continue to flow even after the primary charge carriers produced in the semiconductor reach the electrodes. Second, the duration of the detector current pulse can be tailored by changing the lifetime of the free charge carriers. High speed photoconductive radiation detectors can be manufactured by purposely adding lifetime shortening dopants, or by shortening the lifetimes with intentional radiation damage. These detectors are ideal for fast timing measurements of large radiation bursts.

15.3.8 Photon Drag Detectors

A special type of photoconductor is the *photon drag detector*, which operates by sensing momentum changes of free charge carriers. These special photoconductive detectors are used primarily to measure high intensity beams of infrared radiation, such as laser emissions. Photon drag detectors consist of a semiconductor bar, generally cylindrical, around which ring electrodes have been fashioned near the ends [Gibson and Kimmitt 1980]. The semiconductor is selected such that the band-gap energy is greater than the photon energy under investigation, thereby allowing a large fraction of photons to pass directly through the semiconductor without being absorbed. For instance, initial photon drag experiments were conducted with p-type Ge ($E_g \simeq 0.7$ eV) for $\lambda = 10.6$ μm (0.117 eV) light [Grinberg 1970; Danishevskiĭ et al. 1970; Gibson et al. 1970].

When photons and electrons interact, the electrons can gain energy and momentum. Consider a beam of photons having a cross section A impinging lengthwise upon a semiconductor cylinder of length L_0. These electrons, having gained some momentum, acquire an ordered motion in the direction of the light propagation and a momentum transfer rate of

$$M = \frac{\alpha W \mathrm{n} e^{-\alpha L}}{Ac}, \tag{15.169}$$

where c is the light speed, W is power in watts, n is the index of refraction, α is the optical absorption coefficient in cm^{-1}, L is the location along the semiconductor length. The motion of charge carriers produces an opposing electric field

$$q_e\mathcal{E} = \frac{\alpha W \mathrm{n} e^{-\alpha L}}{n_c Ac}, \tag{15.170}$$

where n_c is the majority charge carrier density. If the majority carriers are holes, then the electric field polarity is reversed. Hence, momentum is transferred to holes in the valence band. Integration of Eq. (15.170) over the device length gives the resulting voltage per unit power illuminating the detector. After reflection at both ends of the device are included [Gibson et al. 1970], the voltage per unit power is

$$\frac{V}{W} = \frac{-\rho\mu \mathrm{n}(1-R)(1-e^{-\alpha L_0})}{Ac(1+Re^{-\alpha L_0})}, \tag{15.171}$$

where R is the semiconductor reflection coefficient (two facets), ρ is the semiconductor resistivity, μ is the majority charge carrier mobility, and L_0 is the length of the sample. For heavily doped samples, the product αL_0 is relatively large, and Eq. (15.171) reduces to

$$\frac{V}{W} \approx \frac{-\rho\mu \mathrm{n}(1-R)}{Ac}, \tag{15.172}$$

Hence, the photon drag detector operates as an infrared detector in which radiation passes through a doped semiconductor crystal, creating a measurable voltage drop associated with the photon beam intensity. Overall the effect is small and photon drag detectors are generally only useful for the detection of high fluxes of sub-band-gap radiation, such as from an infrared laser source. Numerous semiconductors have been investigated for these detectors, including Ge, Si, Te, GaAs, GaP, an InAs, as described in the literature [Gibson and Kimmitt 1980]. Photon drag detectors can be acquired through several commercial manufacturers of light sensors, the most common one composed of p-type Ge.

15.4 Measurements of Semiconductor Detector Properties

Synthesis and development of semiconductor materials and semiconductor detectors requires characterization of certain properties to better understand expected performance of a detector. For instance, the energy resolution from a semiconductor material is strongly dependent upon the product of the charge carrier mobility and the charge carrier mean free drift time, commonly referred to as the $\mu\tau$ product. Analysis of semiconductor detectors is often accomplished through measurements of fundamental properties, which include measurements of current, capacitance, the $\mu\tau$ product, electrical contact resistance, and charge carrier trapping. There are many excellent books devoted to this topic (see for examples [Look 1989; and Schroder 1990]). Only the more fundamental characterization methods are briefly described here.

15.4.1 *IV* Measurements

The current-voltage characteristic, or IV characteristic, is a fundamental property that yields leakage currents, normally under reverse bias. The quality of a blocking contact is generally revealed by the overall leakage current density that is observed. The measurement is typically performed with a probe station, manual or automated, that applies a voltage across a junction device and measures that resulting current. Common commercial systems allow reverse (negative) or forward (positive) voltage to be applied across a junction, automated with incrementally increasing steps. Many systems have built-in safety circuits that allow the establishment of a "compliance" limit to the measured current, beyond which the voltage is turned off.

The measurement is simple and the logarithm of the *absolute value* of the current is typically plotted against the applied voltage on a linear voltage scale showing both the forward and reverse currents. Recall the thermionic current for a pn junction is (see Eq. (15.75) and also Eq. (15.112))

$$I = \left| I_s \left(\exp\left[\frac{q_e V}{\breve{n} k T} \right] - 1 \right) \right|. \tag{15.173}$$

The resulting plot, shown in Fig. 15.37, is useful in (a) revealing the reverse leakage current and diode quality, and (b) issues with series resistance and space-charge limitations for the forward bias characteristic.

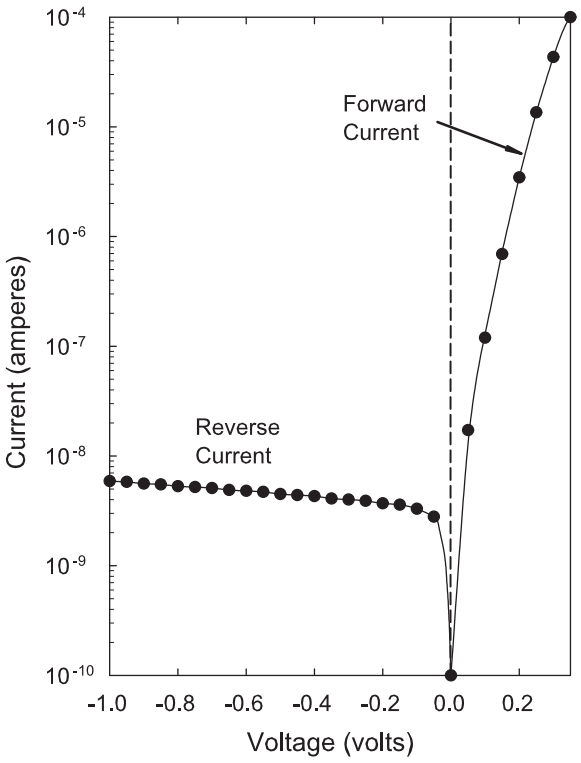

Figure 15.37. Conventional IV method of plotting the iv characteristic of a diode. The device is a 1 cm^2 Schottky barrier Si detector.

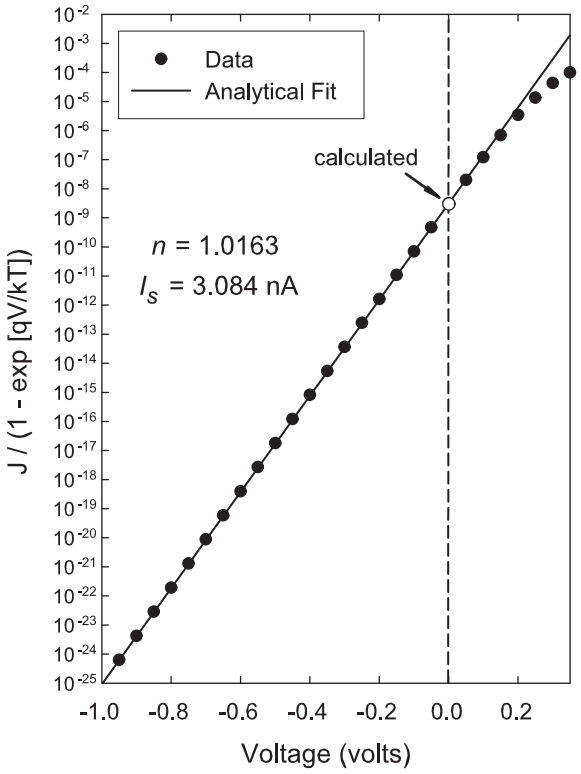

Figure 15.38. The IV plotting method proposed by Missous and Rhoderick [1986]. The plot yields $n = 1.0183$ and $i_s = 3.084$ nA.

Missous and Rhoderick [1986] propose another method, based on Eq. (15.112), that yields additional information about n. In this method a plot of the quantity

$$\ln\left(\frac{I}{1-\exp\left[\dfrac{-q_eV}{kT}\right]}\right), \tag{15.174}$$

versus the applied voltage V gives a linear plot of the IV characteristic at all values of V, including those values of $V < 3kT/q_e$, as shown in Fig. 15.38. From Eq. (15.112), the following relationship is obtained

$$\left[\ln(I_s) + \frac{q_eV}{\breve{n}kT}\right] \propto V. \tag{15.175}$$

The slope of the resulting graph yields the value of n, but primarily from the forward current. Also possible is a determination of I_s (or J_s) at the $V = 0$ intercept. From the relationship of Eq. (15.108), these measurements can yield information on the rectifying barrier height. Note that deviation from linearity can still occur from space charge limited current under forward bias, and charge carrier trapping and recombination can also cause distortions for reverse bias currents.

15.4.2 CV Measurements

The capacitance-voltage (or CV) characteristic can be used to determine a semiconductor doping concentration or the depletion width as a function of voltage for a junction device. The original CV measurement method was developed by Hilibrand and Gold [1960] for a parallel plate design. Recall the relationships

$$C = -\frac{dQ}{dV}, \tag{15.176}$$

in which the differential change in charge is negative from electron contributions, and

$$dQ = -q_e A|N_D(W) - N_A(W)|dW, \tag{15.177}$$

where q_e is the unit charge, A is the device area, $|N_D(W) - N_A(W)|$ is the net doping concentration as a function of depletion width W, and W is the depletion width. From these two results

$$C = -\frac{dQ}{dV} = q_e A|N_D(W) - N_A(W)|\frac{dW}{dV} = q_e A N_b \frac{dW}{dV}. \tag{15.178}$$

The general assumption for a planar device is that the capacitance is a function of the depletion layer width, i.e.,

$$C = \frac{\epsilon_s A}{W}. \tag{15.179}$$

Substitution of Eq. (15.59) or Eq. (15.103) into Eq. (15.179) yields,

$$C^2 = \frac{q_e \epsilon_s N_b A^2}{2(V_{bi} - V)}. \tag{15.180}$$

This result can be rearranged to give

$$V = -\frac{1}{C^2}\frac{q_e \epsilon_s N_b A^2}{2} + V_{bi}. \tag{15.181}$$

The result of Eq. (15.181) is rather important. A plot of $1/C^2$ versus the applied voltage V yields the semiconductor doping concentration and the built-in potential V_{bi} (see Fig. 15.39). Further, knowledge of A and C determines the active region width W from Eq. (15.179). Muller and Kamins [1986] point out that the value determined for N_b is generally accurate, although the value determined for V_{bi} can be have significant error.[9] The slope of $1/C^2$ can be determined by simple differentiation, namely

$$\frac{d}{dV}\left[\frac{1}{C^2}\right] = \frac{d}{dV}\left[\frac{2(V_{bi} - V)}{q_e \epsilon_s N_b A^2}\right] = \frac{-2}{q_e \epsilon_s N_b A^2}. \tag{15.182}$$

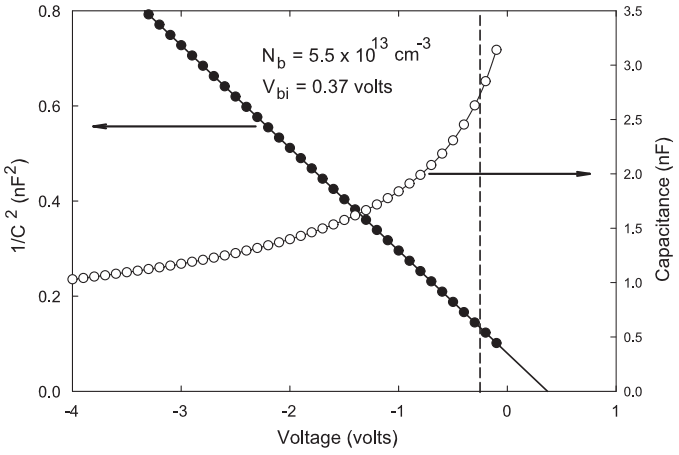

Figure 15.39. The two types of capacitance plots most often used in semiconductor radiation detector analysis. Shown is the case for a Si Schottky diode 1 cm^2 area, $N_b = 5.5 \times 10^{13}$ cm^{-3}, and $V_{bi} = 0.37$ volts.

[9] A small change in the slope causes a large change in the intercept value V_{bi}.

A common method of determining full depletion for a junction diode is to observe the voltage at which the CV characteristic curve stops changing and reaches a constant value.

The capacitance can be measured with a CV system consisting of an applied simultaneous DC voltage and a smaller AC voltage through a capacitance bridge, and yields the general relationship for current

$$I = \frac{V}{Z} = \frac{V}{(j\omega C)^{-1}} = j\omega VC, \tag{15.183}$$

where j is $\sqrt{-1}$, ω is the modulation frequency, Z is the device impedance, V is the applied voltage, and C is the capacitance. Typically, the modulation frequencies range between 10 kHz to 10 MHz. These measurements work well for the smaller band-gap semiconductors such as Ge and Si. However, problems can arise with the larger band-gap semiconductors having band energies above 1.2 eV.

For wide band-gap semiconductors, the series resistance in the substrate region can become problematic and yield incorrect results. The simple assumption of Eq. (15.183) is that the impedance of the diode is dominated by the depletion region capacitance and the undepleted substrate region capacitance is essentially shorted by the semiconductor conductivity. However, there is a parallel resistance with the depletion layer capacitance, which is also true for the undepleted substrate. Hence, there is a series resistance R that can confuse the capacitance measurement

$$I = \frac{V}{R + (j\omega C)^{-1}} = V\left[\frac{R\omega^2 C^2}{1 + (\omega RC)^2} + \frac{j\omega C}{1 + (\omega RC)^2}\right]. \tag{15.184}$$

The true capacitance can be determined from the measured capacitance C_m by [Look 1989]

$$C_m = \frac{C}{1 + (\omega RC)^2}. \tag{15.185}$$

The actual doping concentration, corrected for series resistance, is [Wiley 1975]

$$|N_D(W) - N_A(W)| = -\frac{C_m^3}{q_e \epsilon_s A^2 \sin^4\phi[dC_m/dV - 2C_m(d\phi/dV)\cot\phi]}, \tag{15.186}$$

where ϕ is the phase angle obtained from $\tan\phi = (\omega RC)^{-1}$. If the product $\omega RC \gtrsim 0.2$, then the measured doping profile is distorted [Look 1989].

If the substrate is a semi-insulator, the result can become unreliable. Consider the small signal model of a detector in (Fig. 15.40), simplified by showing a depletion region, a substrate region, and the electrical contacts. If it is assumed that the electrical contacts are well made, then the resistances short out the contact capacitance, rendering their contributions minor. However, that is not the case for the substrate region, where R is significant and cannot be ignored.

Hence, the simple small signal circuit has an impedance

$$Z = \left[\frac{R_D}{1 + j\omega R_D C_D} + \frac{R_S}{1 + j\omega R_S C_S}\right], \tag{15.187}$$

where the D and S subscripts indicate the depletion region and substrate regions, respectively. For high modulation frequencies ω and high substrate resistivities, the impedance takes the form [McGregor and Kammeraad 1995]

$$Z \approx \frac{\rho(W_D + W_S)}{A(j\omega\rho\epsilon_s + 1)}, \tag{15.188}$$

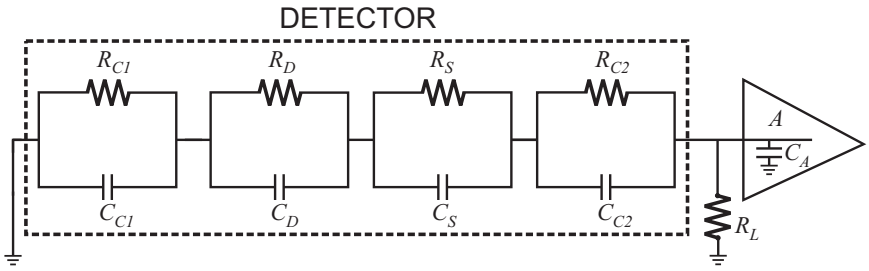

Figure 15.40. Small signal equivalent circuit model of a semiconductor detector. [Adapted from Walter 1960].

where ρ is the substrate resistivity, W_D is the depletion layer width, and W_S is the substrate layer width. The current is approximated by

$$I = V\left[\frac{1}{(R_D + R_S)} + j\omega C_T\right], \tag{15.189}$$

where C_T is the series combination of C_D and C_S, representing the total capacitance between the electrical contacts. This important result shows that (1) sufficiently high frequencies and (2) sufficiently high semiconductor resistivities reduce the measured capacitance to C_T. In either case, the observed capacitance does not change with voltage, erroneously misleading the measurement to indicate that the device active region[10] extends completely across the device, when in fact it does not [McGregor and Kammeraad 1995].

15.4.3 Measurement of Contact Resistance

Contact resistance is another fundamental property used as a quality metric for semiconductor detectors. The resistance of a blocking contact gives a measure of the rectification quality, while the resistance of an ohmic contact is used as a measure of conductance quality. The higher the blocking contact resistance, above the natural resistivity of the semiconductor, the more the leakage current is reduced. The lower the resistance of an ohmic contact, the smaller is the voltage drop at the contact so that there is better charge carrier collection and lower shot noise. IV measurements do provide a good first measurement of the rectifying behavior of a semiconductor diode detector, but do not disclose the contact resistance R_C. There are many methods to measure this contact resistance (see Look [1989] and; Schroder [1990]), a few of which are described here.

The *transmission line model* (TLM), based on the pattern of Fig. 15.41, is a simple three-terminal design with which the contact resistance can be estimated. The total resistance from one contact to an adjacent contact is

$$R_{Ti} = \frac{r_s l_i}{W + 2R_c}, \tag{15.190}$$

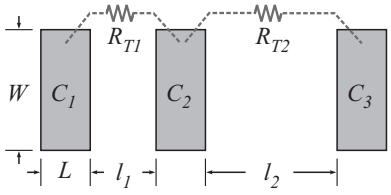

Figure 15.41. The transmission line model pattern, with ohmic contacts of width W, length L, and gap distances of l_1 and l_2. The contacts, labeled C_1, C_2, and C_3, are presumed identical.

where r_s is the sheet resistance,[11] W is the contact width, R_c is the contact resistance, and l_i is the distance between the contact edges. The measurement is made by placing a voltage across contacts C_1 and C_2 to

[10] The substitute use of 'active region' is much more accurate than the term 'depletion region'. The active region describes the region in a detector where the electric field is high enough to drift the charges, whereas the depletion region describes the region where the semiconductor is devoid of charge carriers. Because semi-insulating semiconductors, such as GaAs and CdTe, are already devoid of charge carriers, the description 'depletion region' has less meaning than 'active region'.

[11] The units for sheet resistance are $\Omega/\square$, meaning that any square of semiconductor surface yields the very same resistance. For instance, the sheet resistance of a 1 cm × 1 cm of semiconductor square surface is the same as a 2 cm × 2 cm square surface.

yield a current of I_1, followed by a second measurement across C_2 and C_3 to yield I_2. The total resistance for either measurement is simply $R_{Ti} = V/I_i$. The two equations formed from this pattern are solved to yield the contact resistance

$$R_c = \frac{R_{T1}l_2 - R_{T2}l_1}{2(l_2 - l_1)}. \tag{15.191}$$

The transmission line model is simple in application, but does have accuracy problems. Errors in the measured distances l_i can lead to measurement inaccuracy. Also, from Eq. (15.191), the difference between two large numbers, combined with small contact resistances, can lead to an inaccurate determination of R_c.

The *transfer length model* (unfortunately also termed TLM) is a popular method used to test the specific contact resistance of an ohmic contact. The method consists of placing consecutive planar contacts upon a semiconductor surface and performing a series of current measurements. Consider the pattern shown in Fig. 15.42 that has a series of identical contacts, labeled C_1 through C_5, each with a width W and length L, placed apart at increasing spacings. A resistance measurement is made by placing a known voltage across two contacts and measuring the resulting current. The total resistance is

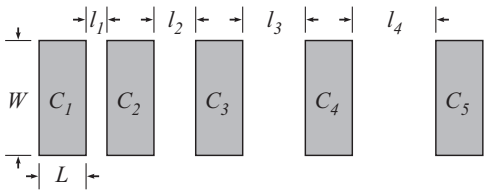

Figure 15.42. A common TLM pattern, with ohmic contacts of width W, length L, and gap distances of l_1, l_2, l_3, and l_4. The diagram depicts gap distances of increasing integer values, i.e., $l_4 = 4l_1$.

$$R_T = 2R_c + r_s\frac{l_i}{W}, \tag{15.192}$$

where R_c is the contact resistance of a single contact, r_s is the sheet resistance *between* the contacts, and l_i is the distance between the contacts. This measurement is repeated for the four pairs of contacts shown in Fig. 15.42. The total resistance R_T (where $R_T = V/I$) can be plotted against the intercontact distances l_i, and noting that Eq. (15.192) is a linear equation, the y intercept yields the value of $2R_c$ as shown in Fig. 15.43. The x intercept is a function of the transfer length, defined as

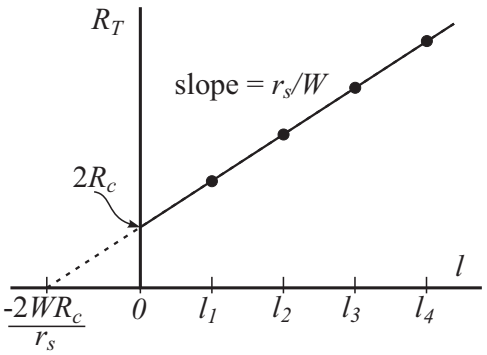

Figure 15.43. The measured resistance as a function of the distance l_i between the ohmic contacts, showing the method used to find R_c.

$$2L_T = \frac{2WR_c}{r_s}. \tag{15.193}$$

Three important values are derived from this transfer length method, namely, R_c, r_s, and the sheet resistance $R_s = r_s/W$.

This method is one of the most commonly used techniques to measure the quality of an ohmic contact, but does have a few potential problems. First, this method is based on the assumption that current flows uniformly from the contacts when, in reality, the current actually flows between the closest edges [Look 1989]. This non-uniform current is termed *current crowding*. To correct for current crowding, Look [1989] shows that the contact resistance is better described by

$$R_c = \frac{\sqrt{R_s\rho_c}}{W}\coth(kL), \tag{15.194}$$

where ρ_c is the specific contact resistivity under the metal-semiconductor interface, R_s is the sheet resistance *under* the contact, L is the contact length, and $k^2 = R_s/\rho_c$. If $kL \gtrsim 2$, then ρ_c is well approximated by

$$\rho_c \simeq \frac{W^2R_c^2}{R_s}. \tag{15.195}$$

Note that it is assumed here that r_s and R_s are interchangeable, an assumption that may not necessarily be true. During contact processing and development, it is possible to alter the material sheet resistance such that $r_s \neq R_s$. The inclusion of effects from the *end resistance* can compensate for errors introduced when r_s and R_s are different. This compensation is made by either placing a guard ring around the TLM structure, or (originally) by placing an extra contact C_e to the left of C_1 (in Fig. 15.42) at distance L [Reeves and Harrison 1982]. This extra end resistance can be found by measuring the voltage at C_e while applying a bias between the C_1 and C_2. Hence, the end resistance is [Look 1989]

$$R_e = \frac{V(C_e) - V(C_1)}{I} = \frac{R_c}{\cosh(kL)} = \frac{R_c}{\cosh(L\sqrt{R_s/\rho_c})}, \tag{15.196}$$

where I is the measured current. Here the actual value of R_s is found from the ratio

$$\frac{R_c}{R_e} = \cosh(kL) = \cosh(L\sqrt{R_s/\rho_c}). \tag{15.197}$$

Reeves and Harrison [1982] show that the difference between R_s and r_s can be significant, with examples of GaAs having a r_s/R_s ratio of 19.55 and Si having r_s/R_s ratio of 4.88. Issues with end resistance have been addressed with a circular transmission line model proposed by Reeves [1980], in which a circular "bull's eye" pattern takes the place of the TLM pattern of Fig. 15.41. The method employs Bessel function solutions and requires careful design considerations for the method to converge on a solution.

There is another difficulty encountered with many of the high-resistivity semiconductors, such as SI-GaAs, CdTe, CdZnTe, and HgI_2. The substrate resistance is such a dominant factor that determining the contact resistance can be statistically challenging. One can observe from Eq. (15.192) that if the total resistance measured R_T is large, then the error associated with a small change in the slope r_s/W produces a large variance in the transfer length. Hence, the error associated with the measurement of r_s becomes large. To reduce this error, often a contact scheme is tested on a conductive semiconductor substrate and then applied to a semi-insulating substrate of the same type of material. However, the actual substrate resistance can make a significant contribution to the contact resistance and lead to an incorrect result.

The chemical compatibility of electrical contacts can also be a major issue, especially with the softer high-Z semiconductors such as HgI_2 and TlBr. For instance, there are only a few conductive materials that can be used on HgI_2 that do not destructively react with the compound, namely, carbon, Pd, and Pt. Gold rapidly diffuses in Si and, thus, produces a deep acceptor. Aluminum with gold produces a purple corrosion (the "purple plague" - $AuAl_2$) on GaAs. Hence, some amount of caution should be exercised when deciding upon the contact material.

Finally, there are some semi-conductors used for radiation detectors with band gaps exceeding 2 eV. Hence, they are better classified as semi-insulators. Examples include HgI_2, PbI_2, TlBr, and SiC. Contact formation to these materials need not be rectifying, mainly because the intrinsic resistivity is sufficient to reduce the leakage current to manageable levels. Hence, additional resistance from electrical contacts is less of a problem, although poor contact formation may cause capacitance issues that create multiple energy peaks in a pulse height spectrum.

15.4.4 Measurement of Resistivity

A fundamental property of a semiconductor is its resistivity, i.e.,

$$\rho = \frac{1}{q_e(\mu_e n + \mu_h p)}. \tag{15.198}$$

Perhaps the simplest method of measuring resistivity is to place ohmic contacts on opposite ends of a semiconductor bar of length L, followed by a measurement of the current (I) resulting from voltage (V)

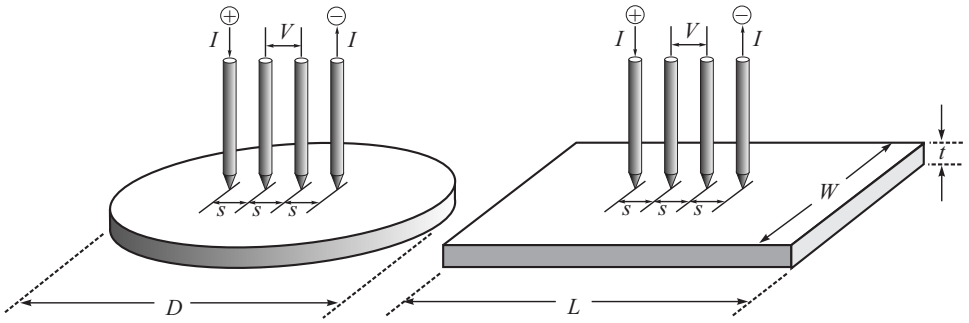

Figure 15.44. Geometries for four-point probe measurements on circular and rectangular samples.

applied across the bar. If the area of each end is A, then the current density is

$$\frac{I}{A} = J_n + J_p = \frac{V}{L}(q_e n \mu_n + q_e \mu_h p), \tag{15.199}$$

or

$$\rho = \frac{VA}{IL}. \tag{15.200}$$

Usually a semiconductor is dominated by one of the charge carriers, previously named the majority carrier. Hence, the resistivity is usually due to n-type or p-type charge carrier conduction.

A common method of measuring resistivity is with a four-point probe. The system has four equally spaced point probes, arranged in a straight line, that are brought into contact with a semiconductor surface (see Fig. 15.44). The spacing between each probe is denoted by s. A current is supplied to the outermost probes with a constant current source and the resulting voltage is measured between the two inner most probes. For a thin semiconductor sample in which the thickness under investigation is much smaller than the lateral dimensions of length L and width W, the sheet resistance is given by [Sze 1981]

$$r_s = \frac{\pi}{\ln(2)} \frac{V}{I} K = 4.5324 \frac{V}{I} K. \tag{15.201}$$

where K is a geometric correction factor. The volume resistivity is determined from

$$\rho = r_s t. \tag{15.202}$$

Schroder [1990] points out that geometric correction factors have been calculated by many researchers using a variety of techniques. However, all reduce the correction factor to three important components, $K = f_1 f_2 f_3$. The correction factor f_1 corrects for differences with the sample thickness, f_2 corrects for the lateral sample dimensions, and f_3 corrects for the location of the probes with respect to the sample edges. If the sample width W is much larger than the probe spacing ($W \gg s$), then Eq. (15.202) reduces to

$$\rho = 4.5324 \frac{Vt}{I}, \tag{15.203}$$

where t is the sample thickness.

For thinner samples of smaller widths W, the proper corrections must be applied. The factor f_1 addresses corrections for finite thickness t, and is given by

$$f_{1a} = \frac{\ln(2)}{\ln\left(\dfrac{\sinh(t/s)}{\sinh(t/2s)}\right)}, \tag{15.204}$$

if the bottom underlayer is an insulator and by

$$f_{1b} = \frac{\ln(2)}{\ln\left(\dfrac{\cosh(t/s)}{\cosh(t/2s)}\right)}, \tag{15.205}$$

if the bottom underlayer is a conductor. The limiting values are found for $t \ll s$ as

$$f_{1a} \approx 1 \qquad \text{and} \qquad \rho \approx 4.5324 \frac{Vt}{I} f_2, \tag{15.206}$$

$$f_{1b} \approx \frac{8}{3}\frac{s^2}{t^2}\ln(2) \qquad \text{and} \qquad \rho \approx \frac{8\pi}{3}\frac{s^2}{t}\frac{V}{I} f_2, \tag{15.207}$$

and for $t \gg s$ as

$$f_{1a} = f_{1b} \approx 2\ln(2)\frac{s}{t} \qquad \text{and} \qquad \rho \approx 2\pi s \frac{V}{I} f_2. \tag{15.208}$$

The factor f_2 addresses corrections for a finite width W. Smits [1958] calculated and published a table of these values as $\pi f_2/\ln(2)$ for rectangular and circular samples. The correction f_2 is plotted in Fig. 15.45 for values D/s and W/s between 1 and 40. As W/s becomes large, f_2 approaches unity. The third correction factor has four possible expressions, depending on whether the probes are near a conducting or non-conducting boundary [Valdes 1954], and also depending upon the orientation of the probes with that boundary. Plotted in Fig. 15.46 are corrections factors for f_3 for both conducting and non-conducting boundaries, according to the probe orientation and distance-to-spacing ratio d/s. Note that in all cases f_3 approaches unity provided that the probe is at least $3s$ distance away from the sample edge.

15.4.5 Measurement of Charge Carrier Mobility

Recall that the mobility of an extrinsic semiconductor is

$$\mu_e = \frac{1}{|q_e|\rho_e n} \quad \text{for } n\text{-type material,} \tag{15.209}$$

$$\mu_h = \frac{1}{|q_e|\rho_h p} \quad \text{for } p\text{-type material.} \tag{15.210}$$

This result shows that the charge carrier mobility can be found by measuring the carrier concentration and resistivity. The carrier concentration is commonly measured using the Hall effect, named after E.H. Hall [1879] who discovered the effect. Hall discovered that a magnetic field applied to a material perpendicular to a current flowing through the same material induces a voltage perpendicular to both the magnetic field and current. Putley [1968] devotes a textbook to the study of this effect. Consider the block of semiconductor material depicted in Fig. 15.47. Electrical contacts are applied to the ends, with additional electrical contacts applied to central portions on surfaces of the width. A voltage is applied across the longitude of the block (depicted in the x direction) and is labeled V_s. A magnetic field is applied perpendicular to the applied voltage as shown (depicted in the z direction). Connection across the semiconductor width measures the induced Hall voltage V_H.

The force on a charged particle is described by

$$\mathbf{F} = q_e(\mathcal{E} + \mathbf{v} \times \mathbf{B}), \tag{15.211}$$

where $\mathbf{v}$ is the charge carrier velocity vector and $\mathbf{B}$ is the magnetic field vector. A current I in the sample of Fig. 15.47 flows in the positive x direction. For p-type material this current is given by

$$I = \frac{V_s}{R_s} = \frac{WtV_s}{\rho L} = |q_e| p W t v_h, \tag{15.212}$$

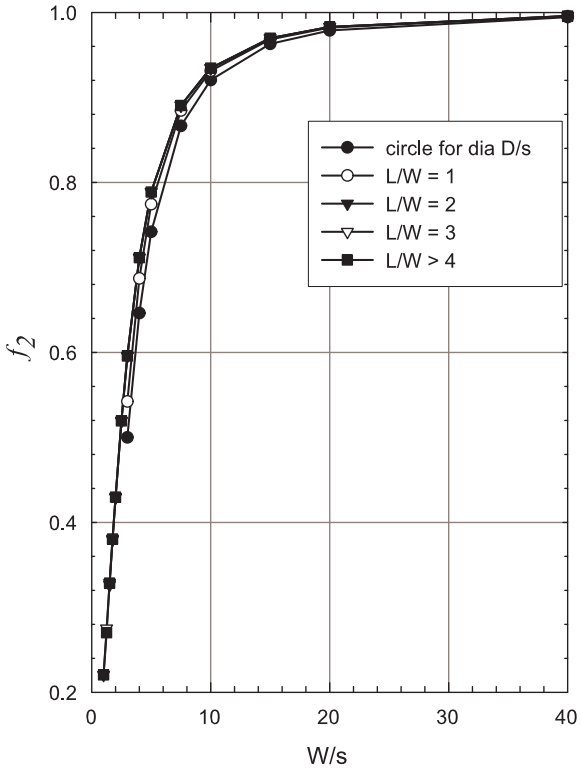

Figure 15.45. The correction factor f_2 as a function of W/s for many rectangular shapes L/W. Also shown is the correction f_2 for a circular sample as a function of the diameter D/s. Data from Smits [1958].

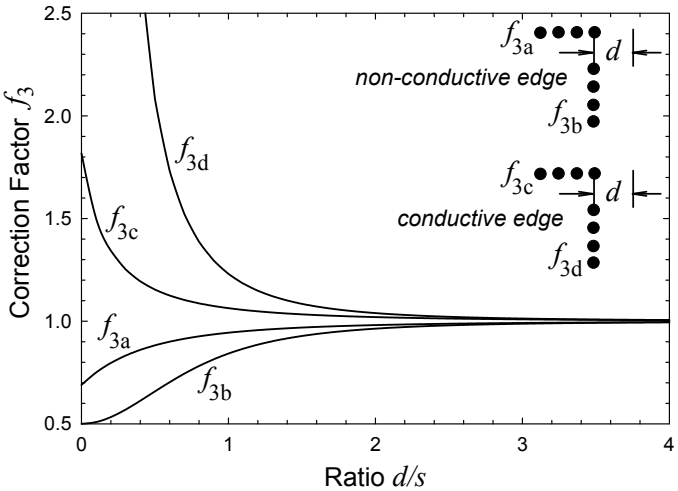

Figure 15.46. The correction factor f_3 as a function of d/s. f_{3a} and f_{3b} address non-conductive boundaries and f_{3c} and f_{3d} address conductive boundaries. The probes are placed distance d either parallel or perpendicular to the boundary edge.

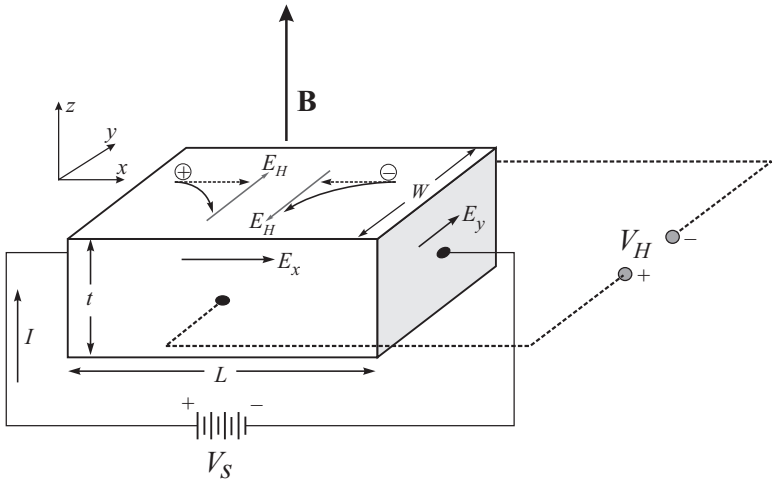

Figure 15.47. Configuration of a Hall effect measurement.

where R_s is the resistance in the longitudinal direction, t is the sample thickness, W is the sample width, and L is the sample length. Holes accumulate near the negative y surface and produce an electric field. But a current cannot flow out of the device. The net result is the y forces must be equal and opposite; hence, the force F_y in the y direction must be zero. Then from Eq. (15.211)

$$q_e\mathcal{E}_y = q_e v_{hx} B_z \qquad \text{or} \qquad \mathcal{E}_y = v_{hx} B_z, \tag{15.213}$$

where $\mathcal{E}_y$ is the *Hall field*, and the resulting induced voltage $V_H = \mathcal{E}_y W$ is the *Hall voltage*. Substitution of the hole drift speed gives

$$V_H = \mathcal{E}_y W = \frac{B_z I}{q_e p t W} W = R_H \frac{I B_z}{t}, \tag{15.214}$$

where R_H is the Hall coefficient and $R_H = 1/(q_e p)$.

In a similar manner, the Hall coefficient for n-type material is,

$$R_H = -\frac{1}{q_e n}. \tag{15.215}$$

Therefore, from the measured current and known magnetic field, the hole and electron concentrations are found as

$$p = \frac{1}{q_e R_H} \qquad \text{and} \qquad n = -\frac{1}{q_e R_H}. \tag{15.216}$$

Notice that the resulting positive or negative sign yields the type of majority charge carrier (n or p). The Hall mobility is determined from

$$\mu_H = \frac{|R_H|}{\rho}, \tag{15.217}$$

a useful result, but is not the carrier drift mobility. The actual drift mobility for holes is found by substituting the resistivity into Eqs. (15.209) and (15.210), namely

$$\mu_h = \frac{\mu_H}{q_e p |R_H|}, \tag{15.218}$$

and for electrons

$$\mu_e = \frac{\mu_H}{q_e n |R_H|}. \tag{15.219}$$

When both holes and electrons are present, the Hall coefficient is represented by [Schroder 1990]

$$R_H = \frac{\left[\left(p - n\left(\frac{\mu_e}{\mu_h}\right)^2\right) + (\mu_e B)^2(p-n)\right]}{q_e\left[\left(p + \frac{n\mu_e}{\mu_h}\right)^2 + (\mu_e B)^2(p-n)^2\right]}. \tag{15.220}$$

Unfortunately, if $p \approx n$, the result of Eq. (15.220) can be difficult to interpret.

Overall the Hall measurement can be used to determine the majority charge carrier drift mobility and the type of majority carrier (n or p). Although the geometry of Fig. 15.47 is perhaps the simplest, it can have practical difficulties when dealing with thin samples such as epitaxial crystals. Further, errors associated with the measurement can render R_H inaccurate, as outlined in Look [1989]. To address these issues, a variety of alternative contact geometries have been developed for such cases, as outlined in Look [1989] and Schroder [1990].

15.4.6 Measurement of the $\mu\tau$ Product

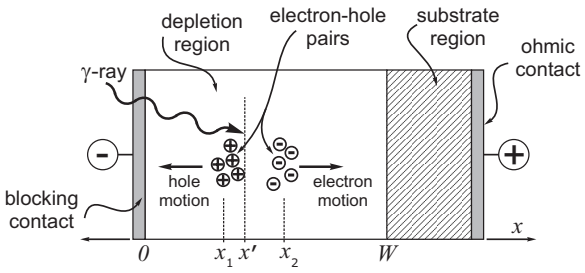

Figure 15.48. Electron-hole pairs are excited from a radiation interaction.

A useful measure of expected performance from a semiconductor is the mobility-lifetime (or $\mu\tau$) product. The speed of charge carriers can be estimated from the linear relation $v = \mu\mathcal{E}$ provided that the electric field is below the onset of scatter limited saturation speeds. The lifetime of a charge carrier is generally defined as the recombination time, which can be much longer than the mean free drift time. The mean free drift time is the average time period that a charge carrier conducts before being removed from the process, either by trapping or recombination. Consequently, it is the mean free drift time that defines the average time between charge carrier excitation and its removal from conduction, usually through traps. Hence, it is customary to replace the lifetime τ with the mean free drift time τ^*. For a planar device, the carrier extraction factor can be described by

$$\varrho = \frac{v\tau^*}{W} = \frac{\mu\mathcal{E}\tau^*}{W} = \frac{\mu\tau^* V}{W^2}. \tag{15.221}$$

In the next section a model is developed for the induced charge in a planar device (see Fig. 15.48) when trapping is present. The final result Eq. (15.240) is

$$Q(x') = -q_e N_o\left[\varrho_e\left(1 - \exp\left[\frac{x' - W}{\varrho_e W}\right]\right) + \varrho_h\left(1 - \exp\left[\frac{-x'}{\varrho_h W}\right]\right)\right], \tag{15.222}$$

where x' is the location of the ionizing event. Substitution of Eq. (15.221) into this result gives

$$-\frac{Q}{q_e N_o} = \frac{V}{W^2}\left\{\mu_e\tau_e^*\left(1 - \exp\left[\frac{(x'-W)W}{\mu_e\tau_e^* V}\right]\right) + \mu_h\tau_h^*\left(1 - \exp\left[\frac{-x'W}{\mu_h\tau_h^* V}\right]\right)\right\}. \tag{15.223}$$

From Eq. (15.223) it is observed that the $\mu\tau^*$ product yields a measure of the induced charge which has an effect on the detector energy resolution. The usual method of conducting a $\mu\tau^*$ measurement is to irradiate one of the contacts on a planar detector with an alpha-particle source. The reason for this arrangement is because the range of alpha-particles is short, confining the excitation of charge carriers in the semiconductor to a region adjacent to the electrical contact, i.e., $x' \simeq 0$. If a planar detector is irradiated from the cathode, Eq. (15.223) reduces to

$$-\frac{Q}{q_e N_o} = \frac{V}{W^2}\left\{\mu_e\tau_e^*\left(1-\exp\left[\frac{-W^2}{\mu_e\tau_e^* V}\right]\right)\right\}. \tag{15.224}$$

The $\mu\tau^*$ measurement is conducted by observing the relative pulse heights from the detectors at increasing intervals of voltage. The data is plotted and an interpolative method is used to fit the data to Eq. (15.224). For high-resistivity materials, W in Eq. (15.224) adequately describes the boundaries of the detector. However, for detectors requiring depletion to produce an active region, either Eq. (15.59) or Eq. (15.103) is substituted for W^2 to produce

$$-\frac{Q}{q_e N_o} = \frac{q_e N_b}{2\epsilon_s(V_{bi}-V)}V\left\{\mu_e\tau_e^*\left(1-\exp\left[\frac{-2\epsilon_s(V_{bi}-V)}{\mu_e\tau_e^* V q_e N_b}\right]\right)\right\}, \tag{15.225}$$

or

$$-\frac{Q}{q_e N_o} \approx \frac{q_e N_b}{2\epsilon_s}\left\{\mu_e\tau_e^*\left(1-\exp\left[\frac{-2\epsilon_s}{\mu_e\tau_e^* q_e N_b}\right]\right)\right\}, \tag{15.226}$$

which has the form

$$\frac{Q}{Q_o} \approx C_1\left\{\mu_e\tau_e^*\left(1-\exp\left[\frac{-1}{\mu_e\tau_e^* C_1}\right]\right)\right\}, \tag{15.227}$$

where the constant $C_1 = q_e N_b/(2\epsilon_s)$.

One difficulty with using Eq. (15.226) and Eq. (15.227) is that the value of Q/Q_0 appears constant until the full depletion condition is met, at which point W becomes constant and Eq. (15.224) adequately describes the measurement.[12] The measurement method based on Eq. (15.224) is commonly used to determine the $\mu\tau$ product, which can then be used in Eq. (15.223) to develop a Q-map for the detector. Measurements of electron $\mu\tau^*$ products are typically easier to conduct than hole $\mu\tau^*$ products, mainly because (1) the mobility of electrons is usually larger than for holes, and (2) τ^* is usually larger for electrons than holes.

If the hole $\mu\tau^*$ is so small that pulse heights are drastically reduced for anode irradiation, a method developed by Baciak and He [2003a] may be of practical use. This method involves the accumulation of pulse height spectra from both cathode and anode irradiation. The centroid of each distribution is chosen to represent $\langle Q_C\rangle$ (cathode irradiation) and $\langle Q_A\rangle$ (anode irradiation). The ratio of charge collected from the anode $\langle Q_A\rangle$ and cathode $\langle Q_C\rangle$

$$\frac{\langle Q_A\rangle}{\langle Q_C\rangle} = \frac{\mu_h\tau_h^*\left(1-\exp\left[\frac{-W^2}{\mu_h\tau_h^* V}\right]\right)}{\mu_e\tau_e^*\left(1-\exp\left[\frac{-W^2}{\mu_e\tau_e^* V}\right]\right)}, \tag{15.228}$$

can be used to extract information about $\mu_h\tau_h^*$. This method requires prior knowledge of $\mu_e\tau_h$ so that the denominator of Eq. (15.228) is known. Hence, the only unknown is $\mu_h\tau_h$, which is found from Eq. (15.228)

[12] The value of τ^* often does change with applied voltage, although determining τ^* requires knowledge of N_b and μ, and a new solution for C_1 for each voltage increment.

with iterative methods. There are limitations to the method, mainly because the pulse height distribution from holes can occupy the lower energy channels and, thereby can be severely contaminated by electronic noise in the system. Hole pulses lost in the noise and contamination in the pulse height spectrum from noise can introduce a significant uncertainty in $\langle Q_A \rangle$.

15.5 Charge Induction

A depiction of a planar semiconductor radiation detector is shown in Fig. 15.48. The detector is separated into a depletion (or active) region and a substrate region. The substrate region does not contribute to charge induction but rather acts as a series resistance in the circuit. Hence, charge motion in the depletion region produces the induced charge under investigation.[13] Upon the excitation of electron-holes pairs in the depletion region, these charges are drifted to their respective contacts, electrons towards the anode and holes towards the cathode, to produce an induced current. This drifting occurs because of the applied electric field produced by operating voltage applied across the detector. The charge induction produced by a planar radiation detector was developed in Chapter 8 (see Eq. (8.44)) and is represented here as

$$\Delta Q = q_e N_0 \left(\frac{x_2 - x_1}{W} \right), \tag{15.229}$$

where W is the detector width. As also derived in Chapter 8, full charge collection reduces Eq. (15.229) to $Q = q_e N_0$. Hence, the total charge excited is preserved on the output signal provided that the charge carriers are collected during the electronic integration time of the detector and circuitry. The other geometrical cases derived in Chapter 8 also apply to semiconductor detectors, in which the depletion or active region is the radiation sensitive region.

15.5.1 Charge Induction With Trapping

The ideal cases of charge carrier collection, induced current, induced charge, and the weighting potential were developed in Chapter 8. However, semiconductors are typically manufactured from crystalline solids or polycrystalline solids and typically have intrinsic and extrinsic defects. These defects may arise from vacancies, interstitials, impurities, and complex combinations of defects. Defects may be electrically active, or may be neutral and serve mainly as scattering centers. Regardless, the presence of crystalline defects affects the transport of charge carriers, and may serve to trap charge carriers, assist with recombination, or delay the conduction process so as to effectively remove them from adding to the induced charge of its corresponding signal.

Four distinguishable trapping and recombination conditions may exist in a semiconductor radiation detector [Dearnaley and Northrop 1966]. These are as follows.

1. Complete carrier extraction in which both electrons and holes are removed from the active region of the device. Hence, there are no trapping effects.

2. Short-term trapping in which carriers are briefly trapped, but undergo detrapping and are extracted from the detectors within the shaping time of the pulse. The output pulse may be elongated, and may suffer from some ballistic deficit, but the charge carriers are collected.

3. Partial recombination of the carriers in which some charge carriers are permanently lost.

[13] There are special cases in which there is no actual "depletion region," but instead only an "active region" defined by the electric field strength. Under such a condition, the entire semiconductor length can take part in producing the induced charge. These special cases arise in compensated wide band-gap materials.

4. Long-term trapping in which charge carriers that are trapped are not detrapping during the signal shaping time. Hence, these trapped charges are also effectively lost. Moreover, detrapping over time can produce a residual background current.

Consider the design of a common planar semiconductor detector in which electrical contacts are placed on opposite sides of a planar semiconductor slab. This detector is then irradiated from the side so that the probability of radiation interactions is constant at all points between the contacts. If a radiation event occurs at one of the electrodes, the cathode for instance, the pulse is entirely conditional on electron motion. If the event occurs at the anode, the pulse becomes entirely conditional on hole motion. At other event locations within the detector, both carriers contribute to the output signal to a greater or lesser degree. If a carrier collection time is longer than the trapping time, then the effective mobility changes as

$$\mu' = \mu \frac{\tau_t}{\tau_t + \tau_d}, \tag{15.230}$$

where μ is the charge carrier mobility without trapping effects, τ_t is the mean trapping time and τ_d is the mean detrapping time (or average time spent in the trap). Similarly, the charge carrier extraction time t' is reduced to

$$t' = t \frac{\tau_t}{\tau_t + \tau_d}, \tag{15.231}$$

where t is the expected collection time in the absence of trapping. If the situation exists in which one charge carrier follows condition 1 (no trapping), while the other charge carrier follows condition 2 (short-term trapping and detrapping), the pulse shape is deformed depending on the interaction location of the radiation absorption.

Building on the results of Sec. 8.6 for a planar detector, the charge induction when trapping occurs can be derived by first considering the contributions from electrons and holes, namely

$$\Delta Q = N_o \left(-q_e \left[\frac{x_2 - x_0}{W} \right] \Bigg|_{e^-} + q_e \left[\frac{x_1 - x_0}{W} \right] \Bigg|_{h^+} \right), \; x_1 < x_0 < x_2, \tag{15.232}$$

$$= \frac{N_o}{W} \left(-q_e \Delta x_e - (+q_e) \Delta x_h \right), \tag{15.233}$$

where N_o is the number of electron-hole pairs created by a radiation event and x_0 is the radiation interaction location. The corresponding current is

$$I = \frac{dQ}{dt} = \frac{-q_e N_o}{W} \left(\frac{dx_e}{dt} + \frac{dx_h}{dt} \right), \tag{15.234}$$

in which the signs indicate the unit charge (positive or negative) and direction. Equation (15.234) is rewritten, after charge carrier speeds and trapping terms are inserted, to yield

$$I = \frac{dQ}{dt} = \frac{-q_e N_o}{W} \left(v_e e^{-t/\tau_e^*} + v_h e^{-t/\tau_h^*} \right), \tag{15.235}$$

where τ_e^* and τ_h^* are the mean free drift times for the electrons and holes, respectively, before the charge carriers are permanently removed from conduction. Integration of Eq. (15.235) yields the induced charge

$$Q = \frac{-q_e N_o}{W} \left(\int_0^{t_e} v_e e^{-t/\tau_e^*} dt + \int_0^{t_h} v_h e^{-t/\tau_h^*} dt \right) = \frac{-q_e N_o}{W} \left[v_e \tau_e^* \left(1 - e^{-t_e/\tau_e^*} \right) + v_h \tau_h^* \left(1 - e^{-t_h/\tau_h^*} \right) \right], \tag{15.236}$$

where the terms t_e and t_h are the time intervals required to collect all electrons and holes, respectively, from their point of origin. The speed is the distance $x_{e,h}$ that a charge carrier travels over time period $t_{e,h}$, so that Eq. (15.236) can be rewritten as

$$Q = \frac{-q_e N_o}{W}\left[\frac{x_e\tau_e^*}{t_e}\left(1-e^{-t_e/\tau_e^*}\right)+\frac{x_h\tau_h^*}{t_h}\left(1-e^{-t_h/\tau_h^*}\right)\right]. \tag{15.237}$$

The *carrier extraction factor* is defined as

$$\varrho \equiv \frac{v\tau^*}{W} = \frac{x\tau^*}{tW} = \frac{\lambda^*}{W}, \tag{15.238}$$

where λ^* is the mean free drift length. Equation (15.237) can be rewritten as

$$Q = -q_e N_o\left[\varrho_e\left(1-\exp\left[\frac{-x_e}{\varrho_e W}\right]\right)+\varrho_h\left(1-\exp\left[\frac{-x_h}{\varrho_h W}\right]\right)\right]. \tag{15.239}$$

Suppose the detector orientation shown in Fig. 15.48 is chosen for a coordinate system, such that electrons drift in the positive x direction and holes drift in the negative x direction. For any location x' within the detector, the drift distance for electrons is $W - x'$ and the drift distance for holes is simply x'. In terms of x' Eq. (15.239) becomes

$$Q(x') = -q_e N_o\left[\varrho_e\left(1-\exp\left[\frac{x'-W}{\varrho_e W}\right]\right)+\varrho_h\left(1-\exp\left[\frac{-x'}{\varrho_h W}\right]\right)\right]. \tag{15.240}$$

Radiation events occurring at the contacts, at either $x = 0$ or $x = W$, reduce Eq. (15.240) to

$$Q = -q_e N_o \varrho_e\left(1-\exp\left[\frac{-1}{\varrho_e}\right]\right), \quad \text{for electron dominated signals,} \tag{15.241}$$

$$Q = -q_e N_o \varrho_h\left(1-\exp\left[\frac{-1}{\varrho_h}\right]\right), \quad \text{for hole dominated signals.} \tag{15.242}$$

The probability distribution of induced charge is found by multiplying Eq. (15.240) by the interaction probability distribution function $P(x')$ where $P(x')dx'$ is the probability an interaction creating change Q_0 occurs in dx' about x'. The evaluation of $P(x')$ generally requires the use of numerical transport theory if all the various ways photons interact are to be considered. Further, the interaction PDF also generally depends on the amount of energy deposited as well as the interaction location. The only situation in which an analytic expression for the interaction probability can be obtained is one in which only the photoelectric effect is present. This situation is discussed further later in this section.

A special case is one in which $P(x') = 1$ for all x', i.e., radiation events occur uniformly throughout the detector volume. Such a case may be observed for highly penetrating radiation that irradiates the device from a side between the contacts. In this case

$$P(x')\frac{Q(x')}{Q_0} \rightarrow \frac{Q(x')}{Q_0}.$$

The pulse height distribution with $P(x') = 1$ and with both carrier extraction factors equal is shown in Fig. 15.49. This Q-map shows that if both charge carrier extraction factors are large (≥ 50), the variance in the pulse height spectrum is small. This difference is detectable by comparing the largest pulse height (at $x = 0.5$) to the smallest pulse height (at $x = 0$ and $x = 1$). The Q-map can be interpreted as follows:

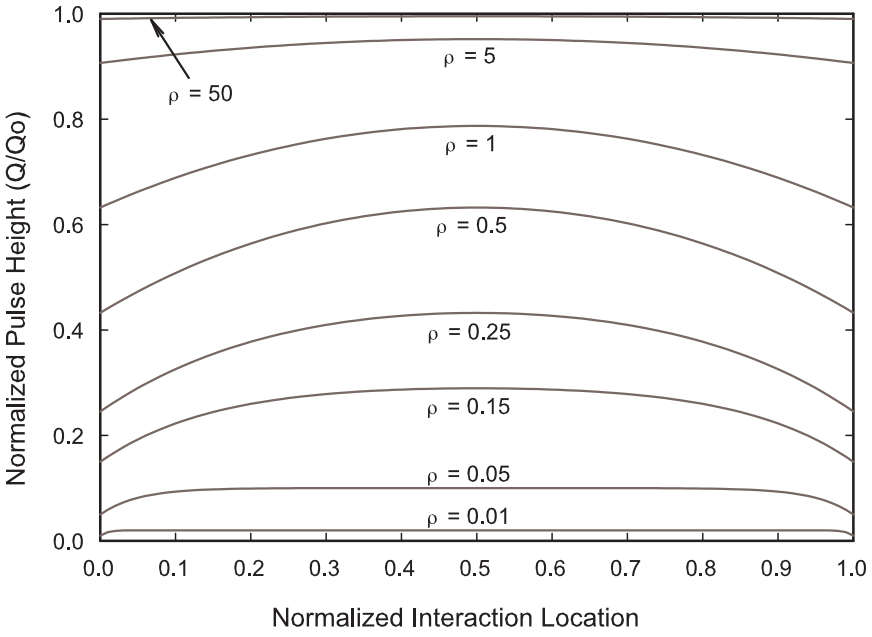

Figure 15.49. Q-map for different cases in which $\varrho_e = \varrho_h$. For large values of ϱ_e and ϱ_h, the variance in normalized pulse height is minimal. As ϱ for both charge carriers decreases, the variance broadens.

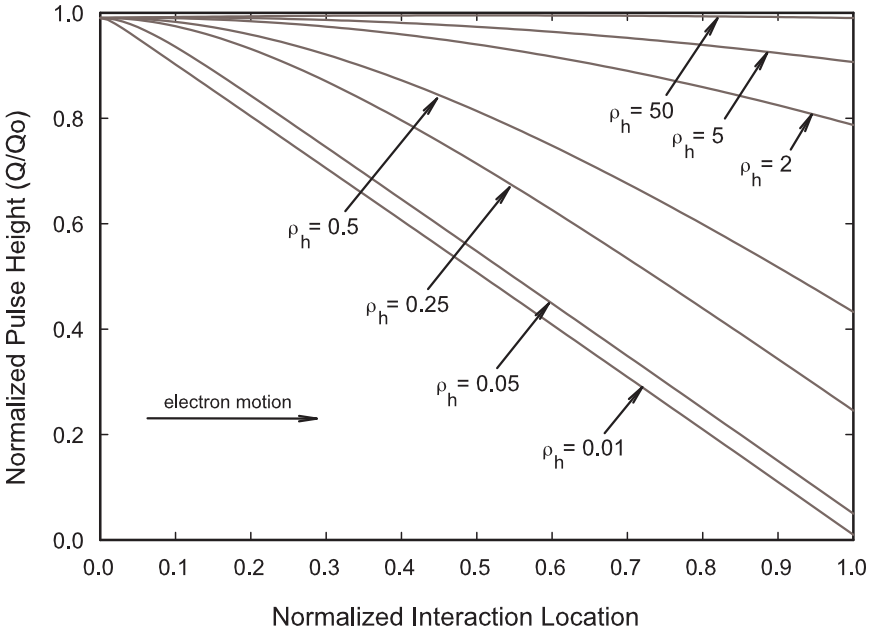

Figure 15.50. Q-map for different cases in which ϱ_e is large (= 50) and ϱ_h changes. As ϱ_h is decreased, the variance broadens.

a relatively horizontal region in a curve represents the formation of an energy peak in the pulse spectrum, whereas sloped regions represent the formation of a tail in the pulse height spectrum. The curve in Fig. 15.49 for $\varrho_e = \varrho_h = 50$ is horizontal and indicates that all pulses fall into an energy peak, thereby rendering good energy resolution. Further, the magnitude of the pulse is nearly 100% of the maximum possible and indicates that all of the charge carriers are collected. However, the curve for $\varrho_e = \varrho_h = 0.5$ shows a short horizontal region between $x = 0.3$ to $x = 0.7$, an indication that approximately 40% of pulses appear in an energy peak, while the remaining 60% of pulses appear in a tail. The largest pulse height appears at approximately 63% of the expected value, which indicates severe losses of the charge carriers. Further the tail extends from 63% of the expected pulse height down to 43% of the expected pulse height. Note that a considerable horizontal region appears for low values of $\varrho < 0.15$. However, the expected pulse height is small for these conditions and indicates that system electronic noise ultimately competes with the radiation signals, thereby compromising the energy resolution of the detector.

The energy resolution is much worse if $\varrho_e \neq \varrho_h$, as is usually the case. For example, shown in Fig. 15.50 are several cases in which ϱ_e is constant at 50 while ϱ_h is changed. Notably, the signal variance is worse in all cases than those shown in Fig. 15.49 (except for $\varrho_e = \varrho_h = 50$). For instance, the comparative case with $\varrho_e = 50$ and $\varrho_h = 0.5$ indicates the appearance of a small energy peak from events in the region between $x = 0$ and $x = 0.15$. Only 15% of interactions accumulate in an energy peak. The remaining signals accumulate in a tail region extending from approximately 100% of the expected pulse height down to 43% of the expected pulse height. An example of this result is shown in Fig. 15.51, from which it is clear that the full energy peak is not Gaussian and most of the pulse height spectrum appears in an elongated tail.

The solution of the variance for Eq. (15.240) can be shown to be [Day et al. 1967; Knoll and McGregor 1993]

$$\begin{aligned}\sigma_Q^2 = q_e^2 N_o^2 \Bigg[& \varrho_e^2 + 2\varrho_e^3(e^{-1/\varrho_e} - 1) + \frac{\varrho_e^3}{2}(1 - e^{-2/\varrho_e}) + \varrho_h^2 + 2\varrho_h^3(e^{-1/\varrho_h} - 1) + \\ & \frac{\varrho_h^3}{2}(1 - e^{-2/\varrho_h})2\varrho_e\varrho_h + 2\varrho_e^2\varrho_h(e^{-1/\varrho_e} - 1) + 2\varrho_e\varrho_h^2(e^{-1/\varrho_h} - 1) \\ & + 2\frac{(\varrho_e\varrho_h)^2}{\varrho_e - \varrho_h}(e^{-1/\varrho_e} - e^{-1/\varrho_h}) \Bigg] - \langle Q \rangle^2, \end{aligned} \tag{15.243}$$

where

$$\langle Q \rangle = q_e N_0 \left[\varrho_e + \varrho_e^2(e^{-1/\varrho_e} - 1) + \varrho_h + \varrho_h^2(e^{-1/\varrho_h} - 1) \right]. \tag{15.244}$$

The percent fractional standard deviation can be found from

$$\sigma_q = \frac{100\sigma_Q}{\langle Q \rangle}, \tag{15.245}$$

and is plotted as a function of electron and hole extraction factors in Fig. 15.52. Note that the values in Fig. 15.52 do not depict the energy resolution, typically defined as the FWHM, where the usual definition is derived from a Gaussian peak, namely

$$\text{FWHM} = 2\sqrt{2 \ln 2}\sigma = 2.355\sigma. \tag{15.246}$$

For moderate to severe charge carrier trapping, the peaks in pulse height spectra are usually not Gaussian, but instead are skewed to the lower energies with a salient tail region and, thus, the use of Eq. (15.246) is inaccurate. For example, the pulse height distribution for full energy absorption (photoelectric effect), without Gaussian spreading, is shown in Fig. 15.51 for the case in which $\varrho_e = 50$ and $\varrho_h = 0.5$. Most of the

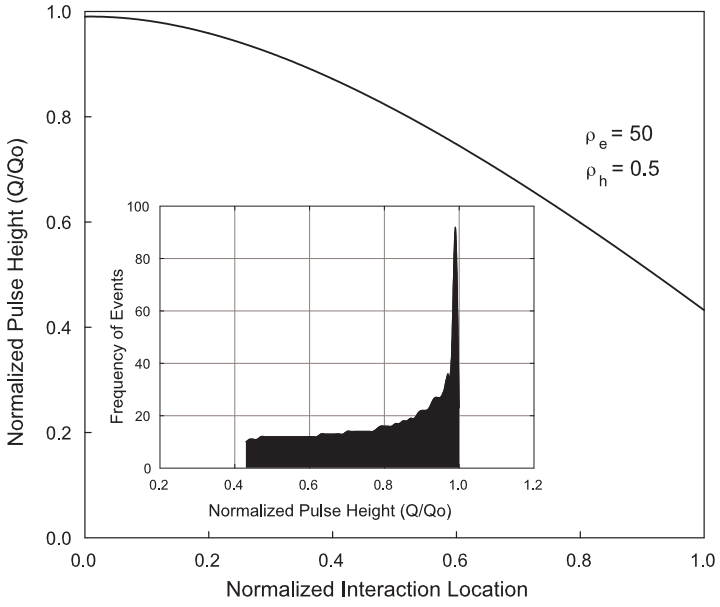

Figure 15.51. A comparison of the Q-map for $\varrho_e = 50, \varrho_h = 0.5$ and the resulting pulse height spectrum with 1000 solution bins divided over 100 channels.

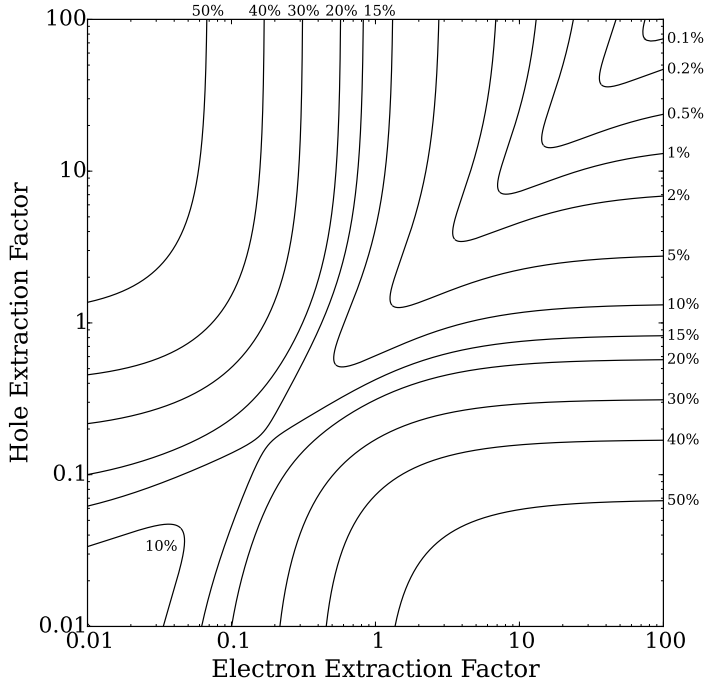

Figure 15.52. The expected percent standard deviation in the observed induced charge signal as function of ϱ_e and ϱ_h. From [Knoll and McGregor 1993].

distribution appears in a long tail region, with approximately 19% of the events appearing in the full energy peak. Overall, Eq. (15.240), Eq. (15.243), and Eq. (15.244) serve to illustrate the effect of trapping on the energy resolution of a planar radiation detector.

Radiation detectors are often irradiated with one side exposed to the source. For instance, the condition for Eq. (15.240), Eq. (15.243), and Eq. (15.244) is uniform irradiation between the detector contacts, as with irradiating a semiconductor block from the side between the contacts. Often a detector is irradiated towards one of the electrical contacts, in which exponential absorption from one contact to the other render a non-uniform gamma-ray interaction distribution. The resulting pulse height distribution is weighted by the probability the gamma ray interacts within the detector, thereby changing the result of Eq. (15.240) and Eq. (15.243), a condition especially true for low-energy gamma rays. If it is assumed that a gamma-ray deposits all energy for each event in a defined small region (i.e., the photoelectric effect dominates), then the pulse height distribution for a planar detector can be corrected by multiplying Eq. (15.240) and the gamma-ray interaction probability density function, namely

$$P(x')\frac{Q(x')}{Q_0} = \frac{Q(x')}{Q_0}\frac{\mu_p \exp^{-\mu_p x'}}{1-\exp^{-\mu_p W}}, \tag{15.247}$$

where μ_p is the photoelectric interaction coefficient which, for low energy photons, is much greater than μ_C and μ_{pp} for scattering and pair production, respectively. However, the predominant method of gamma-ray interactions for moderate to high-energy gamma rays is Compton scattering, which further confuses the evaluation of Q, $\langle Q \rangle$, and σ_Q^2. Geometries other than planar can be used to improve the energy resolution by increasing the charge induction influence of one charge carrier over the other, as already described in Secs. 8.7 and 8.8. Corrections must also be made to the expected value of $Q(x)$ to account for differences in the induced charge and differences in the gamma-ray absorption probability. Such a calculation is best accomplished by using transport theory methods to determine location and energy deposited, coupled to the weighting potential to determine the effect on induced charge, and multiplying the results by Eq. (15.240). These concepts are further explored in a latter chapter on radiation spectroscopy.

15.5.2 Energy Resolution Improvement Methods and Designs

Because of the severe hole trapping and the degradation in energy resolution, multiple methods have been developed to improve the spectroscopic performance of CdZnTe detectors [Zhang et al. 2013]. Electronic corrections such as rise time rejection and rise time correction were introduced to mitigate hole trapping problems. The usual difficulties accompanied these methods. For instance, rise time rejection helps to eliminate undesirable pulses, thereby decreasing the effective volume of the detector and consequently reducing the efficiency. Rise time correction has also been successfully used, a method that artificially adds "charge" to the signal as a function of the initial slope of the current and induced charge. More clever methods used device weighting fields and geometric effects to counter charge loss from hole trapping. These techniques used for Si and Ge detectors altogether eliminated the need for complicated electronics and required only common preamplifier and amplifier circuits. Finally, there are hybrid detectors that used both clever weighting potential corrections and rise time corrections to achieve improved energy resolution and detection efficiency.

Pulse Shape Discrimination and Pulse Rise Time Compensation

Electronic corrections have been used to improve the gamma-ray energy resolution of many different semiconductor detectors, most of them fabricated as planar-style detectors. Jones and Woollam [1975] are credited with first introducing the idea of improving the results of poor charge collection and trapping effects by discarding pulses with rise times greater than 100 ns. In so doing, pulses dominated by hole drift were eliminated, leaving only those pulses that were mainly electron dominated. This technique of discarding

undesirable pulses is referred to as *pulse shape discrimination* (PSD), and can be used to improve the spectroscopic performance of detectors in which one type of charge carrier undergoes problematic trapping [Holzer 1983]. The use of PSD has been reported for CdTe detectors [Richter and Siffert 1992 (shown in Fig. 15.53); Bargholtz et al. 1999], CdZnTe detectors [Cardoso et al. 2003] and HgI_2 detectors [Holzer 1983]. Unfortunately, PSD also reduces the effective volume of the detectors, thereby also reducing the detection efficiency.

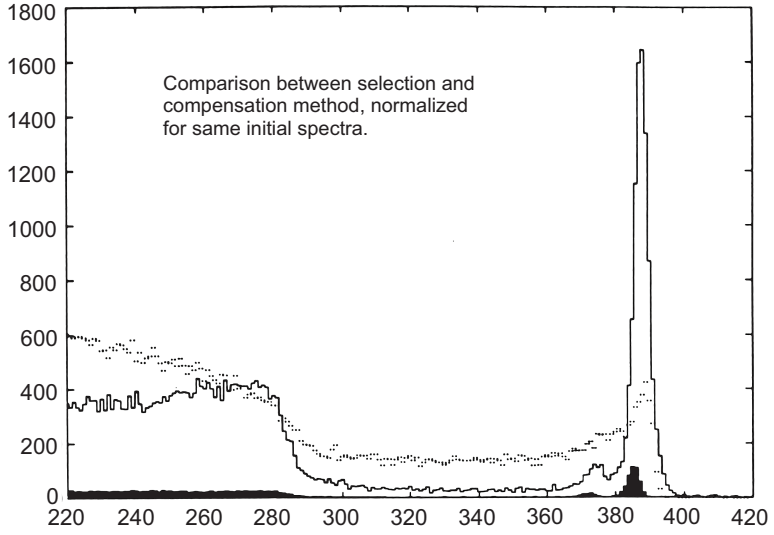

Figure 15.53. A comparison of results from a planar 5 mm × 5 mm × 2 mm CdTe detector. The comparison shows the result for ^{137}Cs without correction (light dots), with PSD (blackened spectra), and PRC (black outline). From Richter and Siffert [1992]; copyright Elsevier (1992), reproduced with permission.

Another electronic method to improve energy resolution was introduced by Matsushita et al. [1981; 1982], and is generally referred to as *pulse rise-time compensation* (PRC).[14] Matsushita et al. applied the technique to correct for charge losses in neutron damaged Ge or Ge(Li) detectors. The technique can involve (1) the recognition that the initial slope of the pulse is an indicator of the number of charge pairs liberated by the radiation event, and (2) the resultant pulse height is a manageable function of the trapping charge loss. Various methods of accomplishing PRC have been reported, including results by Richter and Siffert [1992; 1993], Keele et al. [1996], and Auricchio et al. [2005]. Although the method was originally applied to planar detectors, it was found that PRC could be applied to coaxial and trapezoidal geometries, although the corrections were complicated by the non-uniform electric fields Matsushita et al. [1981; 1982]. Richter and Siffert [1992] found that the full energy peak shifts linearly with pulse height, thereby allowing an electronic correction by artificially adding value to a smaller pulse height. The PRC technique gives improved spectroscopic results while retaining relatively good counting efficiency. Combining PSD and PRC, Ivanov et al. [1995] report best energy resolution of 1% FWHM for 662-keV gamma rays with a 2 mm × 5 mm × 5mm detector at room temperature without a decrease in full energy peak efficiency. Although both the PSD and PRC methods give improved performance, Richter et al. [1993] point out that differences in detector

[14] Matsushita et al. [1982] originally named the method the "pulse-height correction" (PHC) technique.

performance, including problems with space charge limited currents, can diminish the effective use of these correction methods.

Coaxial and Hemispherical Two-Terminal Devices

In Secs. 8.7 and 8.8 it was seen that the weighting function can be made strongly non-linear by adjusting the relative sizes of the cathode and anode contacts. The fundamental geometries evaluated were planar, coaxial and spherical. The problem of using planar designs in the presence of highly trapped charge carriers was evaluated in Sec. 15.5.1 and the consequences shown in prior sections of this chapter. Lund et al. [1996] attempted to reduce the effect of hole trapping in CdZnTe detectors by producing coaxial devices; however, the performance was only marginally improved over that of a planar detectors. Unlike the coaxial geometry commonly used for HPGe detectors, in which charge carrier trapping for both holes and electrons is negligible, the non-uniform electric field in a coaxial CdZnTe detector produces non-constant charge carrier speeds and, consequently, changes in the mean free drift times compromising the performance [McGregor and Rojeski 1999]. There are relatively few reported results for coaxial compound semiconductor detectors, mainly because of the difficulty with producing coaxial detectors from soft and brittle semiconductors. A partial coaxial geometry, literally a wedge segment from a coaxial geometry, was reported by McGregor et al. [1999] with improved results.

Hemispherical detectors have also been investigated [Malm et al. 1975; Zanio 1977; Alekseeva et al. 1985]. The detectors are semiconductor hemispheres with the rounded surface acting as the cathode with a small dot anode positioned at the hemisphere focus. The geometric weighting of the device causes most pulses to originate near the cathode, thereby most pulses are electron dominated and consequently the energy resolution is improved. The field dependent speed and mean free drift times must also be considered when predicting the spectroscopic performance. Khusainov [1992] describes the performance of CdTe hemispherical detectors, slightly chilled with a Peltier cooler, and obtained an energy resolution of 10 keV FWHM at 662 keV. Back in 1992, these CdTe hemispherical detectors were commercially available and in use by the IAEA for control of SNM. Sensitive volumes reported by Khusainov were, at maximum, only 32 mm^3, while Richter and Sifferet [1992] report energy resolution averaging about 5% FWHM at 662 keV and show results from a 65 mm^3 device. Bale and Szeles [2006] report the results from a commercial "quasi-hemispherical" CdZnTe detector, fabricated by covering five of the six faces of a semiconductor right cuboid with an electrode that serves as the cathode, and then placing a small dot anode in the center of the sixth face. A right cuboid shape is much easier to fabricate than a hemisphere, and the spectroscopic performance is practically the same, reported to be 20 keV FWHM (3%) for 662 keV gamma rays. The $\mu_e\tau_e$ product limits the practical radius of the device (see Fig. 15.54), a limitation which is also true for a coaxial detector. While a coaxial detector volume can be increased without affecting the radius by simply lengthening the device, the same is not true for a hemisphere. Consequently, the useful volume of a hemispherical device is limited by a radial dimension that has efficient electron collection.

There is a fundamental problem with almost all two terminal devices designed to enhance the induced current of one charge carrier over the other; mainly, the weighting potential is the normalized distribution of the actual operating potential. Although the presence of space charge complicates the analysis by further altering the voltage and electric field distribution in a detector, for simplicity consider the case without space charge. Detectors with strongly non-linear weighting potentials also have strongly non-linear operating potentials, thereby also producing large regions of low electric field. Consequently, the charge carrier speeds of both electrons and holes are also low in the low electric field region and reduces the $\mu\tau$ products. Detectors with three or more terminals can be used to counter this problem by decoupling the weighting potential from the operating potential.

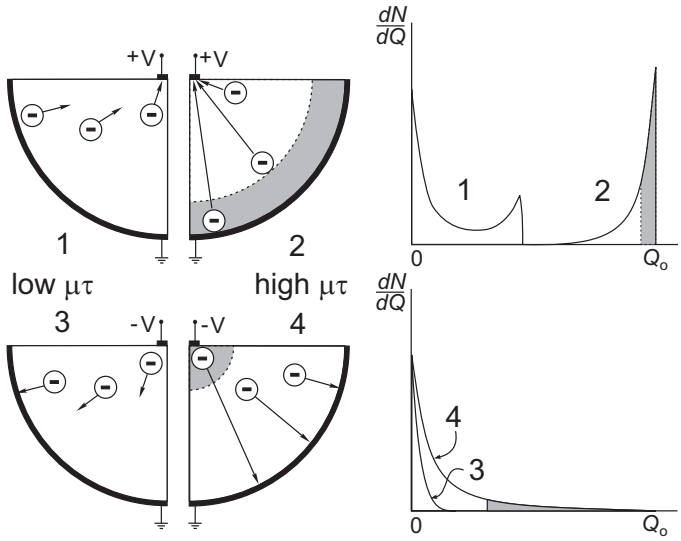

Figure 15.54. Expected pulse height spectra from a hemispherical detector with severe hole trapping for four cases: (1) positive focus with low $\mu_e\tau_e$, (2) positive focus with high $\mu_e\tau_e$, (3) negative focus with low $\mu_e\tau_e$, and (4) negative focus with high $\mu_e\tau_e$. After Malm et al. [1975].

Weighting Field Optimization

Another method to improve spectroscopic resolution employs clever electrode designs to force the appearance of strongly non-linear weighting potentials [Zhang et al. 2013]. These electrode designs are used to enhance the importance of charge induction of one charge carrier type (usually electrons) while reducing or negating the influence of the other charge carrier (usually holes). Quite often these detectors are referred to as single carrier detectors. There are many such designs and a few important types are briefly described here.

A common method used to solve the detector weighting potential is to employ Laplace's equation

$$\nabla^2\phi = 0, \tag{15.248}$$

where ϕ is the electrical potential. As explained in Section 8.6, space charge does not affect the weighting potential and, hence, Laplace's equation is used instead of Poisson's equation. Equation (15.248) is solved with the boundary conditions that the output conductive contact is normalized to one volt and *all* other contacts are grounded at 0 volts. This computational method is described and used by Shockley [1938].[15]

Radiation spectrometers with optimized weighting fields to improve performance are often designed with the methods introduced in Chapter 8. Although simple designs using planar, coaxial, and spherical geometries are easily calculated with analytical methods, complex geometries and electrode patterns require numerical methods to analyze the weighting field and weighting potential. There are available many finite-difference software programs designed to analyze the electric fields and voltage potentials within a dielectric material.

Co-Planar Grid Luke [1994, 1995] introduced a contact geometry referred to as the *coplanar grid detector*. The method mimics the Frisch grid ion chamber. The detector is generally planar in form, with a planar cathode contact on the lower surface and a series of parallel contact strips on the upper surface. It has

[15] The method is derived from Green's theorem, although over the years it has been named Ramo's theorem or the Shockley-Ramo theorem. The core solution is derived from either Green's theorem or the reciprocal Green's theorem.

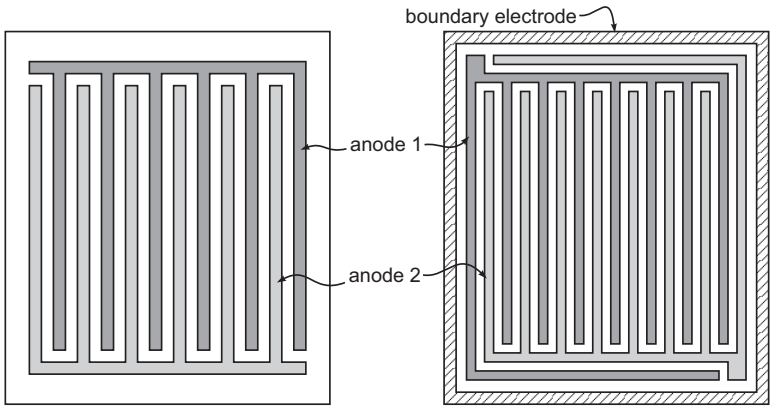

Figure 15.55. Simple coplanar grid design (on left) and a balanced coplanar grid design (on right).

no actual drift region as with the Frisch grid ion chamber, but instead has a virtual drift region defined by the strip widths and pitch as shown in Fig. 15.55. In the original work, alternating contact strips were connected to two different preamplifiers, labeled in the present case as high and low preamplifiers. The high contacts operate as collecting anodes and the low contacts act as secondary non-collecting anodes with a lower positive voltage than the collecting anodes. Both contacts are biased positively with respect to the planar back cathode.

The signal from the low preamplifier is subtracted from the signal of the high preamplifier, thereby producing a virtual Frisch grid effect. As electron charge carriers move toward the anodes, they induce current to flow on all anodes, both collecting and non-collecting. At distances relatively far from the anodes, these induced currents are practically identical, hence, the net output result is zero. The same is true for hole charge carriers moving in the opposite direction. However, as charge carriers reach the strip electrodes, the higher bias applied through the high preamplifier causes electrons to turn into the collecting electrodes, producing a positive current flow on the high preamplifier and negative current flow on the low preamplifier. As electrons are completely collected, the net subtracted result between both outputs is the appearance of full charge collection on the combined output. Because holes move the opposite direction towards the planar back electrode (cathode), their net contribution is practically zero, thereby negating the deleterious effect of trapping. The biasing scheme and resultant induced signal are depicted in Fig. 15.56, and the resulting weighting potential is shown in Fig. 15.57. Although the improvement was dramatic and an important innovation for room temperature radiation spectroscopy, effects from electron trapping and weighting field imbalances between the anode strips caused broadening of energy peaks. The resulting full energy peaks typically had low and high energy tails, producing a flared appearance to the base of the energy peak, and thus limited the improvement in energy resolution.

He et al. [1998] and Sturm et al. [2004] corrected the weighting field imbalance by optimizing the coplanar strip design, which included two balancing strips around the coplanar strips with an additional boundary electrode around the detector perimeter as shown in Fig. 15.55. In doing so, He et al. [1998] dramatically improved the performance of the coplanar grid detector. The flared base of the full energy peak was practically eliminated, and with charge compensation through electronic methods, energy resolution below 2% FWHM at 662 keV was usually realized. This balanced configuration, in various forms, is now a standard design feature for commercial coplanar grid CdZnTe detectors.

Small Pixel Detectors Detectors with pixels have been fabricated from a variety of semiconductors, including Ge, Si, GaAs, and CdZnTe, for the purposed of two-dimensional imaging of radiation. Ultra-small pixels on CdZnTe detectors were initially introduced by Doty et al. [1992]; however, it was Barrett et al. [1995] who identified what is now commonly referred to as the *small pixel effect* by analyzing the results from pixelated CdZnTe detectors. The basic design is essentially another two-terminal device, but there is instead an array of small pixel anodes on one surface and a single planar cathode contact on an opposing surface as shown in Fig. 15.58. Barrett et al. [1995] correctly point out that the weighting potential is strongly non-linear for each pixel, giving stronger influence to charge carriers moving near the anode pixels. As charge carriers, electrons for instance, approach any particular pixel, the induced charge accumulates almost entirely on a single pixel. Hence, connecting separate outputs to each pixel allows one to determine the charge location while benefiting from improved charge collection. For pixel size $\epsilon \times \epsilon$ and detector thickness L, the total induced charge for electron-hole pairs excited at location $z = 0.2L$ near a pixel is plotted as a function of ratio ϵ/L in Fig. 15.59. From this figure it becomes clear that the single carrier effect becomes stronger as the ϵ/L ratio diminishes.

If the same *operating* potential is applied to all pixels, the overall effect is to have a near constant electric field across the detector thickness, thereby negating the non-uniform electric field effects observed with cylindrical, trapezoidal, and hemispherical detectors. The simple pixel design, however, suffers from charge sharing and charge loss problems. Charge sharing is caused by electrons produced by a single initial event are collected by two or more electrodes, and causes pulse height reduction on all electrodes involved. Charge loss is caused by trapping of slow moving electrons in the low field region between pixels, ultimately reducing the pulse height.

The small pixel effect can be enhanced by adding a third electrode around the pixels (see Fig. 15.58), which performs as a non-collecting steering electrode much like that in the co-planar grid [He 1995]. Under such a condition, the pixels can be biased positive with respect to the steering grid, while the steering grid

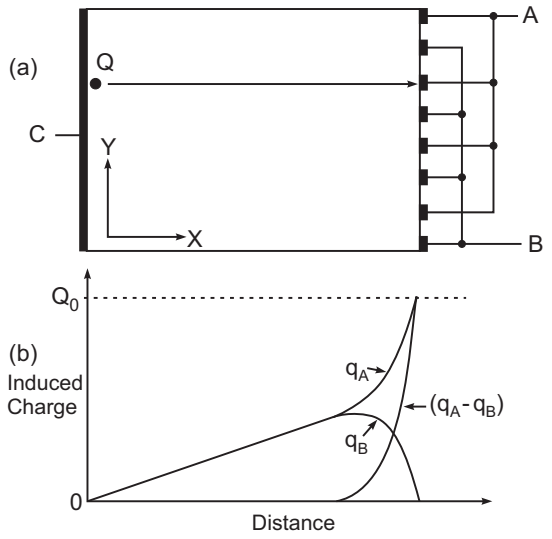

Figure 15.56. Shown are (a) the basic structure of a coplanar grid detector, (b) induced charge on the electrodes A (q_A) and electrodes B (q_B) and the resultant difference signal. After Luke [1995].

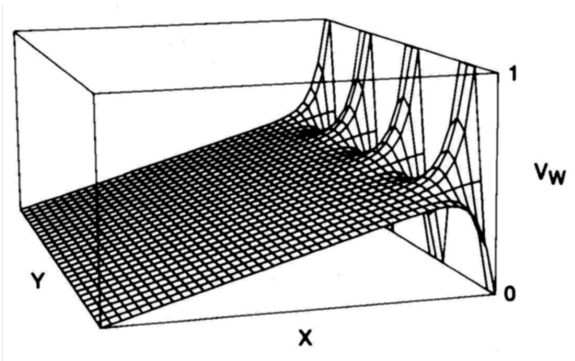

Figure 15.57. Weighting potential distribution for the set of collecting grid electrodes in the coplanar grid configuration. Reproduced from P.N. Luke, *Appl. Phys. Lett.*, **65**, 2884, (1994), with the permission of AIP publishing.

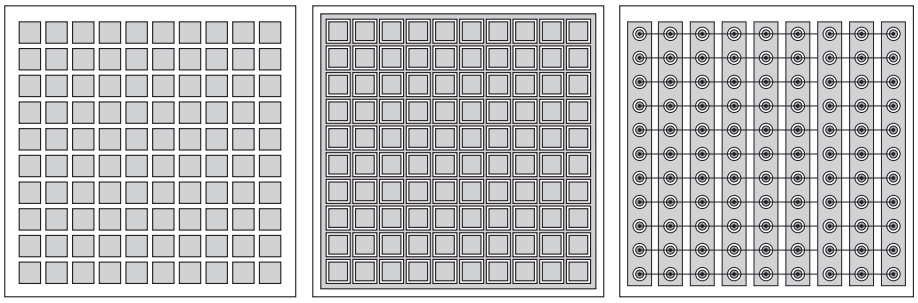

Figure 15.58. Simple pixel detector design (left), a pixel detector design with a steering grid (middle), and a hybrid pixel-strip design (right).

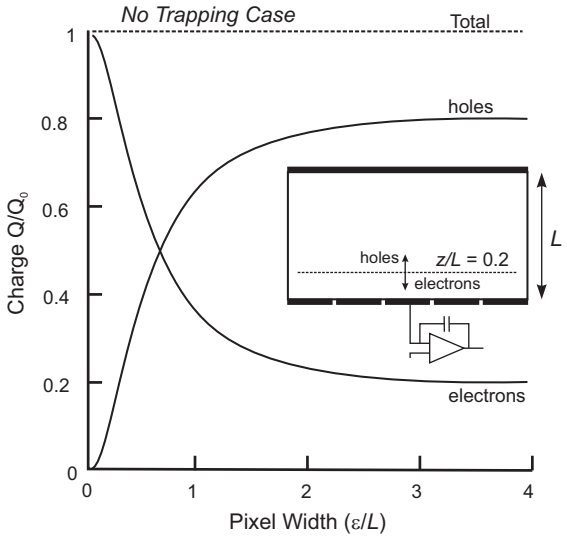

Figure 15.59. Total collected charge for holes and electrons excited at depth $Z = 0.2L$ as a function of pixel size. After Barrett et al. [1995].

is biased positive with respect to the cathode. Usually the pixels are just a few volts higher in positive bias than the grid, enough to efficiently collect electrons while minimizing leakage current between the anodes and grid. Hence, the steering grid functions as a non-collecting electrode which (1) assists with electrically steering electrons into a collecting pixel and (2) reduces the leakage current impact on the anode outputs [He et al. 1999]. Energy resolution was further enhanced by applying electronic correction methods to the pixel/grid structure. Because a lateral electric field is applied between the grid and pixels, the steering grid helps reduce the problem with charge losses observed in simple grid designs.

Another pixelated electrode configuration, a hybrid between a pixel detector and a strip detector, was studied by Mayer et al. [1999] and Montemont et al. [2007]. Each strip electrode has an embedded row of pixels, in which the strip acts as the non-collecting electrode. The design attempts to produce a simple scheme for two-dimensional radiation imaging, thereby greatly reducing the number of electronics readout points from a basic pixel detector, while retaining the advantage of the small pixel effect. The strips each have a separate readout and operate as steering grids, while the rows of pixels are interconnected, each row having a separate readout (see Fig. 15.58). Readout information from the x-y grid yields position information, while the small pixel effect improves gamma-ray energy resolution.

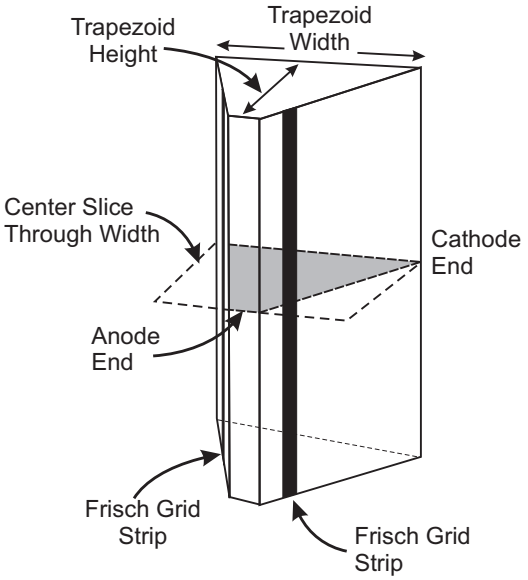

Figure 15.60. A 3-D depiction of a trapezoid frustum semiconductor Frisch grid detector. Also shown is a plane sliced through the middle of the device. From McGregor et al. [2001].

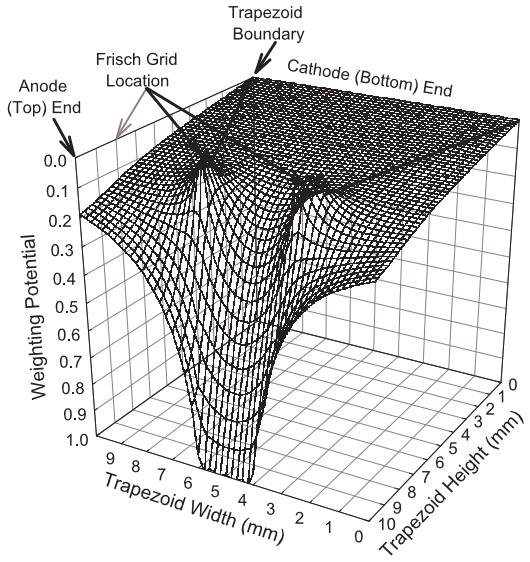

Figure 15.61. The weighting potential of a trapezoid frustum geometrically weighted CdZnTe Frisch grid detector, sliced through the center of the detector as shown to the left. After McGregor et al. [1999a].

Frisch Style Constructions McGregor et al. [1997; 1998] introduced the parallel strip and geometrically weighted parallel strip CdZnTe detector designs in 1997. The simplistic design required only one preamplifier output, and was designed to mimic the operation of a Frisch grid ion chamber. The detector consisted of a CdZnTe bar, nominally 2-3 mm thick, with surface areas of 5 mm × 5 mm or 10 mm × 10 mm. Parallel edges of the planar device had electrical contacts applied. On opposite surfaces, centering approximately 1 to 2 mm from one edge contact, gate contacts were applied through physical vapor deposition. One edge contact was biased negatively, the parallel gate contacts were grounded, and the output anode edge contact was biased positively through a commercial preamplifier. Room temperature energy resolution of 41 keV FWHM for 662-keV gamma rays was reported for a 1 cm × 1 cm × 2 mm device. The device worked to demonstrate the concept, and was later improved by using a trapezoidal frustum shape. The small end of the frustrum operated as the output anode, the large bottom of the frustum operated as the cathode, that the gate electrodes were centered at 1.5 mm from the anode (see Fig. 15.60 and Fig. 15.61). As explained in the literature [McGregor et al. 1999a; McGregor and Rojeski 1999b, 2001], more gamma-ray interactions occur in the drift region near the base, thereby causing the majority of pulses to be electron dominated. The multiple-electrode design provides the benefits of both a non-linear weighting potential and also, through appropriate application of voltages to the anode and grid, a nearly uniform electric field through the detector. Room temperature energy resolution of 17.76 keV FWHM for 662-keV gamma rays was reported for a 1 cm^3 device. Initially there were some issues with leakage current between the grid and anode. Theory shows that the grid need not be in direct contact with the semiconductor; hence, surface leakage current was practically eliminated by applying a thin Al_2O_3 layer atop the semiconductor sides, followed by the application of the

grid strips. Although the trapezoid Frisch grid detectors worked well,[16] the detector cutting, shaping, and polishing proved challenging and difficult to fabricate.

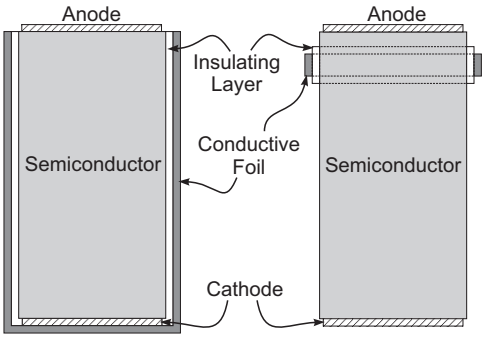

Figure 15.62. Cross section depictions of a (left) Frisch collar and (right) Frisch ring semiconductor detector.

McGregor and Rojeski [2001] (and McGregor [2004]) introduced another simple device, commonly referred to as either a *Frisch collar detector* or *Frisch ring detector*, depending on the length of the gate contact (see Fig. 15.62). The detector is designed as an elongated semiconductor bar with contacts at each end. The bar is wrapped in an insulating coating followed by a conductive wrapper or sleeve. The insulating layer eliminates leakage current between the Frisch ring/Frisch collar and the collection electrode. Much like the strip grid designs, the Frisch ring design produces both a non-linear weighting potential and, with the proper application of potentials to the grid ring and anode, a nearly uniform electric field throughout the detector (see Fig. 15.63). However, the Frisch collar design is simpler to manufacture than the trapezoid or Frisch ring designs, and generally produces better energy resolution, despite being a two-terminal device. The conductive wrapper or sleeve is grounded and the remaining anode contact is positively biased.

The first such detector was reported by McNeil et al. [2004] whose detector had dimensions of 3 mm × 3 mm (area) × 6 mm (length). Electroless gold contacts were applied to the 3 mm × 3 mm ends and Teflon tape was wrapped around the bar as the insulator. Afterwards, thin Cu foil was used as the conductive wrapper. Using a commercial charge sensitive preamplifier, the detector delivered room temperature energy resolution of 15.3 keV FWHM (2.31%) for 662 keV gamma rays. Kargar et al. [2006; 2009] and Harrison et al. [2009] worked to optimize the design and performance of the Frisch collar detector, eventually achieving room temperature energy resolution of 5.9 keV FWHM (0.89%) for 662 keV gamma rays [Ugorowski et al. 2011]. It was discovered that performance improved as the dielectric constant of the insulating layer decreased, and Teflon tape, with a dielectric constant of only 2.1, was an obvious choice and yielded superior results over alternative insulators, including Al_2O_3 and SiO_2. The Frisch collar design has also been successfully applied to HgI_2 detectors [Ariesanti et al. 2010, 2011; Kargar et al. 2011a, 2011b], and a 2.1 mm × 2.1 mm × 4.1 mm device yielded room temperature energy resolution of 11.9 keV FWHM (1.8%) for 662 keV gamma rays. A considerable advantage of the Frisch collar design is the simple construction from a common planar bar of semiconductor material and low cost materials, thereby eliminating the need for electrode patterning altogether. These detectors can be arranged in an array for imaging purposes [McGregor 2004; Cui et al. 2007, 2008; Ugorowski et al. 2011]. The robustness of the Frisch collar design has been verified by other research groups [Kim et al. 2015; Jeong et al. 2015; Bolotnikov et al. 2012].

Drift Style Detectors The semiconductor drift chamber (SDC), originally designed for large area Si detectors [Gatti and Rehak 1984; Rehak et al. 1985, 1986], has been adapted to compound semiconductors as a means of countering the effects of charge carrier trapping. The original intent of the SDC was to increase the active area of a semiconductor detector while reducing capacitive noise. The basic design uses a series of microstrip electrodes, either in a linear array or a series of concentric circles (bull's eye) on opposing sides of a semiconductor block [Rehak et al. 1985; Bertuccio et al. 1992]. At least one of the electrodes serves as an anode, while the remaining electrodes serve as guiding electrodes. These guiding electrodes are biased

[16] At the time, the trapezoid parallel strip detectors set the room temperature resolution record for CdZnTe, but was surpassed by other technologies within only a few years.

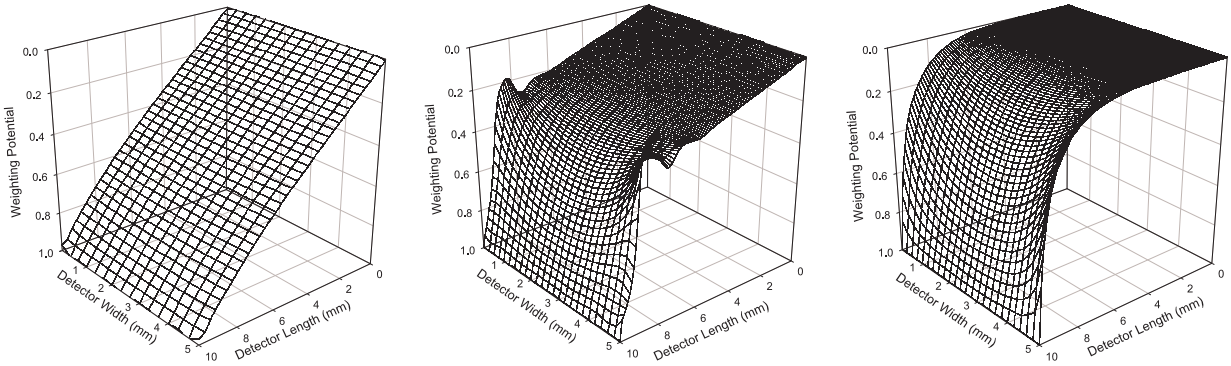

Figure 15.63. Comparison of weighting potentials from a (left) planar device, (middle) Frisch ring device, and (right) Frisch collar device. Each detector is modeled as a 5 mm × 5 mm × 10 mm CdZnTe detector. The insulating material is 100-micron thick Teflon.

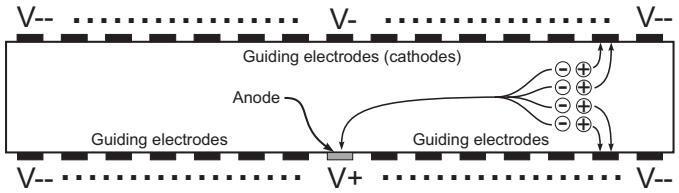

Figure 15.64. Side view depicting the operation of a semiconductor drift chamber.

so as to drift electrons to the anode, typically a bias scheme with sequentially increasing positive electrodes towards the anode or sequentially decreasing negative electrodes toward the anode (see Fig. 15.64).

Immediately one can observe that the electrode geometry has much in common with the coplanar, pixel, and Frisch style detectors, in which most of the induced charge accumulates on the anode as electrons are transported in the region nearest the anode [Patt et al. 1996]. Consequently, the SDC can be operated as a single carrier device for materials with hole trapping problems. Patt et al. [1996], van Pamelen and Budtz-Jørgensen [1998], and Kuvvetli et al. [2001, 2005] describe HgI_2 and CdZnTe SDCs with linear array strips while Owens et al. [2007] reports on a CdZnTe SDC with a concentric ring pattern. These detector configurations show improved performance over simple planar detectors. Van Pamelen reports 6.89 keV FWHM (1.1%) for 662-keV gamma rays on a small (1.5 mm thick) CdZnTe detector and Patt et al. [1996] report 6.62 keV FWHM (1%) for 662-keV gamma rays on a small 6 mm × 6 mm area × 2 mm thick HgI_2 detector. An alternative drift style detector was reported by Butler [1997], composed of a single pixel surrounded by a drift/focusing electrode. A planar cathode was applied upon the opposing surface. The detector was operated by applying equal negative voltage to the focusing electrode and cathode with respect to the anode[17] [Apotovsky et al. 1997]. A best energy resolution of 3.67 keV (0.72%) at 511 keV was reported for a 3 mm × 3 mm × 3 mm cube of CdZnTe.

Hybrid Improvements

Resolution improvement has also been realized by combining multiple effects, particularly, PRC methods with single carrier detector designs. The use of PRC methods helps to offset energy degradation from electron

[17] Named "Spectrum Plus" detectors, these devices were commercially available for a short time during the late 1990s.

trapping. He et al. [1998] introduced hybrid solutions with balanced co-planar grid detector geometries to achieve energy resolutions on the order of 1% FWHM at 662 keV. The combination of the small pixel effect with PRC methods has also been explored by He et al. [1999] who reported a high energy resolution of less than 1.5%. An added benefit of the hybrid pixelated detector is the ability to determine the interaction location within the bulk of the semiconductor detector as a function of x, y and z. Consequently, using Compton scattering deconvolution methods, the actual direction of a gamma-ray source (or sources) can be determined in a relatively short time [Wahl et al. 2015]. These hybrid methods have been successfully applied to different compound semiconductors, including CdZnTe [Wahl et al. 2015], HgI_2 [Baciak and He 2003a, 2003b], and TlBr [Hitomi et al. 2008].

PROBLEMS

1. Determine the following:

(a) kT at 300 K

(b) kT/q_e at 300 K

(c) The band-gap energy of Si and Ge at 300 K

2. Calculate the electron and hole concentrations, the material resistivity, and the Fermi energy level for Si doped with $p = 5 \times 10^{15}$ cm^{-3} with background dopants $n = 3 \times 10^{15}$ cm^{-3}.

3. An Si pn junction diode has $N_A = 8 \times 10^{17}$ cm^{-3} and $N_D = 5 \times 10^{15}$ cm^{-3}, with $\tau_p = 10^{-7}$ s and $\tau_n = 10^{-6}$ s, with the device area of $A = 25$ mm^{-2}. (a) Determine the theoretical saturation current at 300 K. (b) Calculate the forward and reverse currents at ± 0.7 V.

4. A Si pn junction diode has $N_A = 10^{17}$ cm^{-3} and $N_D = 10^{15}$ cm^{-3}. Calculate the value of V_{bi} for T = 100 K, 200 K, 250 K, 300 K, 350 K, 400 K, and 500 K. Determine both W and $\mathcal{E}_{max}$ at 300 K.

5. It is the goal in making a semiconductor detector to create the largest possible depletion width. Explain how this goal is best realized by using the purest semiconductor material available.

6. Given a 600-micron thick Si semiconductor $p\nu n$ diode with $p = 10^{16}$ cm^{-3}, $\nu = 10^{12}$ cm^{-3}, and $n = 10^{16}$ cm^{-3}, find the depletion width when reverse bias of 100 volts is applied. What is the depletion width if the reverse bias is increased 300 volts?

7. You have a Si $p\nu n$ junction device that is 150 microns wide with $\nu = 10^{13}$ cm^{-3}. Determine the punch through voltage. Determine the breakdown voltage.

8. Describe quantitatively how the magnitude of the reverse bias applied to a p-n junction affects (a) the device capacitance, (b) the width of the depletion layer, and (c) the maximum electric field.

9. Given a 1.2-micron sample of CdS with a shallow trap density of 10^{15} cm^{-3}, what is the expected value of V_{TFL}?

10. A young engineer under your direction comes up with the idea of stacking two identical semiconductor detectors in series and applying the bias across both detectors. What is the expected output and the consequence of this device circuit?

11. An n-type Si photoconductor bar (dimensions $W_1 = 0.1$ mm, $W_2 = 0.01$ mm, $L = 2$ mm) is uniformly illuminated for a period of time $\gg \tau_n$, where $n = 10^{14}$ cm^{-3}, $\tau = 1$ μs, and $T = 300$ K. If the initial illumination produces a generation carrier density of $G(0) = G_0 = 10^{16}$ cm^{-3}, and turned off at $t = 0$, what is the time dependent value of Δn? At 5 volts bias, what is the measured current as a function of time?

12. Explain how and why the energy resolution of a surface barrier detector changes as the surface area of the detector is increased.

13. Calculate and plot the Q-map for the case in which the ratio of ϱ_e/ϱ_h is constant at 10, with ϱ_e values of 50, 25, 0.5, 2.5, 0.5 and 0.05. Comment on the expected pulse height distributions. How would you design a planar detector to ensure good energy resolution?

14. For an ideal p-type MOS structure ($N_A = 5 \times 10^{15}$ cm^{-3}) with an oxide thickness of 30 nm, determine the threshold voltage V_T for strong inversion. Note that $\kappa = 3.9$ for SiO_2 and 11.9 for Si.

15. Derive the result of Eq. (15.244).

16. Derive the result of Eq. (15.243).

17. Starting with the material resistivity ρ very high, such as with a semi-insulating material, derive the result of Eq. (15.189). Explain the consequence of this finding.

18. You have introduced an n-type dopant into a Si surface, and the backplane has a conductive layer. The doping depth is 1.5 microns and the feature size is 1 cm L $\times$ 0.5 cm W. Using a four-point probe with spacing of 1.5 mm between the probes, you measure 5 μA at 3 volts. What is the resistivity of the doped region?

19. Derive Eq. (15.247).

20. Given a CdZnTe hemispherical detector with anode $r_1 = 1$ mm and cathode $r_2 = 6$ mm, calculate the weighting potential of the device. What fraction of the induced charge is from electrons if a gamma-ray is completely absorbed at $r = 2$ mm, 3 mm, 4 mm, and 5 mm? Suppose that trapping is present with $\tau_e = 10^{-6}$ s, if $\tau_e \gg \tau_h$, explain why these outcomes are important.

Chapter 16

Semiconductor Detectors

I have lately met with an extraordinary case ... which is in direct contrast with the influence of heat upon metallic bodies ... On applying a lamp ... the conducting power rose rapidly with the heat ... On removing the lamp and allowing the heat to fall, the effects were reversed.

Michael Faraday

16.1 Introduction

Semiconducting behavior was first discovered by Faraday in 1833 when he observed that current flow through AgS increased with temperature,[1] the opposite effect observed with conductive metals. We now know this effect to be a consequence of increased free charge carrier densities in the conduction and valence bands as temperature is increased. Decades later, Braun [1874] observed rectifying behavior from a point contact on a PbS crystal, in which current would flow in only one direction, but not the other, when positive voltage was applied, alternately, to the sample. This fundamental semiconductor physical property would be used nearly a century later as a building block for semiconductor diode and transistor designs.

Soon after the development of the gas-filled detector by Hans Geiger and Ernest Rutherford, some interest was placed in discovering a solid-state material for radiation detection. The concept, correctly, was to increase the radiation detection efficiency by substituting the gas medium with a solid-state medium. Perhaps the earliest recording of such an effort was a study performed by Röntgen and Joffé [1913] on various solids exposed to high levels of x radiation, followed by another study in 1921. Additional work by Schiller [1926] and Jaffé [1932] revealed conduction through dielectric crystals upon the application of high voltages and high irradiation fields. Yet, none of these works resulted in the practical application of solid state conduction counters.

The first semiconductor-based radiation detector was reported by Stetter in 1941, in which several materials were exposed to α-particles, β-particles, and protons. As with earlier works, most of those materials were insulators (alkali halides, sulphur, cerrusite, fluorite) resulting in no observed effect; however, Stetter also reported the observation of electrical current from a diamond sample exposed to ionizing radiation. Several years later, Van Heerden [1945; 1950a; 1950b] published his work on AgCl crystals, "The Crystal Counter",

[1] Published account is in his book *Experimental Researches in Electricity* [1839].

Table 16.1. Chronological initial exploration dates as radiation detectors for selected semiconductors.

Semiconductor	Common Abbreviation	Year	Reference
Diamond	diamond (C)	1941	Stetter
		1947	Wooldridge, Ahearn & Burton
		1948	Curtiss and Brown; Jentschke
Silver Chloride	AgCl	1945	Van Heerden
		1947	Hofstadter, Milton, Ridgway
Cadmium Sulphide	CdS	1947	Frerichs
		1948	Kallman and Warminsky
Thallium Bromide	TlBr	1947	Hofstadter
Thallium Iodide	TlI	1947	Hofstadter
Zinc Sulfide	ZnS	1948	Ahearn
Argon (solid)	Ar	1948	Hutchinson
Silver Bromide	AgBr	1949	Yamakawa
Mercury Sulfide	HgS	1949	Ahearn
Sulphur[†]	S	1949	Georgesco
Germanium	Ge	1949	McKay
Sodium Iodide	NaI	1950	Witt
Silicon	Si	1958	Davis
Gallium Arsenide	GaAs	1960	Harding
Cadmium Telluride	CdTe	1967	Autagawa, Zanio and Mayer
Mercuric Iodide	HgI_2	1971	Willig
Lead Iodide	PbI_2	1971	Roth and Willig
Cadmium $Zinc_{1-x}Telluride_x$	CZT	1992	Doty et al.

[†]Stetter [1941] also studied sulphur, but with negative results.

widely accepted as the first reported semiconductor detector.[2] Upon the publication of Van Heerden's work, numerous semiconductor materials were subsequently investigated, and the investigators along with their introductory years are tabulated in Table 16.1.

Up until 1960, semiconductor detectors, then called "crystal counters", were considered mostly a novelty for radiation detection and were not commercially produced. The main reason, as expressed by Price [1958, 1964], was that semiconductors were of "very little use because of the preponderance of advantages of the scintillation detectors".[3] A significant disadvantage of semiconductors at the time was the high level of background impurities and crystal defects. Under reverse bias, the impurities could become ionized, as explained in Sec. 15.3.5, and trapping of electrons or holes in the defect states would reduce the induced current. In both cases, space charge would be created which tends to counter the applied voltage and reduce both the electric field and the depletion region width. However, in 1960 while working for the General Electric Co. (GE), Erik M. Pell [1960a, 1960b] developed a method of introducing a compensating Li ion into Si that countered the effect of p-type dopants. The method included the application of Li material to a heated bulk Si sample and driving Li ions deep into the semiconductor with a strong electric field, a method known as "Li drifting". The technique was successfully applied to Si [Pell 1960b; Elliot 1961; Blankenship and Borkowski 1962] and Ge crystals [Freck and Wakefield 1962; Tavendale 1963, 1966; Goulding and Hansen 1964; Goulding 1965, 1966], and allowed relatively thick depletion layers to be formed. It was this fundamental improvement

[2]Although Stetter reported his observation years earlier, the work went largely unnoticed. Consequently, Van Heerden has often been quoted as the originator of the first semiconductor detector. Jeschke attempts to correct the record in his 1948 letter to the editor.

[3]Price retracted this opinion in his 1964 book.

that allowed semiconductors to become important radiation detectors, and Ge(Li) and Si(Li) detectors[4] came into common use as high resolution gamma-ray and x-ray detectors.

A drawback to all Ge(Li) detectors was that they required constant cryogenic cooling. If the crystal were to rise in temperature, the Li ions would diffuse away from their compensation locations and the crystal would be ruined. Ge crystals could be re-drifted once, maybe twice, but almost always resulted in lower energy resolution performance. Si(Li) detectors did not suffer the same Li ion diffusion consequence at room temperature, but both Ge(Li) and Si(Li) detectors perform best when operated at or near the temperature of liquid nitrogen (LN2).

A solution to the nuisance of cryogenic cooling for Ge(Li) was explored by two research teams, one team led by Robert Hall at GE and the other team led by William Hansen at the Lawrence Berkeley Laboratory (LBL) [Haller 1996]. The concept was to apply the zone refinement purification technique developed by William Pfann [1966], thereby purifying Ge to such a level that it was practically devoid of impurities and, hence, no longer in need of Li compensation. Both teams succeeded in the mission and produced virtually intrinsic high-purity Ge crystals, or HPGe crystals. Detectors fabricated from this material no longer required constant cooling, but still required cryogenic cooling during operation in order to reduce leakage currents. By the early 1970s, zone refined HPGe, high purity Si, and Si(Li) detectors became standard instruments for radiation spectroscopy.

Yet, the required cryogenic cooling during operation remains inconvenient. There are solutions, mainly, low vibration refrigerators or small handheld dewars can be attached to HPGe detectors. Wide band-gap semiconductors, such as GaAs, CdTe, HgI_2, and CdZnTe (or CZT), that can operate at room temperature (RT) without cryogenic cooling have been investigated as alternative semiconductors for gamma-ray spectroscopy. Perhaps to date the most successful of these RT candidates is CZT, mainly because of the introduction of "single carrier" detector designs by Eskin et al. [1995], Luke [1995], McGregor and Rojeski [1998, 1999], and McGregor [2004]. Included in the present chapter are descriptions of properties for semiconductors important for radiation detection. Descriptions of semiconductor detectors that are either commercially available, or at least show great promise for various radiation measurement applications, are also described in the present chapter.

16.2 General Semiconductor Properties

Desired properties of a semiconductor radiation detector vary with its application. For instance, materials with low atomic numbers are best used for detection of β particles and electrons while materials with high atomic numbers are best for detection of x rays and gamma rays. High energy resolution generally requires a low ionization energy, best accomplished by choosing semiconductors with relatively narrow band gaps. A small ionization energy causes increased numbers of excited charge carriers, thereby improving statistics and enhancing spectroscopic energy resolution. However, semiconductor detectors fashioned from narrow band-gap materials generally require cryogenic cooling during operation. A wide band-gap energy (> 1.5 eV) and high resistivity allow room temperature operation that otherwise would require cryogenic cooling to reduce electronic noise, but at the price of reduced spectroscopic energy resolution. Other properties sought for gamma-ray detectors include high atomic density, long charge carrier lifetime, high resistivity, and high electron and hole mobilities. High atomic density and high Z components increase the γ-ray interaction probability (see Fig. 16.1). Long charge carrier lifetimes and high charge carrier mobilities increase the charge collection efficiency and produce better spectroscopic results. Unfortunately, no existing semiconductor actually has all of these characteristics; hence the investigator should select a semiconductor

[4]Pronounced "jelly" and "silly" detectors.

Table 16.2. Common semiconductors used as radiation detectors and their properties at 300K.

Semiconductor	Atomic Number (Z)	Density (g cm^{-3})	Structure	Fano Factor	Ionization Energy (eV/e-h pair)	Dielectric Constant (ϵ_s/ϵ_0)

detector best suited for the desired application. The basic properties of several semiconductors used for semiconductor detectors are listed in Tables 16.2, 16.3, and 16.4.

16.2.1 Atomic Numbers and Mass Density

The choice of detector material depends on the type of radiation to be detected. As discussed in Sec. 7.2.1 and Sec. 7.2.2, the backscatter coefficient for charged particles (both electrons and alpha particles) increases with the atomic number of the absorber. Likewise the absorption coefficient for photons (see Sec. 4.4) also increases with the atomic number of the absorber. Hence, it is generally better to fabricate charged particle detectors from low Z materials, such as Si. By contrast, high Z materials are preferred for gamma-ray

Table 16.4. Common semiconductors used as radiation detectors and their properties at 300K.

Semiconductor	N_C (cm^{-3})	N_V (cm^{-3})	m_t^*	m_l^*	m_o^*	m_{lh}^*	m_{hh}^*
C (Diamond)	$\sim 10^{20}$	$\sim 10^{19}$	0.36	1.4	–	0.3	1.1

TlBr							

detection. There are special materials that react to neutrons, which can be adapted if neutron detection is the goal, or should be avoided if neutron discrimination is desired. One such semiconductor material is CdTe (and CdZnTe), which offers good gamma-ray detection, but also reacts to low energy neutrons to produce prompt gamma-rays. Special attention to material selection should be applied to low-energy gamma-ray and x-ray detection, for which the K absorption edge may become important. For example, as seen in Fig. 16.1, the total photon absorption coefficient below the two K edge energies of CdTe drops below that of Ge; hence the lower Z material actually performs better than the higher Z material at energies below 26.727 keV. Si is generally selected over Ge for characteristic x-ray analysis because its K edge is at a lower energy (1.840 keV) than Ge (11.115 keV); hence, the transition K edge has less effect on the photon absorption efficiency.

The mass density is of obvious importance, because increased mass density generally indicates higher electron density. Further, photoelectric absorption is a strong function of Z; hence, the interaction efficiency is strongly influenced by the atomic density of the highest Z component. Selection of materials with at least one high Z component is important for gamma-ray detection. For instance, InP has one component with a relatively high atomic number $Z_{In} = 49$, and one relatively low atomic number $Z_P = 15$. Overall, the gamma-ray absorption characteristic is predominately influenced by the density of indium because the phosphorus component makes little contribution. Atomic number and mass density for several semiconductors are listed in Table 16.2.

16.2.2 Band Gap

The energy band gap of a semiconductor E_g, introduced in Sec. 12.2.5, is

$$E_g = kT \ln \left[\frac{N_C N_V}{n_i^2} \right] \tag{16.1}$$

or, more traditionally, is described by

$$n_i = \sqrt{N_C N_V}\, e^{-E_g/2kT}, \tag{16.2}$$

where n_i is the intrinsic charge carrier concentration, N_C is the effective density of state in the conduction band, N_V is the effective density of states in the valence band, k is Boltzmann's constant, and T is the

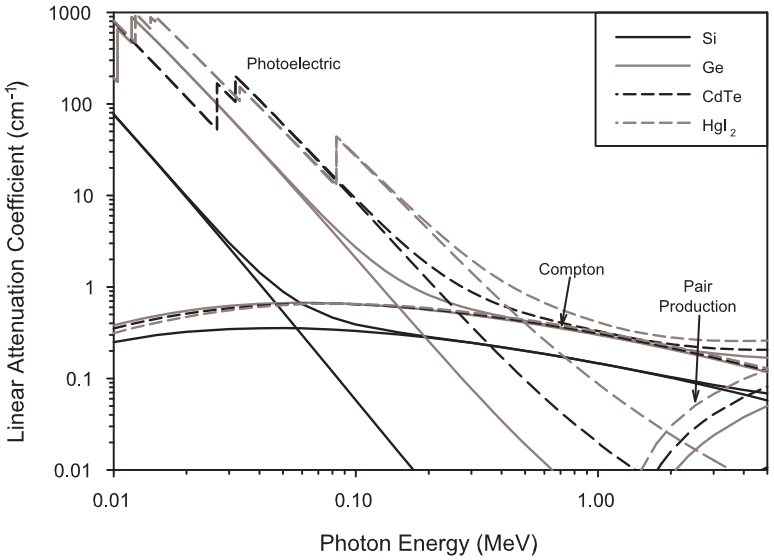

Figure 16.1. The linear attenuation coefficients for several representative semiconductors.

absolute temperature. The relationship between n_i and E_g is of major importance because a small increase in the band-gap energy has a significant effect upon the free charge carrier concentration. Hence, to reduce leakage current, it is desirable to use semiconductors with relatively large band-gap energies. Note that lowering the temperature also reduces the value of n_i, a method often used to suppress leakage current for semiconductors that have relatively small values or E_g.

For most semiconductor radiation detectors, indirect band gaps are preferred over direct band gaps mainly because the charge carrier lifetimes are theoretically much longer [Shockley and Read 1952; Hall 1952, 1959; Varshni 1967]. The reason for the difference is that electrons in the conduction band of an indirect band-gap semiconductor must change in both momentum and energy to recombine with a hole, whereas electrons in the conduction band of a direct band-gap semiconductor need only to lose energy to complete the recombination process. Consequently, indirect band-gap semiconductors generally have higher carrier extraction factor values than direct band-gap semiconductors for similar detector dimensions. Listed in Table 16.3 are band-gap energies and types (indirect or direct) for several semiconductors used in radiation detection. Note that the defect and impurity density of a semiconductor, if significant, can have a greater effect on the overall mean free lifetime rather than the type of band gap.

16.2.3 Ionization Energy

A property strongly influenced by the energy band gap is the average ionization energy w, which limits the minimum spectral energy resolution. For materials and detectors that suffer little to no charge carrier trapping losses, the expected variance in charge pair excitation should follow Gaussian statistics so that

$$\sigma_{N_0}^2 = \frac{FE_\gamma}{w} = FN_0, \tag{16.3}$$

where F is the semiconductor Fano factor and E_γ is the energy of the radiation quantum. The resulting pulse height spectrum, representing full energy peaks of radiation quanta, should also have a Gaussian appearance.

Hence, the full width at half maximum (FWHM) of these Gaussian peaks is, in terms of charge pairs N_0,

$$\Gamma = \text{FWHM}|_{N_0} = 2\,[2\ln(2)]^{1/2}\,\sigma, \tag{16.4}$$

which is transformed into units of energy by multiplying by $w = E_\gamma/N_0$ as

$$\Gamma = \text{FWHM}|_{eV} = 2w\left[2\ln(2)\ \frac{FE\gamma}{w}\right]^{1/2} \simeq 2.355\,[wFE_\gamma]^{1/2}\,. \tag{16.5}$$

This result can be written in terms of percent energy by dividing Eq. (16.5) by E_γ

$$\Gamma = \text{FWHM}|_{\%} = 100\frac{2\,[2\ln(2)\ wFE_\gamma]^{1/2}}{E_\gamma} \simeq 235.5\left[\frac{wF}{E_\gamma}\right]^{1/2}. \tag{16.6}$$

It becomes clear from Eqs. (16.5) and (16.6) that w significantly affects Γ and a small value of w is desirable.

The dependence of w upon the band-gap energy was studied by Klein [1968], and it was determined that energy was expended by three mechanisms, namely (1) excitation across the band-gap energy, (2) residual kinetic energy of excited charges, and (3) optical phonon losses. It is obvious that the minimum energy required to produce an electron-hole pair must be E_g. Yet, the energy released from Coulombic interactions of primary excited electrons, from either charged particle or gamma-ray interactions, can excite energetic electrons from deep in the valence band or lower tightly bound energy bands. Further, the energy absorbed may be more than required to transition the band gap into the conduction band. This excess energy is manifested as kinetic energy of the charge carriers. If this excess kinetic energy is less than E_g, then it becomes expended in the material and does not contribute to additional electron-hole pair creation.

The average ionization energy can be represented by

$$w = E_g + \langle W_L\rangle, \tag{16.7}$$

where $\langle W_L\rangle$ is the average energy expended for purposes other than electron-hole production. Klein [1968] breaks $\langle W_L\rangle$ into two fundamental components

$$\langle W_L\rangle = \langle E_R\rangle + \langle E_K\rangle, \tag{16.8}$$

where $\langle E_R\rangle$ represents optical phonon losses and $\langle E_K\rangle$ represents thermalization losses. Optical phonons are out of phase movements of the crystalline lattice and can be produced by energetic charged particles having sufficient energy to excite electron-hole pairs. Their average energy is

$$\langle E_R\rangle = r(\hbar\omega_R),\ 0.5\text{ eV} \le r(\hbar\omega_R) \le 1.0\text{ eV}, \tag{16.9}$$

where r represents the average number of phonons per electron-hole pair created and ω_R is the angular frequency of optical phonon oscillations. Hence, $\hbar\omega_R$ represents the energy per phonon (Raman quanta).

From experimental data of several semiconductors,[5] Klein [1968] estimates a threshold for secondary ionization as

$$E_I \simeq \frac{3}{2}E_g \tag{16.10}$$

and the average residual kinetic energy of excited charge pairs as

$$\langle E_K\rangle \simeq 2\mathcal{L}E_I = 3\mathcal{L}E_g, \tag{16.11}$$

[5]Klein [1968] lists Ge, Si, GaAs, InP as the sources of data.

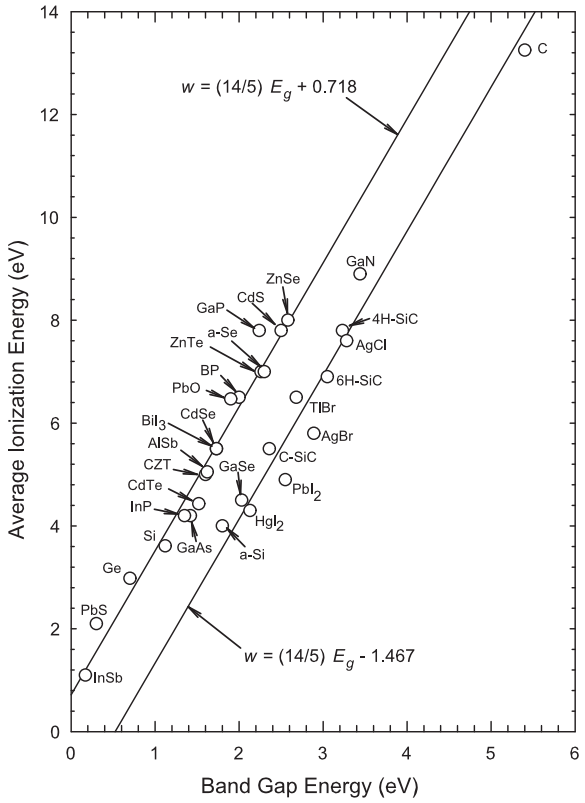

Figure 16.2. The average ionization energy (w) of several semiconductors as a function of the band-gap energy (E_g).

where $\mathcal{L}$ is a dimensionless scaling constant.[6] Klein [1968] assigns a value of $\mathcal{L} = 3/5$, yielding $\langle E_K \rangle = (9/5)E_g$, slightly below the minimum energy required to excite two electrons across the band gap. Klein [1968] thereby produces the following formulation for the average ionization energy:

$$w = \frac{14}{5}E_g + r(\hbar\omega_R). \tag{16.12}$$

Lund et al. [1988] and Shah et al. [1989] note that there appear to be two salient linear dependencies, both following Eq. (16.12) as shown in Fig. 16.2, but having different ordinate intercepts.[7] Using literature values of w, a linear least squares method yields an ordinate intercept of $r(\hbar\omega_R) = 0.718$ for the upper (traditional) dependence. The ordinate intercept for the lower second dependence is found to be $r = -1.467$. The use of $r(\hbar\omega_R) = 0.718$ is within the limits of Klein's theory and therefore has physical significance. However, as pointed out by Owens and Peacock [2004], the use of $r = -1.467$ for the lower dependence does not follow the theory of Klein [1968] and is used strictly as a curve fitting parameter.

[6] This dimensionless scaling constant refers to the average wasted residual kinetic energy described in Van Roosbroeck's [1965] paper on "crazy carpentry".

[7] This discovery seems to have been missed by Alig and Bloom [1975], although it now seems obvious from their data.

16.2.4 Mobility

As discussed in Sec. 12.5, the charge carrier mobility is a strong function of the curvature of the energy bands. Rapid charge carrier extraction reduces trapping and dead time problems and is fundamentally dependent upon the charge carrier drift mobilities. Recall also from Sec. 12.5.1 that the charge carrier mobility is inversely proportional to the charge carrier effective mass, and the effective mass is related to the E-k diagram band curvature by

$$m^* \propto \left[\frac{d^2E}{dk^2}\right]^{-1}. \tag{16.13}$$

The curvature at the minima of the conduction band for most semiconductors is larger than the curvature at the valence band maxima. Consequently, electron mobilities are almost always much larger than the hole mobilities in a semiconductor. A few methods of measuring the charge carrier mobility of both electrons and holes are described in the Sec. 15.4.5.

Also discussed in Sec. 12.5, the mobility tensor sums to a constant value for cubic crystals regardless of the electric field force vector direction. However, this convenient condition does not necessarily hold true for non-cubic lattice systems, and mobilities can be quite different depending on the electric field direction. The mobility symmetry makes cubic crystals generally more desirable for radiation detectors than non-cubic crystals.

Mobility decreases as the probability of charge carriers encountering motion impeding collisions increases. Sources of motion impeding collisions include phonon (lattice) scattering (μ_l), ionized impurity scattering (μ_i), neutral impurity scattering (μ_n), crystal defect scattering (μ_D), ionized deep donor and deep acceptor scattering (μ_{di}), carrier-carrier scattering (μ_{cc}), and piezoelectric scattering (μ_p). Phonon scattering refers to collision events caused from lattice vibrations of thermally excited lattice atoms. Ionized impurity scattering refers to collisions from coulombic interactions between ionized impurities and charge carriers. Neutral defect scattering becomes important at low temperatures and in polycrystalline materials. Piezoelectric scattering is important in piezoelectric materials (for instance, GaAs and CdTe), in which displacement of atoms from their lattice sites produces an internal electric field. Carrier-carrier scattering, in which charge carriers scatter off each other, is important for high carrier densities, which is usually not the case for most radiation detector applications. The resulting mobility is

$$\mu = \left[\frac{1}{\mu_l} + \frac{1}{\mu_i} + \frac{1}{\mu_n} + \frac{1}{\mu_D} + \frac{1}{\mu_{di}} + \frac{1}{\mu_{cc}} + \frac{1}{\mu_p} + \ldots\right]^{-1}. \tag{16.14}$$

Of the many possible scatter mechanisms, the most influential on mobility are phonon scattering and ionized impurity scattering. The mobility dependence of phonon scattering (μ_l) is described by [Bardeen and Shockley 1950]

$$\mu_l = \frac{\sqrt{8\pi}q_e\hbar^4 C_{11}}{3E_{ds}(m^*)^{5/2}(kT)^{3/2}}, \tag{16.15}$$

where C_{11} is the average longitudinal elastic constant of the semiconductor and E_{ds} is the band-edge displacement per unit dilation of the lattice from vibrational motion, and m^* is the charge carrier effective mass. Eq. (16.15) shows that phonon (lattice) scattering decreases mobility with increasing temperature and effective mass. The mobility dependence of ionized impurity scattering is [Conwell and Weisskopf 1950]

$$\mu_i = \frac{64\sqrt{\pi}\epsilon_s^2(2kT)^{3/2}}{N_i q_e^3 (m^*)^{1/2}} \left\{\ln\left[1 + \left(\frac{12\pi\epsilon_s kT}{q_e^2 (N_i)^{1/3}}\right)^2\right]\right\}^{-1}, \tag{16.16}$$

where N_i is the ionized impurity concentration. From this result it is clear that increasing the impurity concentration reduces mobility, typically becoming significant at ionized impurity densities greater than

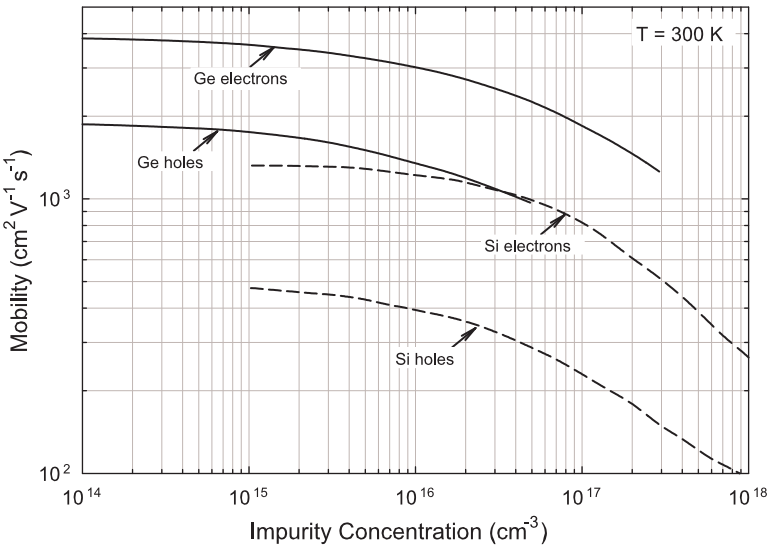

Figure 16.3. The mobility of Si and Ge as a function of impurity concentration at 300 K. Data are from Prince [1953] and Jacoboni et al. [1977].

10^{15} cm^{-3} as can be seen in Fig. 16.3. Notice also from Eq. (16.16) that the mobility from ionized impurities decreases as T decreases. Hence, μ_l decreases with increased T while μ_i increases with increased T. Hence, the overall dependence of mobility on temperature can be approximated by

$$\mu \approx \left[\frac{1}{\mu_l} + \frac{1}{\mu_i}\right]^{-1}. \tag{16.17}$$

The general expression for charge carrier group velocity at relatively low electric fields is

$$v_g\Big|_{\text{low } \mathcal{E}} = \mu\mathcal{E}, \tag{16.18}$$

where the mobility μ is an intrinsic property of the semiconductor. Hence, it becomes clear that large mobilities are desirable for rapid charge carrier extraction from the detector. At high electric fields, the charge carrier group velocity for many indirect band-gap semiconductors can be modeled as [Sze 1981]

$$v_g\Big|_{\text{high } \mathcal{E}} = v_s\left[\frac{1}{1+(\mathcal{E}_o/\mathcal{E})^\beta}\right]^{1/\beta}, \tag{16.19}$$

where v_s is the saturation velocity at high electric fields and both $\mathcal{E}_o$ and β are experimentally determined constants.

The simple empirical model of Eq. (16.19) does not take into account the crystal orientation, which does in fact affect the charge carrier velocity (see Figs. 16.4 and 16.5). Indeed, under equilibrium conditions the total effective mass tensor is constant regardless of electric field direction; however, at high electric fields the charge carrier distribution in the transverse and longitudinal conduction band energy ellipsoids does change, depending on the force vector of the electric field (Jacoboni et al. [1977]). Consequently, the effective mass tensor also changes, and the charge carrier velocity characteristics are slightly different for electric fields applied in different crystal directions.

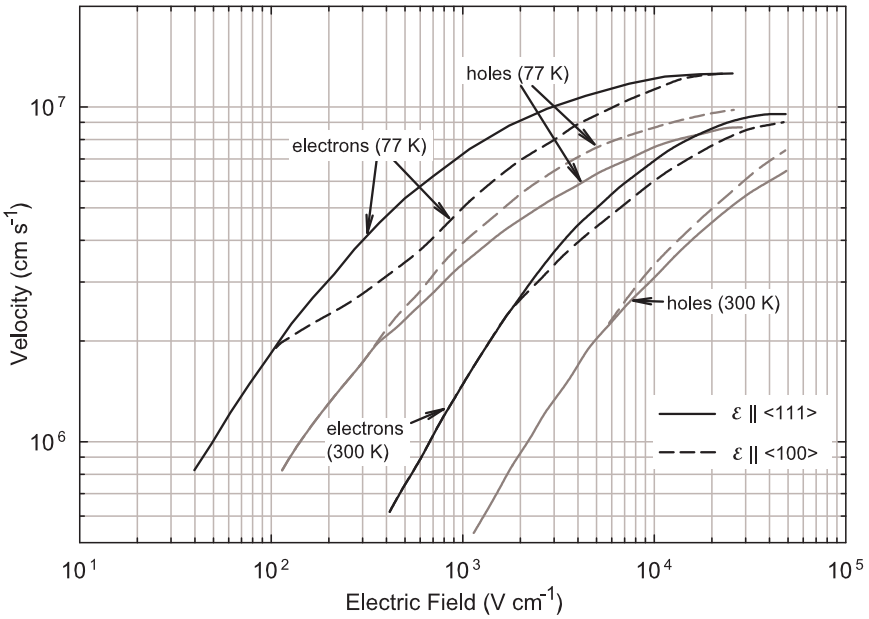

Figure 16.4. The charge carrier velocities of Si as a function electric field and temperature (77 K and 300 K). Data are from Jacoboni et al. [1977].

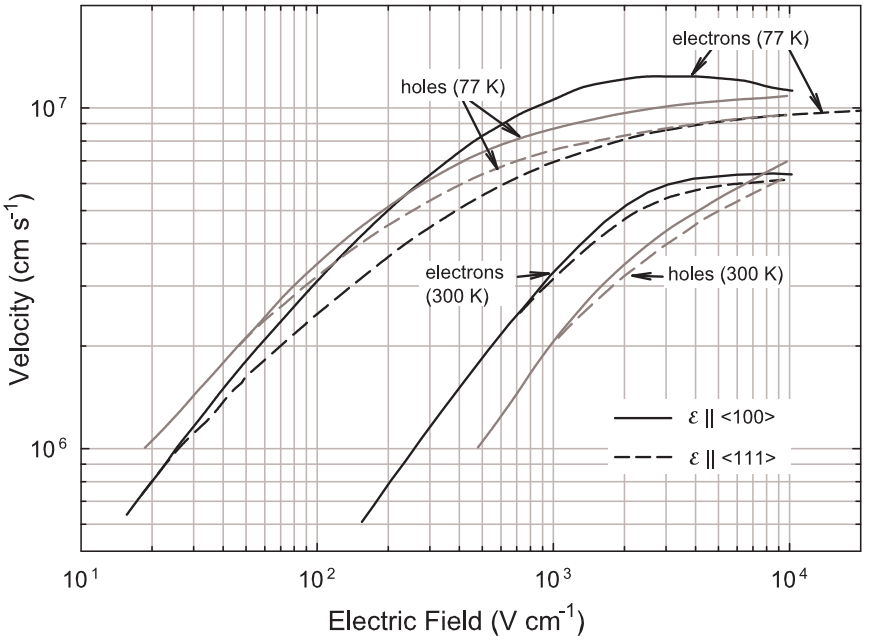

Figure 16.5. The charge carrier velocities of Ge as a function electric field and temperature (77 K and 300 K). Data are from Reggiani [1978] and Jacoboni et al. [1981].

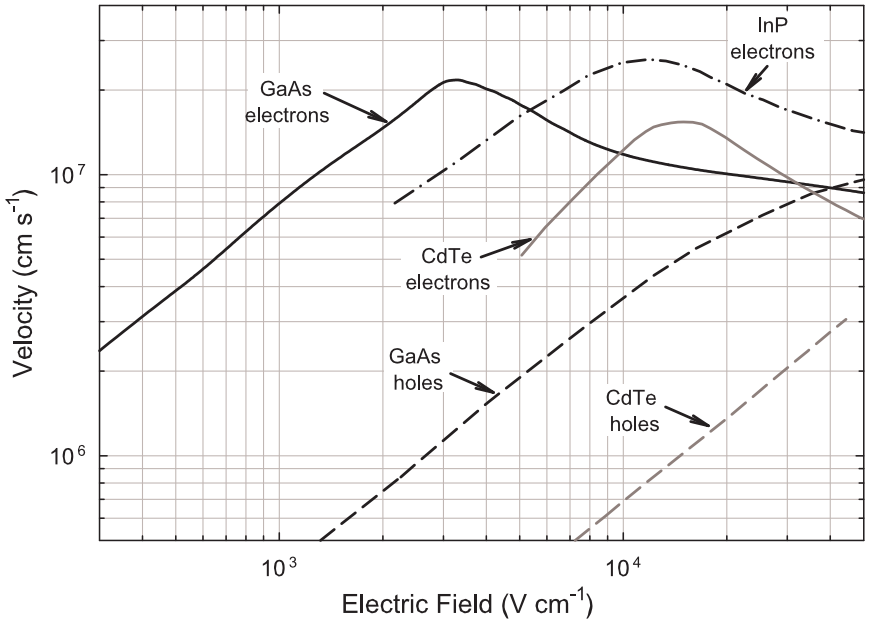

Figure 16.6. The charge carrier velocities of GaAs, InP, and CdTe as a function electric field at 300 K. Data are from Ruch and Kino [1967], Dalal et al. [1971], Canali et al. [1971a, 1971b], Smith et al. [1980], Blakemore [1982], and González Sánchez et al. [1992].

There are a few semiconductors in which more than one conduction band minima can play a part in electron transport. For instance, GaAs, InP, and CdTe are direct band-gap semiconductors, yet also have indirect band-gaps that can accept electrons at high enough electric fields, and these indirect band gaps have larger electron effective masses than their corresponding direct band gaps. Consequently, the high electric field velocity for direct band-gap semiconductors, in which electron transfer to upper indirect bands is possible, is much more complicated than given by Eq. (16.19) (see, for example, Pozela and Reklaitis [1980]), and must take into account the change in effective mass for the upper valley minima. Hence, at low voltages, the velocity is defined by the direct band-gap minimum, at medium voltages the velocity is defined by a sharing of mobilities between the direct and indirect band-gap minima, and at high electric fields the mobility is determined by one or more indirect band-gap minima. The sharing of electron mobility between conduction band minima produces a region of *negative differential resistance* [Sze 1981], in which the electron velocity and, consequently, the electrical current decrease with increased applied voltage (see Fig. 16.6). A side effect of the negative differential resistance is to produce an instability, the Gunn effect, that can produce oscillations at high voltage [Gunn 1963].

16.2.5 Resistivity

High resistivity for a material is important to reduce thermally generated current and other forms of leakage current. For pure materials, the resistivity is mainly a function of band-gap energy. Examples include high-purity Ge and float-zone refined Si. However, with a few exceptions, the purification of most compound semiconductors is difficult. Consequently, high resistivity compound semiconductors are usually produced through compensation methods (as outlined in Sec. 12.5.4). The natural resistance of a semiconductor block

can be described by

$$R = \frac{\rho L}{A} = \frac{L}{q_e A(n\mu_n + p\mu_p)}, \tag{16.20}$$

where L is the length of the block, A is the area of each electrical contact at the ends, n is the free electron concentration, p is the free hole concentration, μ_n is the electron mobility, and μ_p is the hole mobility. An impulse current should be significantly higher than the background leakage current.

The type of detector contacts required is strongly influenced by the material resistivity. If the resistivity is $\gtrsim 5 \times 10^{10}$ Ω-cm, a resistive device, or photoconductor, can be fashioned. If the resistivity is below 5×10^{10} Ω-cm, it is usually best to construct a junction diode, as described in Sec. 15.3.1 (and in Sections 15.3.2 and 15.3.3), to suppress electronic noise from leakage currents. There are methods to increase the resistivity of a semiconductor with compensation methods, but there are physical consequences that can arise from the operation of junction diodes fabricated from compensated high-resistivity materials and are addressed later in this chapter.

16.2.6 Mean Free Drift Time

The recombination time τ_r is the average lifetime of an electron before it recombines with a hole, whereas the mean free drift time τ_m is the average time a charge carrier is in motion before it encounters a physical impediment that stops its motion. In a pure defect-free semiconductor, the recombination time is essentially the same as the mean free drift time. However, they are not the same in most semiconductors, mainly because recombination is usually assisted by transitions through band-gap defect states.

The lifetime of a charge carrier is largely a function of the band-gap energy and defect density. Hall [1959] and Varshni [1967] show that the recombination time for indirect band-gap semiconductors can be significantly longer than that observed for direct band-gap semiconductors. The fundamental reason for the difference is electrons must lose energy and change momentum to transcend the band gap to recombine with a hole; however, electrons in a direct band gap need only to lose energy to recombine with a hole. The recombination times predicted by either Hall [1959] or Varshni [1967] are relatively long by comparison to observed values. This difference is explained by the theory of Shockley and Read [1952] and Hall [1952], which attributes recombination mainly to the trap density in a semiconductor.

Ultimately, it is the mean free drift time that affects the performance of a semiconductor detector, and it is τ_m that is usually measured to determine the often quoted $\mu\tau$ product. Recall from Sec. 15.5 that charge carrier collection is directly related to the $\mu\tau$ product, in which the carrier extraction factor for a planar detector is given by Eq. (15.221), namely,

$$\varrho = \frac{\mu\tau_m \mathcal{E}(x)}{W}, \tag{16.21}$$

where W is the detector width. Sufficiently good energy resolution is observed if both carrier extraction factors are greater than 50. The value of ϱ for holes and electrons can be increased by reducing W or increasing $\mathcal{E}(x)$. However, τ_m is an intrinsic property of the material, increased only by improving the crystal quality. Semiconductor materials with relatively large mean free drift times are generally sought for semiconductor spectrometers.

16.2.7 Linearity

The process by which information carriers are produced in semiconductors differs from scintillators and gas detectors. In Sec. 12.3 it was shown how the electron energy states in solids form a quasi-continuum of energy bands and energy gaps. As discussed in Chapter 4, charged particles interact in a medium primarily through Coulombic interactions while photons may interact by several different processes, usually the photoelectric effect, Compton scattering, or pair production (if $E_\gamma > 1.022$ MeV). These initial electrons excited from

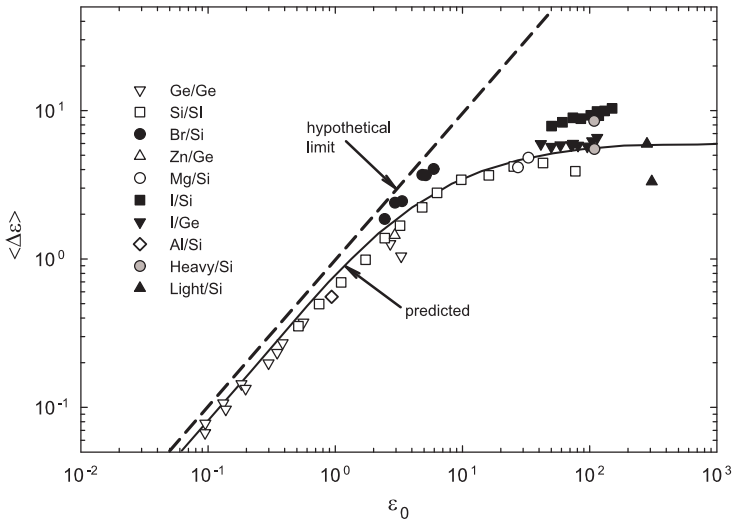

Figure 16.7. Shown are dimensionless measures of the pulse height defect ($\langle\Delta\epsilon\rangle$) vs. dimensionless energy (ϵ_0) of heavy ions absorbed in Si and Ge. The dotted line is hypothetical limit of the expected charge production, where $\langle\Delta\epsilon\rangle = \epsilon_0$. Data are from Haines and Whitehead [1966].

lower bands are either removed from the nucleus (ionization) transferred to the upper bands (excitation), and electrons with sufficient kinetic energy can ionize more free electrons (delta rays) that further excite electrons. This process is common to both semiconductors and scintillators.

Scintillators rely on electrons transitioning through energy states to produce photons subsequently detected by a light sensitive device. However, in a semiconductor, the free electrons are measured directly by the current they produce under an applied voltage, much like a gas-filled detector. For mature semiconductors with relatively long charge carrier mean free pathlengths, and large $\mu\tau$ products, the measured current or charge is a linear function of energy deposition. Such is not the case for scintillators for which phosphor saturation (organic scintillators), exciton losses (inorganics), or other competing mechanisms lead to non-linear responses with respect to energy and particle type. Overall, the average number of electron-hole pairs produced per unit energy in a semiconductor is remarkably linear over a wide energy range.

However, there are some situations that can produce a non-linear output from a semiconductor. For instance, the active thickness of the detector must be capable of absorbing the total energy deposited by an ionizing particle. If the ionizing particle range extends beyond the active region range, then some energy is lost and the resulting signal is diminished. The probability of this form of non-linearity increases with particle energy. For low-energy charged particles, the dead layer surrounding a detector absorbs energy, resulting in energy loss and some amount of energy non-linearity in the output. Charge carrier trapping can also cause the appearance of a non-linear spectrum. Although Si and Ge detectors tend not to suffer much from trapping effects, compound semiconductors almost always do. Hence, it is common to irradiate the cathode of compound semiconductors in order to emphasize electron charge induction over hole charge induction. Still, the average charge *measured* per unit energy deposited reduces with increasing particle or photon energy, typically degrading the energy resolution. For heavy ions, the dense charge cloud produced can cause appreciable recombination, which can also contribute to non-linear output. Recombination problems can be reduced by increasing the detector operating voltage.

Also, heavy ions can lose energy by direct nuclear collisions, which do not produce electron-hole pairs [Lindhard and Nielsen 1962; Haines and Whitehead 1966]. Consequently, there can be appreciable non-

linearity in the number of electron-hole pairs produced from heavy low-energy charged particles. The average dimensionless energy losses $\Delta\epsilon$ as a function of dimensionless energy ϵ_0 for a few heavy ions interacting in either Si or Ge are shown in Fig. 16.7. The greatest fraction of energy loss occurs at ϵ_0 values less than 10, corresponding to approximately 6 MeV for I ions, 3 MeV for Br ions, and 400 keV for Si ions interacting in Si [Haines and Whitehead 1966]. The dashed line indicates the situation in which all energy is lost to nuclear non-ionizing recoil events. Below $\epsilon_0 = 5$ nearly half of the ion energy is lost to recoils, and the situation asymptotically approaches the hypothetical limit with decreasing ϵ_0.

16.3 Semiconductor Detector Applications

Briefly described are common radiation detection applications that employ the use, at times, for semiconductor radiation detectors. In most cases, these applications exploit the low ionization energy of semiconductors to produce radiation spectrometers, and semiconductors are used to detect charged particles, energetic photons, and neutrons. Some systems use the semiconductor properties to make electronic devices and arrays into compact low-power detectors. Some details on specific types of semiconductor detectors are provided as later sections.

16.3.1 Charged Particle Detectors

Semiconductor charged particle spectrometers offer high energy resolution for energetic ions. Typically, the devices are operated in vacuum, along with the source, to eliminate energy losses from a charged particle as its passes from the source to the detector. The detectors are typically designed with thin contacts and/or thin *pn* junctions in order to reduce particle energy loss in the non-sensitive (or dead) region of the contact. Because low Z elements have less problems with ion backscattering, Si is typically the material choice for particle detectors. These detectors can be used for a variety of charged particle identification and characterization purposes, including high resolution spectroscopy of α particles, β particles, protons, and heavy ions, continuous air monitoring, and particle telescopes.

Spectroscopy requires that the full energy of the particle be deposited in the active region of the detector, hence charged particle spectrometers are constructed in such a manner that the depleted region extends beyond the range of the particle under investigation. For most alpha particle spectroscopy applications, a depletion width of 100 microns is adequate. Proton ranges are much longer than those of alpha particles of the same energies, and special detectors that can achieve wider depletion widths may be required. Electrons generally have longer ranges in semiconductors than heavy ions, but also have higher backscatter coefficients.

There are some particle detectors designed for the detection of minimium ionizing particles (MIPs). Note that by definition MIPs can be β particles, protons or any other ionizing charged particles, provided that their kinetic energy is at least twice their rest mass energy. For electrons and β particles, they are classified as MIPs if their kinetic energy exceeds 1.022 MeV. For protons, they must exceed 1.88 GeV energy to be classified as MIPs.

β particles are emitted from a radioactive source with a continuous energy spectrum (see, for example, Fig. 3.20) and, thus, do not have discrete energy peaks in the pulse height spectrum. Further backscattering and self-shielding can often distort the measured spectrum. Because MIPs tend to deposit an even distribution of energy with distance (dE/dx is constant), detectors for MIPs are designed to detect a fraction of the particle energy (ΔE) rather than the total energy. Hence, they are commonly designed to absorb enough energy to identify a MIP, but usually not all of the MIP energy.

16.3.2 Gamma-Ray and X-Ray Detectors

Semiconductors excel above gas-filled and scintillators as energy spectrometers. This nearly universal property is a consequence of the lower ionization energy that allows the excitation of a greater number of charge

carriers (electron-hole pairs) per unit energy than in gas-filled or scintillation detectors. By pure Gaussian statistics, the fractional standard deviation is smaller for semiconductors than other detectors. Further, with few exceptions, the Fano factor is smaller for semiconductors than gases and scintillators. Recall from Sec. 6.8.1 that the FWHM of a Gaussian distribution is

$$\text{FWHM} = 2\sqrt{2\ln(2)\sigma^2} \simeq 2.355\sigma, \tag{16.22}$$

and conversion of this result to the number of charge pairs is done by inserting the Fano factor correction so that the energy resolution is

$$\text{FWHM} = 2\sqrt{\frac{2\ln(2)E_\gamma F}{w}}. \tag{16.23}$$

This number is easily converted to units of energy by multiplying Eq. (16.23) by the semiconductor average ionization energy (w), so that

$$\text{FWHM(energy)} = 2\sqrt{2\ln(2)E_\gamma wF} \simeq 2.355\sqrt{E_\gamma wF}. \tag{16.24}$$

Indeed, the standard for reporting energy resolution for semiconductors is in terms of energy, commonly in units of keV. This standard is different for scintillators, in which the FWHM is usually reported as a percent of the gamma-ray energy. The main reason for the change from the traditional standard used for scintillators is the exceptional energy resolution of semiconductors, commonly sub-percent for Si and Ge semiconductors.[8] Note the energy resolution of a semiconductor detector is expected to increase with the square root of the gamma-ray energy, a dependence that holds relatively well for Si and Ge detectors. However, trapping effects cause the full energy peak to appear non-Gaussian for most compound semiconductors, and Eq. (16.24) is usually not a good predictor of the FWHM.

Semiconductor gamma-ray detectors are usually smaller than their scintillator counterparts, and it is common for a semiconductor detector spectral response to have a relatively high Compton continuum in the spectrum. This problem has been addressed by manufacturing large semiconductor detectors (there are rather sizeable Ge detectors available in the commercial market for high cost), or by producing detectors from large Z materials to improve gamma-ray absorption. However, the improved energy resolution typical of semiconductor detectors is usually enough to permit easy identification of gamma-ray full energy peaks and any additional spectral features (such as escape peaks).

The compactness of semiconductors accompanied by the generally high energy resolution makes them attractive radiation detectors. Further, they do not have a secondary detection device, such as a photomultiplier tube or a SiPM array required to properly operate a scintillation detector. Overall, scintillators are often used when modest energy resolution is acceptable and semiconductors are used when high energy resolution is most important. Note also that semiconductor devices can be fashioned into arrays and electronic readout that can identify the location of where the interaction occured in the detector volume, an advantage not easily duplicated with scintillation detectors. These advantages allow the production of directionally sensitive gamma-ray detectors, either as physical arrays composed of many individual detectors or as pixelated devices with sophisticated electronics that localize events in a semiconductor block. A variety of semiconductor gamma-ray detectors, commercial and experimental, fabricated from different materials are described throughout the remainder of this chapter.

[8] In recent times, energy resolution for compound semiconductor detectors, such as CdZnTe and HgI_2, is often reported in terms of percent. However, this departure from an established system is not strictly correct, and is an unfortunate consequence of the deleterious effect that crystal imperfections and charge carrier trapping have on energy resolution, causing many compound semiconductors to perform with similar energy resolution as the best scintillators.

16.3.3 Neutron Detectors

Semiconductor radiation detectors used as neutron detectors are typically configured as *pn*-junction or Schottky-junction diodes coated with a neutron reactive material. The basic construction of such a detector is shown in Fig. 16.8, in which a Schottky or *pn* junction diode detector has a coating of neutron reactive material applied to the surface. Typically the devices have either ^{10}B or ^{6}LiF as the active coating. The absorption cross sections for both ^{10}B and ^{6}Li follow a $1/v$ dependence. The ^{10}B(n,α)^{7}Li neutron reaction yields two possible de-excitation branches from the excited ^{11}B compound nucleus, namely

$$ {}^{1}_{0}\mathrm{n}+{}^{10}_{5}\mathrm{B} \longrightarrow \begin{cases} {}^{4}_{2}\mathrm{He}\,(1.4721\ \mathrm{MeV}) + {}^{7}_{3}\mathrm{Li}^{*}\,(0.8398\ \mathrm{MeV}) & [93.7\%] \\ {}^{4}_{2}\mathrm{He}\,(1.7762\ \mathrm{MeV}) + {}^{7}_{3}\mathrm{Li}\,(1.0133\ \mathrm{MeV}) & [6.3\%], \end{cases} $$

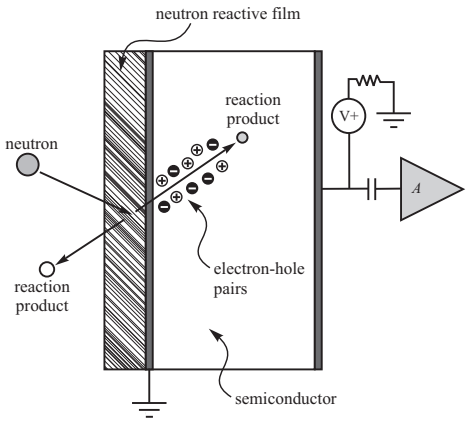

Figure 16.8. Cross section of a coated semiconductor neutron detector.

where the Li ion in the 94% branch is ejected in an excited state, which deexcites through the emission of a 480-keV gamma ray. Fully enriched ^{10}B has a microscopic absorption cross section for thermal neutrons (2200 m/s) of 3840 barns. With a mass density of 2.15 g cm^{-3}, the solid structure of ^{10}B has a macroscopic thermal absorption cross section of 500 cm^{-1}.

The ^{6}Li(n,t)^{4}He neutron reaction yields a single product branch,

$$ {}^{1}_{0}\mathrm{n} + {}^{6}_{3}\mathrm{Li} \longrightarrow {}^{3}_{1}\mathrm{H}\,(2.7276\ \mathrm{MeV}) + {}^{4}_{2}\mathrm{He}\,(2.0553\ \mathrm{MeV}). $$

The reaction products from the ^{6}Li(n,t)^{4}He reaction are more energetic than those of the ^{10}B(n,α)^{7}Li reaction and, hence, are much easier to detect and discriminate from background radiations. ^{6}Li has a relatively large microscopic thermal neutron absorption cross section of 940 b, although it is less than that of ^{10}B. Unfortunately, Li is a chemically reactive metal, and, therefore, it is the stable compound ^{6}LiF, with a 2200-m/s macroscopic cross section of 57.51 cm^{-1}, that is usually used as the reactive coating.

For thermal neutrons, the charged particle reaction products are ejected in opposite directions, meaning that only one reaction product can actually enter the semiconductor detector. Further, the reaction products lose energy as they pass through the neutron absorber to the semiconductor detector, thereby limiting the effective absorber thickness. Detectors of this type are limited to less than 5% thermal neutron detection efficiency. These devices are generally not commercially available as independent units; rather they are sold as an active component inside some electronic dosimeter modules. Advanced versions of coated semiconductor detectors, having etched features backfilled with neutron reactive materials, have reported efficiencies greater than 65%. A detailed discussion on these advanced coated-semiconductor neutron detectors is in Chapter 17.

There have been attempts to use semiconductors in which at least one type of constituent atom is neutron reactive. Semiconductors with neutron reactive isotopes that promptly emit charged-particle reaction products include B-based semiconductors (such as BC_4, BN, BP, and BAs) and Li-based semiconductors (such as LiZnP, LiZnAs, and $LiInSe_2$). Semiconductors with neutron reactive isotopes that promptly emit gamma-ray reaction products include Cd-based semiconductors (such as CdTe and CdZnTe) and Hg-based semiconductors (such as HgI_2). The concept is simple; neutrons interact with the reaction isotopes that promptly emit ionizing radiation back into the semiconductor. The ionizing radiation produces electron-hole pairs in the semiconductor, and these charges are drifted with an electric field to produce an induced current or induced voltage on an electronic output. To date, these types of neutron detectors have been

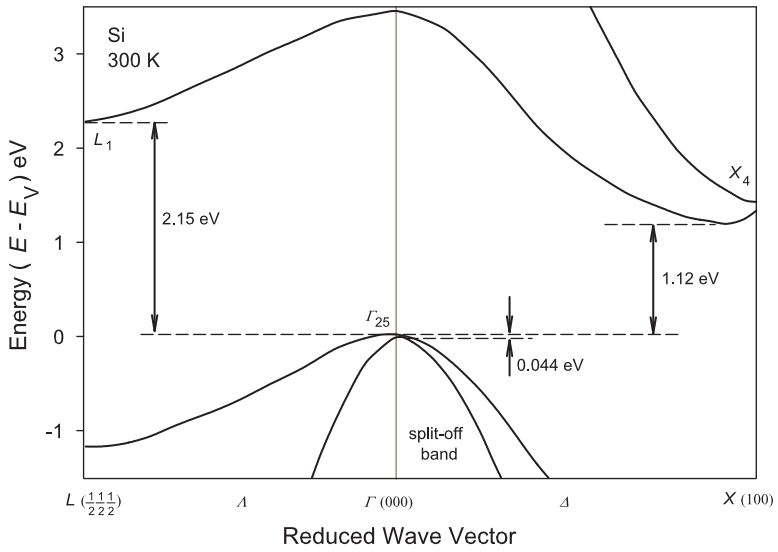

Figure 16.9. The theoretical energy bands of Si at 300 K calculated with a pseudopotential method. Data are from Chelikowsky and Cohen [1976].

largely unsuccessful. Regardless, a section in Chapter 17 is reserved for discussion on these types of neutron detectors.

16.4 Detectors Based on Group IV Materials

The family of semiconductor materials based on group IV materials include Si, Ge, diamond, and SiC. Both Si and Ge detector processing are mature technologies, having been developed as semiconductors for electron devices for over 50 years. By far, most semiconductor radiation detectors are fabricated from either high-purity Si or Ge, although there is a modest market for other semiconductor detector materials. Diamond is also used as a radiation detector material, but its low value of Z diminishes its effectiveness as a gamma-ray detector. Hence, diamond is mainly explored for used as a charged particle detector. SiC is also a group IV material, but it is also a compound semiconductor, which can suffer from intrinsic defects (antisites, for instance) typically not a problem with Si, Ge, or C (diamond) crystals. The processes by which diamond and SiC are produced increase the material costs, hence these materials are used only in cases in which alternative semiconductors are inadequate. For instance, both diamond and SiC can be used in higher temperature environments than Si or Ge, and both diamond and SiC tend to have higher radiation hardness than either Si or Ge. Basic detectors fashioned from these semiconductor materials are described in following subsections.

16.4.1 Detectors Based on Silicon

Silicon is by far the most studied of the semiconductor materials for electronic devices, and it is popular for its many beneficial physical and electronic properties. As can be seen from Fig. 16.9, the energy of the band gap for Si is 1.12 eV, which is just wide enough for room temperature operation of small volume devices. Further, the band gap is indirect, and charge carrier mean free drift times are relatively long for highly purified material. The density of Si is only 2.33 g cm^{-3} and it has an atomic number of 14, low for most gamma-ray detector applications, but still useful as an x-ray and low-energy gamma-ray detector. The average ionization energy of Si is 3.6 eV per e-h pair with 0.115 as the Fano factor. The backscatter

coefficient of Si is relatively small, making it a good choice for charged particle spectrometers. It has a native oxide (SiO_2) that is robust, stable, and electrically and thermally resistant. The production of thicker SiO_2 layers is straightforward, easily grown through 'dry' and 'wet' processes at high temperature ($> 950°C$) in a tube furnace. The crystal has a cubic FCC lattice structure.[9] Recalling from Sec. 12.5, the average charge carrier mobility is practically constant regardless of charge carrier direction. It is easily etched by wet and dry processes, which include anisotropic and isotropic methods. Doping is straightforward, and can be performed with thermal diffusion and ion implantation. Because of its high melting point of 1414°C, activation of these dopants is also straightforward by many methods, including rapid thermal annealing and furnace annealing. Si is notably a material that can be doped through neutron activation, mainly because

$$^{30}\text{Si} + n \rightarrow {}^{31}\text{Si}\ (t_{1/2} = 2.62\ \text{hrs}) \rightarrow {}^{31}\text{P} \tag{16.25}$$

reactions lead to the production of stable phosphorus, an n-type dopant in Si. Uniformity is ensured by the low thermal neutron absorption cross section of only 0.171 barns. Si is a relatively tough material, with a Mohs hardness of 7, and it has high tensile strength. Si crystalline material can be acquired as large diameter ingots and sizeable prepolished wafers. Electronic grade Si wafers can be acquired as 12-inch diameter wafers or even greater for special cases. High purity float-zone-refined Si wafers of 6-inch diameter can also be acquired commercially.

Charged Particle Detectors Based on Si

Charged particle detectors are designed with thin contact regions to minimize energy loss in the electrical contact. Such energy loss can increase the variance on the measured energy, while reducing the total integrated energy deposited within the detector active region. For semiconductors with small band gaps, such as Si and Ge, thin rectifying contacts are fabricated as either Schottky barriers and shallow pn junctions. The Schottky barrier design is perhaps one of the easiest semiconductor detectors to fabricate, requiring a clean semiconductor surface upon which are applied select metals to form a Schottky barrier. These detectors are commonly referred to as *surface barrier detectors*.[10] Shallow pn junctions, prepared by diffusion or ion implantation, require more process steps, but tend to be more robust with lower leakage currents than SSB detectors.

The most commonly used semiconductor for charged particle detection is Si. Si possesses many physical attributes that make it attractive as the select detector material, including low Z to reduce backscatter, a strong and easy to grow high resistivity oxide layer, a relatively strong crystal structure with high tensile strength, and chemical stability that enables a relatively straightforward fabrication of detectors. Further, Si has an indirect band gap of 1.12 eV that produces long charge carrier lifetimes and allows room temperature operation for detectors of conservative size.

Silicon surface barrier (SSB) detectors were amongst the earliest versions of practical semiconductor radiation detectors, introduced in 1958 by Davis as alpha particle detectors. The simplistic construction requires only a pristine etched Si surface upon which a gold layer is evaporated, forming a rectifying Schottky barrier.

An etch commonly used for SSB detectors is CP4A,[11] because it produces a pristine mirror finish on a Si surface [Dearnaley and Northrop 1966]. High purity n-type or p-type Si is etched, mounted and epoxied

[9] Often referred to as a 'diamond lattice', this identification is not one of the Bravais lattices. A diamond structure has two identical atoms, a part of a tetrahedron, on each FCC lattice point.

[10] The origin of "surface barrier" as a detector name is not exactly known by the authors; however, the earliest reference discovered that uses this name is the 1955 Ph.D. dissertation by Simon.

[11] CP4A is a 3:5:3 mixture of HF(48%):HNO_3(73%):CH_3COOH(100%) and must be kept in a plastic container (not glass). The formula rapidly etches Si, and must be cooled (such as in an ice bath) to control the etch rate. This etch is excellent for producing home-made SSB detectors, and leaves a pristine mirror finish if the samples are agitated during the etch process.

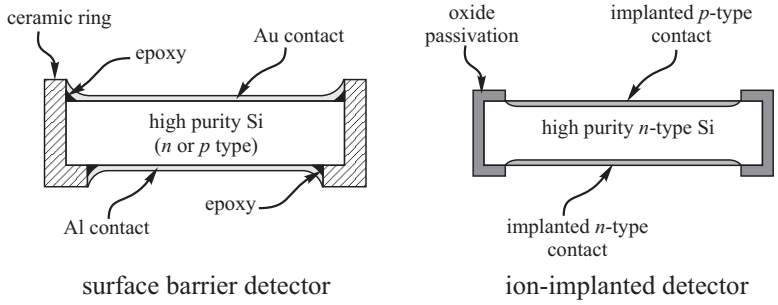

Figure 16.10. General configurations for Si surface barrier detectors and implanted junction detectors.

into a ceramic ring. The samples are bonded into insulating collars with an amine-free epoxy and desiccated, followed by evaporating a metal layer ranging from 80-200 nm thick on opposite surfaces, commonly Au on one side and Al on the other. The thin contact region minimizes the amount of energy lost by particles that enter the device, a necessary precaution to preserve high energy resolution.

At high voltages, it is common to have electrical breakdown at the perimeter of the diode, where the metal crosses from the epoxy bead to the semiconductor surface (see Fig. 16.10). Introduction of an iodine-doped amine epoxy around the perimeter atop the amine-free epoxy bead on the Au side (before evaporation) can produce a reverse biased surface diode, which mitigates electrical breakdown [Gibbs 1988]. Addition of a guard ring helps with the reduction of leakage current noise [Dearnaley and Northrop 1966]. Environmental conditions can affect the performance of SSB detectors, mainly the ambient temperature and humidity. Modernized process methods help mitigate these problems, and include improved surface preparation methods and the addition of a perimeter oxide around Si sample [Fretwurst et al. 1990].

These delicate surface barrier detectors can be easily damaged by improper handling and are often difficult to clean. Detectors can be obtained in a variety of sizes, ranging from a few mm to 50 mm diameter. These detectors are usually light sensitive and must be operated in darkness, although commercial companies do offer versions that can operate in ambient light, at the expense of energy resolution. Depletion depths range from approximately 100 microns up to, for special cases, 5 mm. A simple nomogram representing the depletion width as a function of voltage and impurity concentration can be produced by linearizing Eq. (15.61) [Allcock et al. 1963; Blankenship and Borkowski 1960],

$$\log_{10}(W) = \frac{1}{2}\log_{10}\left[\left(\frac{2\epsilon_s}{q_e}\right)\left(\frac{V_{bi}-V}{N_b}\right)\right]$$

or

$$\log_{10}(W) - \frac{1}{2}\log_{10}(2\epsilon_s\mu) = \frac{1}{2}\left[\log_{10}(\rho) + \log_{10}(V_{bi}-V)\right], \tag{16.26}$$

where N_b has been replaced with $1/q_e\mu\rho$ and the applied voltage V is negative (reverse bias). With the properties for Si listed in Table 16.4, such a nomogram was developed for a silicon surface barrier detector, shown in Fig. 16.11, in which the depletion width is a function of material resistivity (n-type and p-type).

Implanted junction detectors rely upon an abrupt junction pn diode for rectification (see Fig. 16.10). These devices are often fabricated from high purity n-type Si. An oxide is grown on the devices for passivation, followed by etching windows back to the Si surface. Shallow p-type and n-type dopants are implanted on opposite sides of the Si surface and thermally activated. An implanted junction of dopants, usually boron into n-type Si, initially produces a Gaussian distribution displaced from the semiconductor surface by the average ion range. These implants must then be electrically activated, usually through an annealing process,

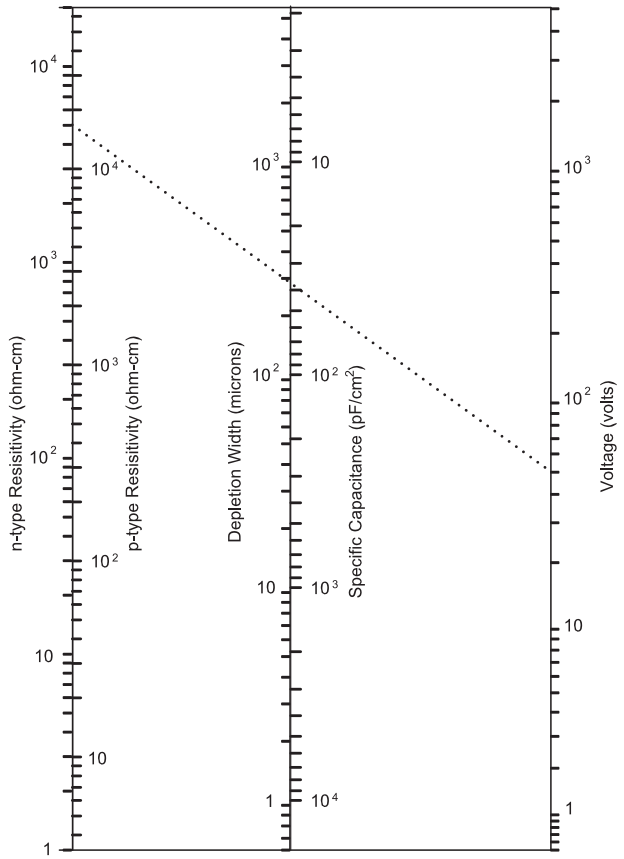

Figure 16.11. The depletion region as a function of material resistivity and reverse voltage for Si particle detectors. A straight line will yield material resistivity (n or p type), the depletion depth and applied voltage, according to Eqs. (15.61) and (15.64). The example shown with the dotted line is for 5 kΩ n-type material at 50 volts reverse bias, which yields $W = 282$ microns.

which serves to also redistribute the dopants. It is typical to model the final doping distribution as an error function (see Sec. 6.8.2). This implantation process produces a dead layer junction with a thicknesses of about 50 nm that serves as the conductive contact so that there is no need for a metal overlayer. Because there is no thin metalization layer over the detector, implanted junction detectors are more robust and easier to clean than common SSB detectors. Implanted junction detectors can be used for the same basic detection functions that SSB detectors are used. SSB and implanted junction detectors can be acquired in numerous shapes, sizes and configurations, making them a versatile choice for particle detection and spectroscopy. Further, the detectors can be acquired as multi-element arrays for position sensing and timing purposes. The adaptation of very large scale integration (VLSI) processing technology to Si detectors allows detector arrays to be fabricated in a vast number of detector designs, including custom devices contracted to commercial vendors.

Both SSB and shallow junction pn diodes operate practically the same. Both rely on a reverse biased rectifying junction to reduce leakage current, and the active region is a function of applied reverse voltage and impurity concentration, as described in Sec. 15.3.1. In both designs, the rectifying contact is insensitive

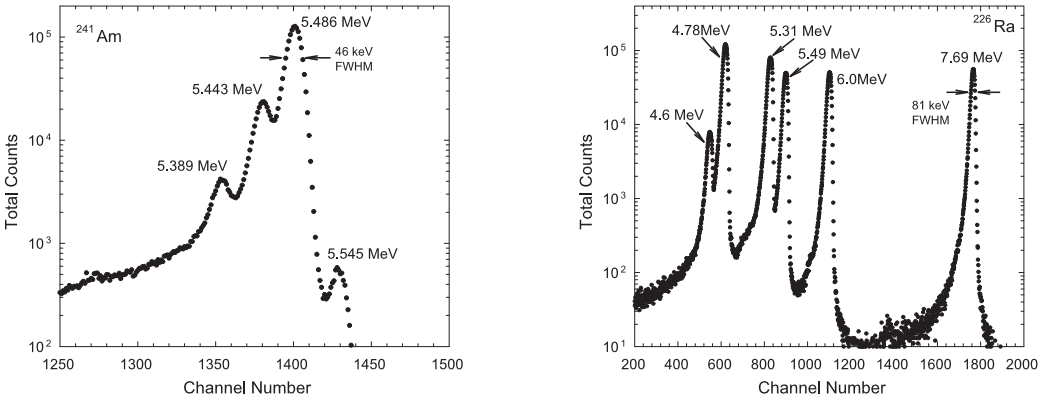

Figure 16.12. Room temperature alpha-particle differential pulse height spectra of spectroscopic grade ^{241}Am and ^{226}Ra sources taken with a 24-mm diameter implanted-junction Si detector operated in vacuum.

to ionizing radiation, considered to be a "dead region". Modern commercial implanted junction detectors have slightly less dead region thickness, an indication, in principle, that they can achieve higher energy resolution than an SSB detector. However, there are many factors that affect the overall energy resolution and include detector area, reverse bias voltage, background impurities, leakage current, thickness uniformity, and crystal orientation. Example alpha-particle spectra from a common commercial implanted-junction Si detector are shown in Fig. 16.12.

The area of a charged particle detector, whether an SSB detector or ion implanted detector, directly affects the capacitance as well as the depletion depth. Capacitance increases linearly with detector area and decreases with depletion width. Consequently, high-purity float zone refined Si is required to achieve large depletion depths at manageable operating voltages, as indicated by the nomogram of Fig. 16.11. The reverse bias leakage current generally increases with applied voltage. Recall from Sec. 15.3 that the leakage current is smaller for a *pn* junction than that of a Schottky barrier, the former being a function of the minority carrier injection condition and the latter being a function of thermionic emission over a potential barrier. Hence, it is expected that for a given detector area the implanted junction detector has a lower leakage current than the SSB detector.

A type of Si particle detector, typically fashioned as an SSB detector, is a transmission device that allows particles to transport all the way through the detector and out the opposite side. These ΔE detectors measure only a fraction of the energy of a charged particle, and because the total energy deposited is a function of the detector mass encountered, flatness and uniformity are important. The resolution of the energy peak from a transmission device is largely dependent upon the total planar flatness of the detector. For instance, a surface deviation of only 1% causes a similar deviation in energy resolution. Transmission detectors can be acquired from commercial vendors with thicknesses less than 20 microns to over one or two millimeters, and are designed to operate under full depletion conditions. Transmission detectors are used for particle identification, time-of-flight measurements, backscatter experiments, and particle telescopes.

Example 16.1:

Assume that you have an SSB transmission detector with average thickness of 15.5 microns, and that it has a thickness deviation from 14 to 15 microns across its thickness. The alpha particle source under investigation is ^{241}Am, measured in vacuum. Assume that the average energy loss for an alpha particle through 15.5 microns of Si is 15.5 eV/Å. How does this thickness deviation affect the energy resolution of that transmission peak?

Solution:

The total energy deposited in the detector is,

$$E \simeq 15.5\ \mu\text{m}\left(\frac{15.5\ \text{eV}}{\text{Å}}\right)\left(\frac{1\ \text{Å}}{10^{-4}\ \mu\text{m}}\right) = 2.403\ \text{MeV}.$$

The total energy spread from the thickness variation is

$$\Delta E \simeq 1\ \mu\text{m}\left(\frac{15.5\ \text{eV}}{\text{Å}}\right)\left(\frac{1\ \text{Å}}{10^{-4}\ \mu\text{m}}\right) = 155\ \text{keV},$$

which is a 6.45% difference.

The crystal orientation is also important. The lattice of a semiconductor forms channels that ions can travel through without suffering ionic collisions, an effect named *channeling*. For cubic semiconductors, channels form as hexagons in the {110} directions, rhombuses (squares) in the {100} directions, and squares in the {111} directions. Ions that enter into the surface below a critical angle with respect to normal incidence, usually 6° or less, scatter down these channels so they penetrate deeply into the semiconductor. To prevent a wide doping distribution depth from implantation, Si wafers are usually oriented beyond this critical angle, and often 7° to 11° from normal is adequate. Otherwise, the implanted dopant can travel much further into the semiconductor, thus causing a much thicker dead layer. The same is true for particle detection. Consequently, SSB and implanted-junction detectors are commonly made with the flat surface polished at an off angle to conventional [100], [111], and [110] directions. Performance data for implanted and SSB Si detectors is given in Table 16.5.

Position Sensitive Particle Detectors Position sensitive detectors are devices that have the capability of simultaneously sensing the absorbed energy and the location of the ionizing event. Semiconductor detectors

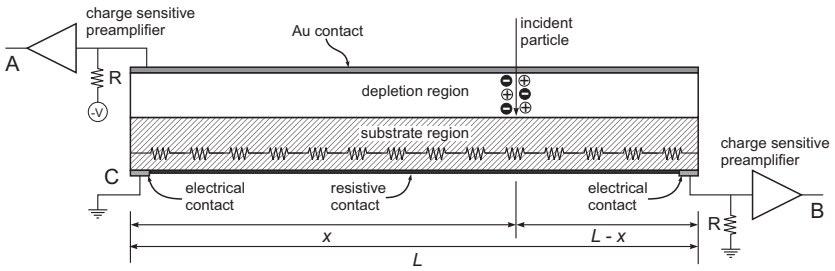

Figure 16.13. The resistive divider position sensitive detector operation principle.

are often used as position sensitive devices because of compactness from VLSI process methods, low operating voltages, and relatively high stopping power as charged-particle detectors. Double-sided cross strip detectors can have spatial resolutions as low as 25 μm, and pixellated detectors can have spatial resolution as small as 0.4 mm. Large arrays of position sensitive Si detectors can be used in collider facilities, x-ray scattering, and Compton cameras. Drift diode configurations, a variant design that drifts electronic charge carriers laterally along the detector to a small collection contact, offer low capacitances with large sensitive areas. These detectors are available in many forms, with some of the more popular configurations described here.

Resistive Divider Detectors Resistive divider detectors operate on the same principle as their gas-filled detector counterparts, described in Sec. 10.6.4. The detector consists of a rectifying contact in the form of a long strip, typically a few millimeters wide and a few centimeters long [Clegg et al. 1966; Bock et al. 1966]. The rectifying contact may be a simple Schottky contact, or can be fashioned as a *pn* junction. A conductive electrical contact, usually gold, is applied to the rectifying junction, and the detector is operated under partial depletion. The back contact has two conductive contacts, one at each end, and a thin relatively resistive contact (such as a layer of Bi, Cr, Ni, or Al) is applied between these two contacts [Bock et al. 1966; Bertolini and Coche 1968]. Because there are essentially three conductive contacts (see Fig. 16.13), it inspired the original name of these devices as 'nuclear triode detectors'. The literature suggests that unannealed implanted surfaces perform better as resistive contacts than evaporated metal layers [Laegsgaard et al. 1968; Elad and Sareen 1974], because the implantation process has superior uniformity and the lattice damage produced by the implantation process increases the surface sheet resistance.

Although in depth analyses of the device operation are available in the literature [Kalbitzer and Melzer 1967; Alberi and Radeka 1976], the general operation of the detector can be simplified as follows. The detector is operated with at least two charge sensitive preamplifiers. A reverse bias is placed on the rectifying contact, which produces a depletion region. One of the bottom conductive contacts is grounded and the conductive contact at the other end of the resistive region is connected through a second preamplifier. Ionizing events that occur at position x produce a total induced charge on the upper preamplifier at position A in Fig. 16.13 proportional to the total absorbed energy (E) in the depletion region. However, the conductive contacts at points B and C are affected by the distributed resistance of the lower contact. Consequently, the current flowing to points B and C is divided by the fractional resistances represented for lengths L-x and x. From Ohms law

$$E_B = E_A \frac{x}{L} = \frac{E_A R_C}{R_C + R_B}, \tag{16.27}$$

where L is the length of the bottom resistive contact, and R_C and R_B represent the resistances of lengths x and L-x, respectively. To find the linear position of the initial ionizing event, one needs to divide only the output from location B by the output of the upper preamplifier at location A, i.e., $x = LE_B/E_A$.

As simple as the concept is, these position sensitive detectors can provide a spatial resolution of about 30 μm FWHM at room temperature, reducing to 10 μm at 77 K [Elad and Sareen 1974]. Further, this type

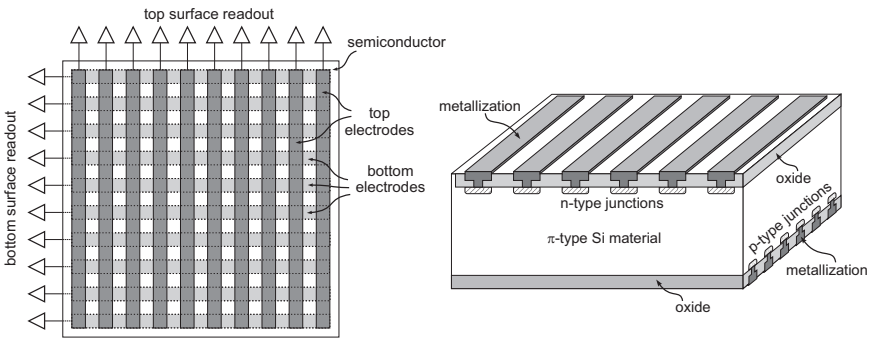

Figure 16.14. Basic structure of a cross-strip position sensitive particle detector. (left) Top view of the readout pattern and (right) isometric view of the basic construction.

of detector can be fashioned as an x-y position sensitive detector by aligning numerous parallel strips, for which the resistive divider identifies the x location, and the strip number identifies the y position. Spatial resolution of approximately 0.2 mm FWHM was reported for one such device [Lamport et al. 1976].

Double-Sided Cross-Strip Detectors Introduced originally by Hofker et al. in 1966, the dual-sided cross-strip detector has orthogonal conductive strips applied to opposite sides of a semiconductor substrate. From the top view depiction of Fig. 16.14, it is easy to understand the original name given by Hofker et al. [1966] as 'checker board counters'. These detectors are designed to operate under full depletion, with one side of the device having rectifying contact strips and the other side having orthogonal ohmic contact strips. The readout scheme becomes obvious by simple inspection. Ionizing events that occur within the detector produce electron-hole pairs. Electrons are swept to the anode strip in closest vicinity and the holes are swept to the closet cathode strip. Consequently, an ionizing particle produces an induced current pulse through the leads of one of the front strips and of one of the back strips. The event location is identified on the x-y grid because the opposing signal strips overlap. The scheme requires at least one preamplifier for each strip on the front and back. It its simplest form, a cross-strip detector can be manufactured by applying conductive contacts to opposite sides of various semiconducting of semi-insulating substrates, such as Si, Ge, GaAs, CdTe, CdZnTe, and HgI_2. For most applications, Si is a preferred choice.

A method to reduce the number of preamplifiers employs a network of external resistors, arranged as a series of resistive dividers, to identify the activated strip [Gerber 1976]. The top array of strips has two preamplifiers, one each attached to outermost strips, connected consecutively to each inner strip through a resistor division circuit. The difference or ratio of signals from each end is used to determine which of the strips was activated by an event. The sum of the signals preserves the energy information. Employing the same scheme on the backside orthogonal strip array, the two perpendicular strips closest to the ionizing event can be identified. Gerber et al. [1977] manufactured these detectors as position sensitive gamma-ray detectors, and, hence, they use Ge wafers instead of Si in order to increase the interaction probability. To prevent cross conduction and isolate the strips from each other, the strips have trenches etched between them.

Particle detectors employing the same external resistive divider scheme as Gerber et al. [1977] have been fabricated with common Schottky barrier designs by applying Au strips and Al strips on opposite sides of a ν-type Si wafer [Lamport et al. 1976, 1981; Heijne et al. 1980]. Position resolution of 150 μm was achieved for energy deposits of 60 MeV from ^{60}Fe ions. To reduce leakage currents between adjacent strips, it is common to use SiO_2 insulation between the strips. This oxide is grown through high-temperature methods, and photolithography is used to pattern and define the locations of the microstrips. The oxide is etched back

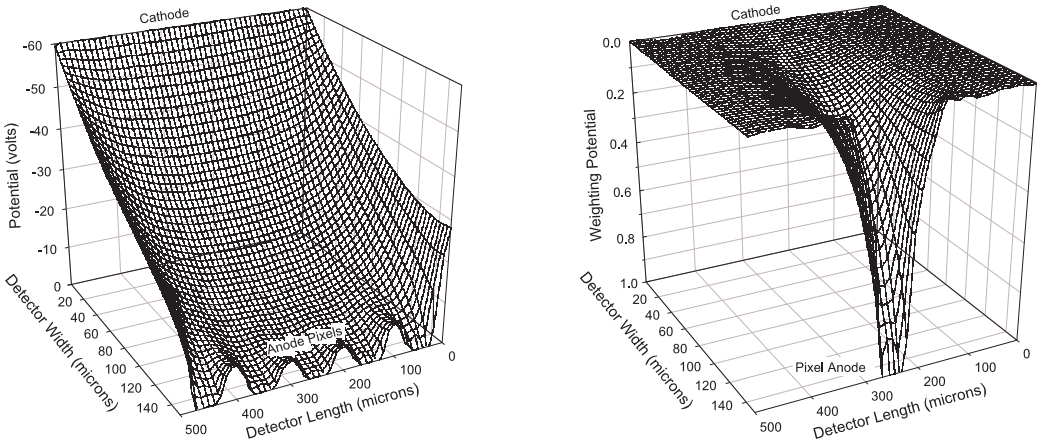

Figure 16.15. (left) For a space charge density of $N_D^+ = 3.33 \times 10^{11}$ cm^{-3}, the calculated voltage distribution for a section of a 150 μm wide pixellated diode with 50 μm $\times$ 50 μm pixels. (right) The resulting weighting potential for a single pixel of the same device.

to the bare Si to which the strips are to be applied. Implantation or traditional dopant diffusion is used to apply the p and n contacts, over which metal is applied, producing the end result shown in Fig. 16.14. However, Lutz [1999] points out that the oxide may be a cause of eventual device failure unless critical design features are not in place. Silicon dioxide can have residual impurity ions (such as Na^+) or may incur radiation damage that produces positive space charge. This space charge attracts electrons at the oxide-silicon interface and can form a conduction path between the strips, consequently, shorting adjacent strips. Proposed solutions to the problem include p-type implantation between the strips and producing negatively biased MOS structure atop the oxide strips [Lutz 1999].

Pixellated Detectors Spatial resolution can be improved by simply placing an array of contacts on a semiconductor surface and connecting each contact to a separate output. These contacts are referred to as pixels (or sometimes pads) and this detector structure has several advantages, which include increased energy resolution from the asymmetric weighting potential, reduced capacitance of each pixel, reduced leakage current flowing to each pixel, and relatively fast response times.

Shown in Fig. 16.15 are the calculated operating and weighting potentials for a $p\nu n$ pixel detector fabricated on high-resistivity Si ($N_D^+ = 3.3 \times 10^{11}$). The back plane of the design is a p-type contact fabricated on a ν-type substrate, with n-type anode ohmic contacts. The voltage distribution is nearly the same as a planar detector, indicating that charge carriers are collected as expected from a common planar device. However, the weighting potential for each pixel is highly non-linear with most of the induced current appearing on the output as free charges drift in the near-anode region. This effect is commonly referred to as "the small pixel effect," and was initially explored by Barrett et al. [1995] (see also Eskin et al. [1995]). If the pixel size is smaller than the final charge carrier cloud size, largely affected by the initial ionizing event and the charge carrier diffusion thereafter, then more than one pixel is expected to sense the arrival of electrons. This problem is denoted as "pixel-sharing" and leads to confusion about where the initial event occurred in the detector. This effect is reduced by increasing the pixel size, but at the expense of spatial resolution.

The capacitance of a pixel strongly affects the electronic noise and ultimately the potential developed by the induced charge. A single square pixel has an area of n^2, where n represents a side dimension, so that a microstrip of length L has an area of $n \times L$. The expected increase in capacitance for the microstrip is L/n; hence, the output voltage for the microstrip decreases by a similar amount for the same induced charge. The

lower leakage current produced by a single pixel also reduces the electronic noise sensed by the preamplifier circuit. Mouthuy [2005] reports on comparisons of various pixel detectors for high energy physics applications with the claim that some pixel devices can have 15× lower electronic noise than microstrip counterparts. Consequently, because of the lower signal-to-noise ratio, thinner detectors can be used while still discerning events from noise, even with the reduction in energy deposition. Finally, because of the asymmetric charge induction from the small pixel effect, most of the charge induction appears on the output within 10 ns, thereby improving timing resolution of events.

However, there are complications with high-density pixel detectors. The pixel detector design requires as many readouts as detector contacts, a requirement that can be very demanding on the readout electronics. As pixel resolution increases, the readout density also must increase and can be cumbersome for traditional wire bonding methods. Instead, it is common to bond the pixel detector to an application specific integrated circuit (ASIC) designed as a miniaturized preamplifier readout for a high-density array of detectors. The detector contacts are connected to the readout electronics by a "flip-chip" method, originally developed by General Electric [1963]. This method permits the face of the pixel device to be aligned directly atop a readout microchip. The contact pads of the microchip have solder patterned on each contact. When heated, the solder forms into a ball from its own surface tension, and is afterwards allowed to cool. Hence, the ASIC chip has an array of soft solder balls exactly placed at the locations of the detector pixels and the readout contacts. The detector is pressed onto the soft solder, commonly an indium alloy, and heated to solder the two parts together [Broennimann et al. 2006]. Indium solder is commonly used because the different alloys have low melting points, ranging from 7°C to 310°C. Under some conditions, the mechanical compression of the lower temperature alloys is adequate to form a bond, thereby removing the heating requirement [Lozano et al. 2001]. Indium is also malleable and less prone to fracture under stress or from thermal expansion mismatch.

Drift Diode Detectors Large area planar detectors can have significant capacitance that reduces pulse height and increases detector electronic noise. Consequently, surface barrier detectors and the like are usually limited to modest diameters, with most commercial units having less than 40 mm diameter, although there are some special-application implanted-junction detectors with up to 60 mm diameter active regions. This problem of increased capacitance is largely mitigated with the drift diode design, a clever device that has a small anode with numerous guiding electrodes, invented by Gatti and Rehak in 1984 (see also Gatti et al. 1985). There are several variants on the design, the most common are the linear drift diode and the concentric ring drift diode [Lutz 1999].

The linear drift diode design concept is shown is Fig. 16.16, having a high purity substrate with multiple reverse biased pn junction strips aligned parallel on the front and back surfaces. One or more collection electrodes are established on one side, usually at one end of the strip array or near the center of the device between several microstrips. Because electrons have higher mobility in Si, it is usual to fabricate the device from ν-type material with p-type cathode strips on the surfaces. The collection electrode(s) is an n-type ohmic contact and is the location of the output electronics.

The device is operated under reverse bias, with gradually increasing positive voltage applied to each drift field electrode from the outermost strips towards the collection anode. This potential distribution can be accomplished by employing a resistive divider along the distribution of microstrips. At full depletion, from both sides of the substrate, the residual space charge forms a potential valley near the center of the volume as shown on the left of Fig. 16.17. It is interesting to note that the potential valley does not form without the benefit of some space charge (N_D^+ or N_A^-) being present. Ionizing events that occur in the device produce electron-hole pairs. Electrons drift to the bottom of this potential valley and are guided to the anode. The resultant weighting potential of the configuration causes most of the induced charge to be sensed as the electrons transit past the last drift electrodes and to the anode (see Fig. 16.17 (right)).

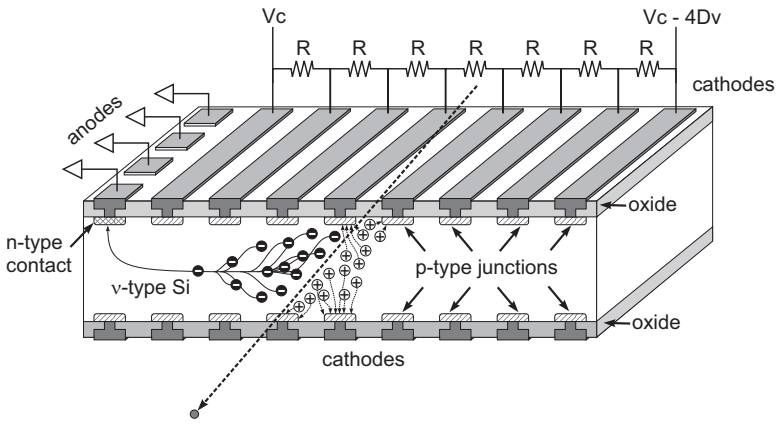

Figure 16.16. Structure of a linear Si drift diode detector. After excitation, electrons are drifted through a central potential channel and collected at an anode. Holes are collected at nearby cathodes. The output signal is heavily weighted on the electron induced charge as they near the anodes. After Gramegna et al. [1995].

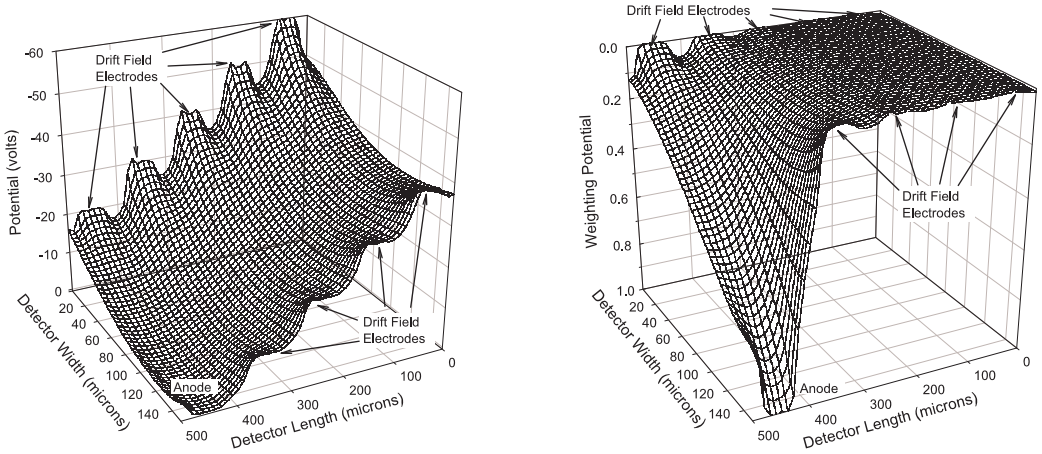

Figure 16.17. (left) For a space charge density of $N_D^+ = 10^{12}$ cm^{-3}, the calculated voltage distribution for a 150 μm wide linear Si drift diode near the anode region. (right) The resulting weighting potential for the same device.

A drift detector design employing ν-type Si material with a series of p^+ contact concentric rings is described by Gatti et al. [1985] and Lechner et al. [1993; 1996]. The device can be larger than the linear design but still have the advantage of low capacitance. Lechner et al. [1993; 1996] include a first stage field effect transistor (FET) input on the detector, which further reduces capacitance and electronic noise. The detector anode is near the center, but actually surrounds the output FET. The design has another difference from the basic linear design first proposed by Gatti et al. [1984a, 1984b], in that the drift field electrodes are only on one side of the device. The backside of the detector is a simple p^+ planar contact, used to promote full depletion of the device. Performance for a 300 μm thick concentric drift diode of 3.5 mm^2 area yielded room-temperature (300 K) FWHM energy resolution of 220 eV for 5.9 keV photon emissions from ^{55}Fe. When cooled to 150 K with a thermoelectric cooler (Peltier cooler), the energy resolution reduced to

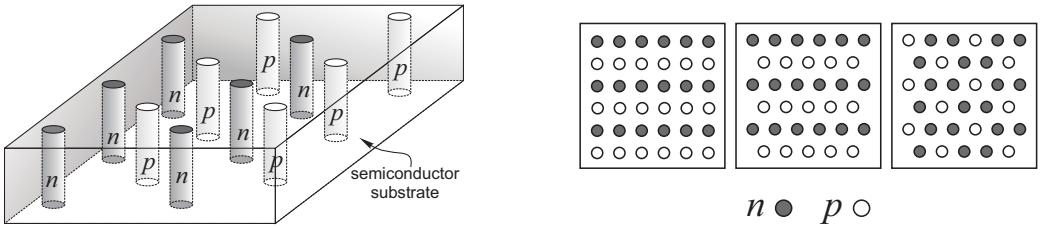

Figure 16.18. (left) Isometric view of the basic 3D architecture, showing interspersed n and p columnar dopant columns in a semiconductor substrate. (right) Top view of a few proposed 3D patterns.

139 eV at FWHM. Lechner et al. [1996] also describe an array of drift diodes on a single substrate that can be read out individually for position sensing information.

There are several advantages to the drift diode design. First, the device design (linear, concentric ring, or variant) allows the realization of a relatively large area device with significantly reduced capacitance compared to a planar device of the same area. Second, these detectors can be fabricated by common VLSI processing techniques, thereby enabling mass production. Finally, drift diode detectors can be used as direct conversion devices for x rays or can be used as light sensitive photodetectors for scintillation detectors, especially for scintillators with longer wavelength emissions which are usually mismatched for bi-alkali photomultiplier tubes. Avset et al. [1991] note that non-uniformities with material resistivities and charge carrier diffusion broadening can adversely affect drift times and position information for two-dimensional readout schemes. They further conclude that best results are obtained with drift fields that exceed 100 V cm^{-1}.

Silicon Three-Dimensional (3D) Detectors Radiation detectors at the Large Hadron Collider (LHC) receive over 10^{15} $\mathrm{n}_{[1\mathrm{MeV}]_{eq}}\,\mathrm{cm}^{-2}$,[12] an indication that these detectors must survive this excessive dose. With upgrades to a high-luminosity LHC, this fluence is expected to exceed 10^{16} $\mathrm{n}_{[1\mathrm{MeV}]_{eq}}\,\mathrm{cm}^{-2}$ [Bates et al. 2011]. Introduced in 1997 by Parker et al., three-dimensional detectors offer an alternative architecture for radiation hardened particle physics detectors than do microstrip or pixel designs. These detectors are constructed as vertically oriented *pin* diodes penetrating deep into a semiconductor substrate (see Fig. 16.18).

There are two salient advantages to the 3D design. First, the short distance between electrodes tremendously reduces the collection time, thereby countering the expected reduction in τ^* and λ^* for electrons and holes after extreme neutron damage. The recoil damage to the crystalline structure increases with fast neutron fluence, and consequently, the charge carrier trap density also increases. This increase in trap density causes a reduction of the electron and hole mean free drift times. Unfortunately, it has been documented that irradiation of 10^{16} $\mathrm{n}_{[1\mathrm{MeV}]_{eq}}\,\mathrm{cm}^{-2}$ for a Si detector reduces the electron and hole mean free drift times τ^* to 0.24 ns and 0.16 ns, respectively [Bates et al. 2011]. These low values of τ^* correspond to mean free drift lengths λ^* of only 24 μm for electrons and 16 μm for holes. Recall from Sec. 15.4.6 the advantage of increasing the carrier extraction factors $\varrho = v\tau/W$ for electrons and holes leads to improved charge collection. The value of $\varrho_{e,h}$ can be increased by reducing the drift distance W between the detector contacts, accomplished with the 3D design by producing adjacent penetrating contacts only tens of microns apart. The resulting induced charge output ΔQ does not suffer as badly for the 3D design as compared to the signal produced for charges drifting across the substrate width of a planar detector. Second, the capacitance of the small electrodes is lower than a planar detector of the same total mass (thickness). Hence, the electronic

[12] The compound unit "$\mathrm{n}_{[1\mathrm{MeV}]_{eq}}\,\mathrm{cm}^{-2}$" describes the equivalent dose damage per square centimeter fluence from a radiation source as expected if the detector were irradiated with monoenergetic neutrons of 1 MeV energy.

noise level should be reduced compared to a planar design, thereby enabling the observation of small pulses. Together these advantages yield particle detectors capable of withstanding high doses of neutron damage.

The first designs had alternating offset rows of p^+ and n^+ holes etched into a 300 to 600 micron thick Si substrate. These holes had diameters of about 15 to 30 microns [Kenney et al. 1999]; later designs had smaller holes down to 10 microns in diameter [Da Viá et al. 2008; Pellegrini et al. 2008]. The holes are etched deep into the substrate, sometimes completely through, with depths usually ranging between 250 to 300 microns. The pitch between adjacent holes is varied, but can be as low as 30 microns [Pellegrini et al. 2008].

The original 3D detectors were fabricated on one surface of a Si semiconductor substrate and are often referred to as "full 3D detectors" [Bates et al. 2011]. Da Viá et al. [2008] comment that p-type wafers are probably a better choice for the detector substrate and apparently are not susceptible to type-inversion.[13] The penetrating holes were etched with inductively coupled plasma reactive ion etching (ICP-RIE) methods [Kenney et al. 1999]. To provide additional mechanical strength during the fabrication process, these first devices were bonded to a Si support wafer. An array of holes was etched and doped p^+, followed by a backfill of polysilicon to produce a relatively flat surface for the next process steps. A second array of holes was then patterned between the first array, etched, and doped n^+. This second array of holes was also backfilled with polysilicon. The final steps included patterning conductive leads to the separate arrays, dicing the detectors from the wafer, and removing the support substrate. To mitigate dead regions around the detector perimeter, electrodes were later patterned around the edges of the detectors [Kenney et al. 2001, 2006]. Da Viá et al. [2008] report that full 3D detectors retained 38% charge collection efficiency after irradiation of 6.8×10^{15} $n_{[1MeV]_{eq}}$ cm^{-2}, equivalent to approximately 10 years of operation within the Super-LHC.

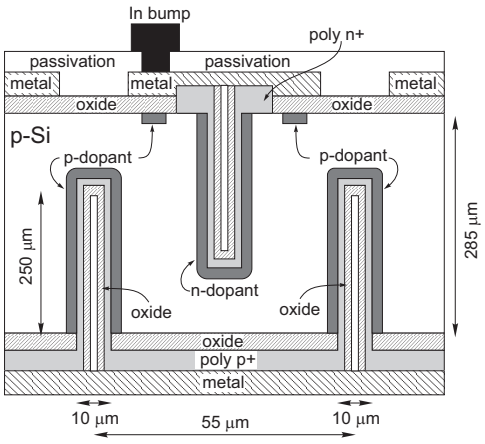

Figure 16.19. Structure of a p-type Si double-sided 3D detector (not to scale). After Pellegrini et al. [2008] and Bates et al. [2011].

The double-sided 3D architecture was introduced to simplify the fabrication process while reducing cross contamination of the p and n doped columns [Pelligrini et al. 2008; Zoboli et al. 2008]. The holes are etched from both sides of a semiconductor substrate, with one side doped p^+ and the other side doped n^+. The holes are arranged in an interspersed pattern such that the p^+ and n^+ columns are adjacent. The holes are etched blind such that they do not penetrate completely through the wafer (see Fig. 16.19). Bates et al. [2011] reports on Si 3D detectors with dimensions shown in Fig. 16.19, and for which the detectors continued to deliver 47% charge collection after irradiation equivalent damage of 10^{16} $n_{1MeVeq}cm^{-2}$ at 150 volt bias. At higher voltage, charge multiplication was observed from the device, indicating impact ionization gain. Additional experiments conducted with double-sided 3D detectors fabricated from both p-type and n-type substrates continued to deliver up to 70% charge collection efficiency at 2×10^{16} $n_{[1MeV]_{eq}}$ cm^{-2} [Köhler et al. 2011]. The n-type detectors did not show type-inversion. Because of the straightforward fabrication process and the high radiation hardness, up to 25% of the insertable B-Layer (IBL) Si detector ring has been populated with double-sided 3D detectors during a recent upgrade [CERN 2010; Lange 2015].

Charged Coupled Devices (CCD) The charged coupled device, or CCD, is an imaging device used to register the intensity of energy deposited as a function of position. When color filters are added to the

[13] The reversal of a rectifying junction that occurs from radiation damage turning n-type silicon into p-type silicon.

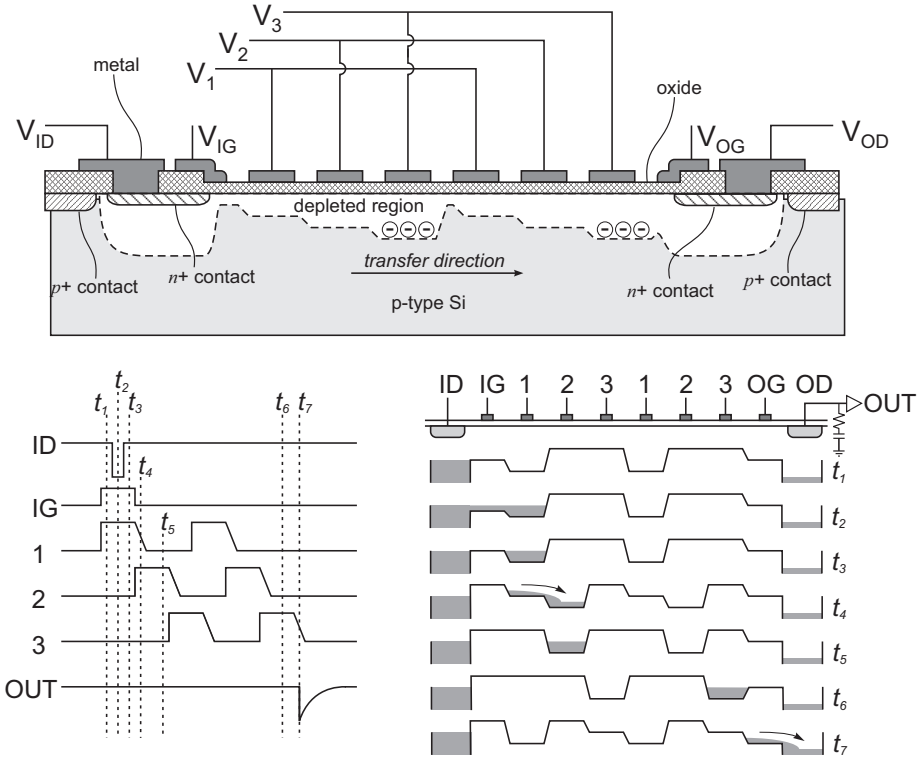

Figure 16.20. Depiction of a MOS n-channel CCD and its operation. (top) A cross section depiction of a surface channel CCD showing only six transfer registers. (left) The clock waveforms and output signal. After Kim [1979].

system, the CCD is used for optical photography and video imaging. The history of the CCD extends back to 1970, when the inventors Boyle and Smith first described its function and operation. The first report on an operating device was also published in 1970 [see Amelio et al. 1970]. This first device was designed as a series of metal pads placed atop a SiO_2 layer grown on a n-type Si substrate to produce a series of MOS capacitors in line on a substrate. Although these first-generation devices had multiple problems with charge sharing and incomplete charge transfer, modern optical devices are still based on improved MOS designs. Damerell et al. [1981, 1987, 1990] and Bailey et al. [1983] report the use of MOS CCDs for radiation detection applications. Advantages of the CCD concept include a reduced number of readout electronics for the large number of pixels, small pixel sizes for good spatial resolution, and relatively rapid response [Stefanov 2006]. Further, CCDs can be tiled to produce a much larger detector array.

The general operation of the CCD is often described with a simple MOS structure as an example, such as the 3-phase surface-channel MOS CCD depicted in Fig. 16.20. The device of Fig. 16.20 has a series of MOS diodes fabricated on a continuous surface of SiO_2. At the ends of the MOS diodes are input and output structures that consist of an input diode and gate (ID and IG) and is used to inject charge and an output diode and gate (OD and OG) that is used to collect charge [Sze 1981]. Because the charge to be measured is excited by radiation events in the depletion region, charge injection is not a necessary requirement for radiation detection CCDs but is used here to provide an example of the charge transport. Every third gate contact, or transfer register, is biased at the same potential, labeled V_1, V_2, and V_3. The transfer registers can be fabricated as strips, and the orthogonal crossing of each register strip along the transverse direction

constitutes a pixel. A digital clock is used to time and apply voltages to the gates in a sequential order. The voltages applied at the input and output diodes are biased high enough to produce deep depletion regions underneath the input and output gates. At time t_1, the voltage applied to V_1 is higher than V_2 and V_3 and produces deeper depletion wells at all positions 1. At t_2, the voltage is adjusted to reduce the barrier between ID and V_1, which allows charge to flow into the first well. At t_3, V_{ID} is increased to close the gate, while excess charge is removed through the ID contact. A t_4, V_1 is lowered and V_2 is increased, causing the depletion wells at 1 to decrease and depletion wells at 2 to increase. Consequently, charge flows from positions 1 into positions 2, a process named *charge transfer*. This process is continued, as depicted for t_5 through t_7, until the charge is transferred to the output diode. The process is often described as analogous to a 'bucket brigade'. A similar shift register, oriented orthogonal to the CCD gate transfer registers, can be used to read the output from each row of transfer registers. There are many variations of MOS CCDs, and Fig. 16.20 depicts only one of many [Kim 2009; Sze 1981; Schroder 1990; Lutz 1999]. Each entire readout of the CCD array is called a 'frame' and the pixels are often termed 'gates'. Each row of registers is read out such that the synchronized clocking electronics can identify the pixel origin when the charge appears on the output.

Recall the description of MOS devices given in Sec. 15.3.4, where again the terms for flat band voltage V_{FB} and gate voltage V_G are used here. The surface potential ψ_s under a CCD gate is defined as

$$V_G - V_{FB} = V_i + \psi_s = \frac{q_e N_A W^2}{C_o} + \psi_s, \tag{16.28}$$

where W is the depletion layer width, N_A is the semiconductor doping concentration, C_o is the oxide layer capacitance in F cm^{-2}, V_i is the potential drop across the insulating oxide layer, and

$$\psi_s = \frac{q_e N_A W^2}{2\kappa_s \epsilon_0}, \tag{16.29}$$

where κ_s is the dielectric constant for the semiconductor. Rearrangement and substitution of the definition of W into Eq. (16.28) gives

$$V_G - V_{FB} = \psi_s + \frac{1}{C_o}\left[2\kappa_s \epsilon_0 q_e N_A \psi_s\right]^{1/2}. \tag{16.30}$$

As charge is accumulated in the potential well under the gate, the gate voltage is altered to become

$$V_G - V_{FB} = \frac{Q_s}{C_o} + \frac{\left[2\kappa_s \epsilon_0 q_e N_A \psi_s\right]^{1/2}}{C_o} + \psi_s. \tag{16.31}$$

Solving this equation for ψ_s gives

$$\psi_s = V_G - V_{FB} + V_0 + \frac{Q_s}{C_o} - \left[2\left(V_G - V_{FB} + \frac{Q_s}{C_o}\right)V_0 + V_0^2\right]^{1/2}, \tag{16.32}$$

where Q_s is the stored charge per unit surface area and

$$V_0 = \frac{q_e N_A \kappa_s \epsilon_0}{C_o^2}. \tag{16.33}$$

The maximum charge that can be stored in a single pixel is described by [Schroder 1984] as

$$Q_{max} = -C_o\left(V_G - V_{FB} - 2\psi_B - V_B\right), \tag{16.34}$$

where

$$\psi_B = \frac{kT}{q_e} \ln\left(\frac{N_A}{n_i}\right) \qquad \text{and} \qquad V_B = \left[\frac{4 q_e \kappa_s \epsilon_0 N_A \psi_B}{C_o^2}\right]^{1/2}. \tag{16.35}$$

Under the assumption that both V_B and ψ_B are small by comparison to the applied effective operating voltage $V_G - V_{FB}$, Eq. (16.34) becomes

$$Q_{max} \approx -C_o \left(V_G - V_{FB}\right). \tag{16.36}$$

The gate oxide is typically about 100 to 200 nm thick and the difference in gate voltage is usually 5 to 10 V. Pixel dimensions for scientific CCDs can range from 50 microns down to 1 micron, and CCDs can have over 2 megapixels in a single device. Commercial CCDs for x-ray imaging applications typically have 20 × 20 micron pixels. If the charge accumulated in a potential well exceeds the capacity, then mobile charges can diffuse into adjacent pixel wells, causing a blurring or a washed out line to appear in the image.[14] A typical charge limit for a MOS CCD potential well is about 5×10^6 electrons [Schroder 1990].

Example 16.2: A common surface channel MOS CCD has pixel sizes of 20 × 20 microns. The oxide thickness is 0.2 microns and the effective operating voltage is 10 volts. Determine the maximum charge that can be stored under the gate.

Solution:

The capacitance per unit area C_o is

$$C_o = \frac{\kappa_o \epsilon_0}{W_o} = \frac{(3.9)(8.854 \times 10^{-14}\ \text{F cm}^{-1}}{2 \times 10^{-5}\ \text{cm}} = 1.73 \times 10^{-8} \text{F cm}^{-2}$$

The maximum charge capacity is

$$Q_{max} = -C_o \left(V_G - V_T\right) = (1.73 \times 10^{-8} \text{F cm}^{-2})(10\ \text{V})(2 \times 10^{-3}\ \text{cm})^2 = 6.9 \times 10^{-13}\ \text{C}.$$

This charge corresponds to

$$\text{number of electrons} = \frac{6.9 \times 10^{-13}\ \text{C}}{1.6 \times 10^{-19}\ \text{C/e}^-} = 4.3 \times 10^6\ \text{electrons}.$$

The surface n-channel device has some problems with efficient charge transfer from one gate register to an adjacent register, mainly because the lowest part of the potential well is adjacent to the oxide layer. To improve transport efficiency, the buried n-channel CCD, or BCCD, was introduced, in which an n-type tub is deep diffused into the p-type bulk, upon which the oxide is grown [Walden et al. 1972]. The BCCD architecture moves the lower point of the potential well away from the surface and into the semiconductor bulk [Schroder 1990].

MOS-based devices can have many problems when used as radiation detectors. First, the oxide can be destroyed by ionizing radiation by producing stationary trapped charge, ultimately changing the operating voltage of individual pixels and causing failure [Killiany et al. 1974, 1975, 1980]. Further, common small pixel CCDs do not have the capacity to store charge for high-energy particles, such as alpha particles, causing charge overflow into adjacent pixels. Finally, the pixel sizes are usually small with depletion region depths

[14] You may have seen this effect when pointing your CCD camera at a candle or other bright light.

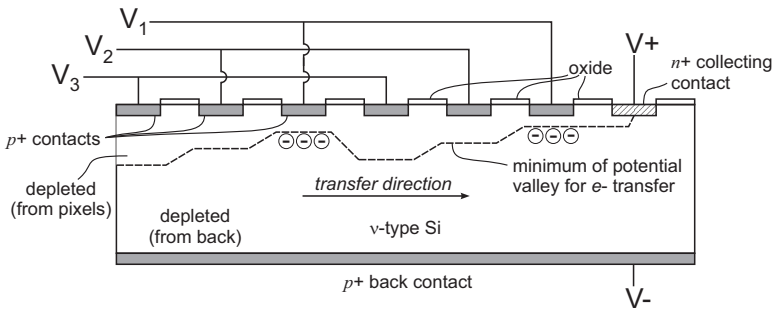

Figure 16.21. Fully depleted *pn* junction type CCD, depicting a cross section portion. After Strüder et al. [1987a, 1990].

of about 1 to 3 μm [Lutz 1999], and energetic particles deposit only a small portion of energy in a single pixel. In some cases, a particle can transit across many pixels.

The *pn*-junction design, proposed by Gatti and Rehak [1984a, 1984b], has received interest as an alternative for radiation imaging applications. A cross section of this device is depicted in Fig. 16.21. The *pn*-junction CCD has three operating voltages synchronized by a clocking circuit [Strüder et al. 1987b, 1990]. The device is reverse biased from an *n*-type contact against a *p*-type back contact and the multiple *p*-type pixel contacts, resulting in a fully depleted ν-type Si substrate. A pixel is defined by the orthogonal crossing of a *p*-type strip transfer register with that of a *n*-type channel guide (see Strüder et al. 1987b). The three operating voltages (V_1, V_2, V_3) are altered to move the potential minimum along the length of register pixel contacts towards the anode. As these voltages are changed, the lowest potential is moved along the contacts towards the anode, ultimately forcing charges to sequentially move from the region under one contact to an adjacent contact. The design is improved by adding channel guides in the direction of motion towards the anode and are composed of an implanted *n*-type region perpendicular to the *p*-type transfer pixels [Strüder et al. 1987a]. These channel guides prevent punchthrough currents between the *p*-type contacts. They also provide a route for the moving charges and reduce lateral diffusion of charges to pixel locations at the sides.

There are additional advantages of the fully depleted *pn*-junction CCD. Because the entire volume is depleted, the *pn*-junction CCD has a large active region, leading to enhanced efficiency over the MOS type. Further, a relatively thin backside *p*-type contact allows the device to be operated with the backside under illumination, thereby producing a much more uniform response of the device area. Because the volume is depleted from top and bottom, the potential minimum is displaced from the surface, unlike that in a traditional MOS CCD, and the charges can travel much faster through the device to the anode. The *pn* junction is more radiation hard than the MOS version; hence the *pn*-junction CCD is more suited for operation in a radiation environment.

There are two common methods by which CCDs function for radiation imaging: (1) as optical detectors for scintillating materials and (2) as direct conversion detectors. Scintillators can be attached to a CCD and the light response spatially measured by the CCD. Methods include the direct attachment of scintillating material to the CCD, although this method puts the CCD in the radiation field. Resolution can be enhanced by having the CCD displaced from a large scintillating screen with the image focused and projected onto the CCD, often with mirrors or a light waveguide [Gruner et al. 2002]. Thick scintillators increase efficiency, but also cause a reduction in spatial resolution. Phosphor-coated screens preserve the spatial resolution, but often have reduced efficiency for high-energy particles. However, for low energy particles and x rays, phosphor screens can provide a suitable detection medium. In a study comparing phosphor screens for x-ray computed tomography, having either lens-coupled CCDs and fiber-coupled CCDs, the lens method provided higher spatial resolution [Uesugi et al. 2011]. However, the light transmission of the fiber-coupled system

was four times more efficient than the lens-coupled device. Consequently, the higher transmission efficiency enables a fourfold reduction in the exposure time. Further, samples prone to deformation are less affected by the reduced exposure time. Finally, the radiation dose to patients is lower because of the shorter exposure time.

The direct imaging method relies on ionizing radiation producing electron-hole pairs in the depleted sensitive region of the CCD. The obvious problem with this approach is that the CCD is placed in the radiation field, and defect formation can eventually cause device failure. This failure is especially problematic when irradiated with heavy ions and reaction products emitted from neutron conversion films. Regardless, the direct conversion method has been used for detection of MIPs in Vertex detectors for high energy physics applications [Damerell 1998, 2003, 2005; Turala 2005; Stefanov 2006; Ishikawa 2015]. Direct conversion CCDs can be commercially acquired for x-ray imaging applications [Hammamatsu 2016]. Windowless CCDs are front irradiated and are designed to detect x-ray energies between 0.5 keV and 10 keV. The back irradiated versions are designed with a thinned surface layer to detect lower energy x rays and also have thicker depletion regions for higher x-ray energies.

For low energy photons, CCDs can be used as photon counters and direct conversion spectrometers. However, charge sharing between pixels can degrade energy resolution and confuse the photon counting, especially for surface channel and BCCD MOS devices in which a large portion of the semiconductor is not depleted. Photon interactions can cause ionization in the undepleted portion, and through charge diffusion, electrons can be shared with many pixels [Lumb and Nousek 1992]. To reduce this problem, CCDs operated as photon counters should have no more than approximately 0.15 photons per pixel per frame to stay within 1% count error. Photon spectroscopy is even more demanding, reportedly requiring about 0.018 photons per pixel per frame [Lumb and Nousek 1992]. The chance of additional interactions during charge transfer process increases with increasing radiation fields, and may pose a problem if radiation spectroscopy is the desired outcome [Lumb and Nousek 1992], mainly because the total background events per frame increases. The clock sampling rate can be increased, but unfortunately this change also causes the signal to noise ratio to decrease. To reduce background charges during the readout process, Lumb and Nousek [1992] also suggest the implementation of a shutter during readout.

As with all semiconductors, leakage current has a generation-recombination component. Hence, CCDs operated at room temperature thermally generate electron-hole pairs during operation and during charge transfer. Usually room temperature operation does not pose a problem. However, for low light or low radiation environments, thermal noise can cause image degradation. This problem is remedied by cooling the CCD during operation between 173 K to 223 K.

Si(Li) X-ray Detectors

The low Z number and low volume density of electrons causes the γ-ray absorption coefficient to be small for Si. Further, the energy at which the photoelectric absorption and the Compton scattering are equal is relatively low at only 60 keV. The Compton scattering coefficient is much lower than most semiconductors used for radiation detection (see Fig. 16.1). Hence, Si is a poor choice for high energy γ-ray spectroscopy. However, its K absorption edge appears at 1.838 keV, meaning that the absorption edge discontinuity does not adversely affect x-ray absorption at higher energies, nor does the appearance of x-ray escape peaks cause significant issues in spectra. By comparison, the K absorption edge for Ge is 11.103 keV. Because higher energy γ rays have less chance of interacting in Si, this property serves to reduce background effects. For these reasons, Si does have importance as an x-ray spectrometer for applications such as x-ray fluorescence, x-ray microanalysis, particle induced x-ray emission (PIXE), x-ray absorption spectroscopy (XAS), x-ray diffraction, and Mössbauer spectroscopy at energies generally below 50 keV. Energy resolution is the full width at half the maximum (FWHM) of a spectral full energy peak. Silicon detectors deliver excellent energy

resolution, and the FWHM, reported in units of energy, is

$$\mathrm{FWHM_{eh}} = 2\sqrt{2\ln(2) w E_\gamma F}, \tag{16.37}$$

where w is the average energy to produce an electron-hole pair, E_γ is the photon energy, and F is the Fano factor (typically 0.12). The Fano factor is a correction factor that accounts for the typically higher energy resolution than predicted from pure Gaussian statistics. With the inclusion of noise sources, the energy resolution becomes

$$\mathrm{FWHM} = \left[(\mathrm{FWHM_{noise}})^2 + (\mathrm{FWHM_{eh}})^2\right]^{1/2}. \tag{16.38}$$

where the $\mathrm{FWHM_{noise}}$ contribution includes electronic noise and fluctuations in the leakage current.

Highly purified Si can be fashioned into a type of pn, $p\pi n$, or $p\nu n$ diode; yet, even with zone-refined high-purity material, Eq. (15.61) (or Fig. 16.11) show these devices are limited to depleted regions less than 2-mm wide, an unsatisfactory thickness for efficient x-ray absorption. The problem is remedied by compensating the remaining impurities in Si with the Li-drifting technique. Pell [1960b] introduced the process of Li drifting in Si, a method to electrically drive Li^+ ions deep into a semiconductor, in which Li behaves as an n-type dopant. If the Si material is π-type, these Li^+ ions exactly compensate the negative space charge effects of acceptor impurities and, thus, the Si material behaves as if it were intrinsic-like. Although other Group I alkali metals such as Na and K also act as donor impurities in Si, it is the small atomic radius and high interstitial drift mobility of Li that makes the drift process possible [Pell 1960b]. Unlike common impurity dopants such as B, P, and As that become electrically active by displacing Si atoms in the crystalline lattice, Li ions become interstitial donors lodged between lattice sites with an ionization energy of 0.03 eV [Mann et al. [1962].

Li drifting is fundamentally a three-step process, starting with producing a pn junction diode, into which Li is introduced as the n-type dopant onto a p-type slab. A purified single crystal of p-type or π-type Si sample is sliced and etched to appropriate dimensions. Afterwards, Li is applied to the surface of the Si slab. There are many processes to apply Li to the Si surface, including physical vapor deposition [Blankenship and Borkowski 1962; Mann et al. 1962; Ristenen et al. 1967] and application of a suspension of Li in oil [Ammerlaan and Mulder 1963; Mayer 1962]. Painting the Li-oil suspension on the sample seems straightforward; however, if done improperly, the layer can be uneven and form cracks, consequently producing a uneven Si surface once the diffusion process is finished. The Si sample is then heated to approximately 400°C for several hours. This Li predeposition process produces a pn junction at the surfaces in contact with the Li dopant. The Li distribution after this predeposition step is

$$N_D(x) = N_0 \ \mathrm{erfc}\left[\frac{x}{\sqrt{4Dt_p}}\right], \tag{16.39}$$

where N_0 is the initial donor concentration, D is the diffusion coefficient, and t_p is the process time. Pell [1960a] measured the diffusion of Li in Si at temperatures between 25°C and 125°C. Combined with data acquired elsewhere [Fuller and Severiens 1954], Pell [1960a] estimates the diffusion coefficient dependence as[15]

$$D(T) = (25 \pm 2) \times 10^{-4} \exp\left[\frac{-q_e(0.655 \pm 0.01)}{kT}\right] \mathrm{cm^2/s}, \tag{16.40}$$

[15] Based on the data from Fuller and Severiens [1954], the Li^+ ion mobility as a function of temperature can be estimated with the result of a least squares fit

$$D(T) = 28.91 \times 10^{-4} \exp\left[\frac{-7733.45}{T}\right] \mathrm{cm^2/s}.$$

Although this result differs from that reported by Fuller and Severiens [1954], it is similar to that found by Pell [1960a].

where T is the absolute temperature in Kelvin. After the Li deposition step, Pell [1960b] approximates the Li distribution by expanding Eq. (16.39) as

$$N_D(x) \simeq \frac{2N_0\sqrt{Dt_p}}{x\sqrt{\pi}} \exp\left[\frac{-x^2}{4Dt_p}\right]. \tag{16.41}$$

Because $N_A = N_D$ at location c in Fig. 16.22

$$N_A \simeq \frac{2N_0\sqrt{Dt_p}}{c\sqrt{\pi}} \exp\left[\frac{-c^2}{4Dt_p}\right], \tag{16.42}$$

so that

$$N_0 \simeq N_A \frac{c}{2}\sqrt{\frac{\pi}{Dt_p}} \exp\left[\frac{c^2}{4Dt_p}\right]. \tag{16.43}$$

Upon substitution of Eq. (16.43) into Eq. (16.41) one finds

$$N_D(x) \simeq N_A \frac{c}{x} \exp\left[\frac{c^2 - x^2}{4Dt_p}\right]. \tag{16.44}$$

Afterwards, the temperature is lowered, usually between 100-200°C, and a reverse bias is applied to the diode [Ammerlaan and Mulder 1963; Miller et al. 1963]. This primary drift serves to force the Li^+ ions deep into the Si material and enlarge the compensated thickness. Miller et al. [1963] point out that the thermally generated charge carrier density (and reverse leakage current) increase with drift temperature. At too high a drift temperature, the thermally generated electron and hole concentrations can exceed the donor space charge concentration. Consequently, the compensation process can become non-uniform and incomplete. Goulding and Hansen [1964] point out the importance of temperature and current control over the process to maintain good compensation uniformity. Periodically during the drifting process, it is possible to stop the drift and measure the reverse current and capacitance to yield a measure of the compensation region width [Ammerlaan and Mulder 1963; Dearnaley and Lewis 1964], mainly because capacitance is inversely proportional to the width while the generation current is proportional to the width.

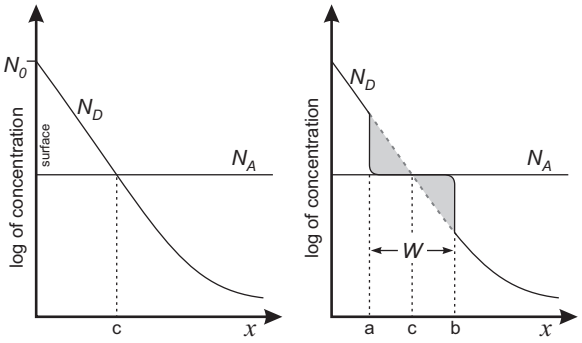

Figure 16.22. The impurity concentrations for Li (N_D) and the acceptors (N_A) (left) directly after the Li diffusion process and (right) after the ion drift process. W represents the compensated region.

For the general analysis of the Li^+ ion drift, it is assumed that the distribution of acceptor impurities N_A is uniform and constant. The Li^+ ion mobility in Si can be described by [Blankenship and Borkowski 1962]

$$\mu_{Li}(T) = 2.78 \times 10^{-2} \left(\frac{1000}{T}\right) \exp\left[-7.5\frac{1000}{T}\right], \tag{16.45}$$

where T is the absolute temperature in Kelvin. Assuming that the drift force $\mu_{Li}\mathcal{E}N_D$ is much greater than the diffusion force $D\nabla N_D$, the initial Li^+ concentration at locations $x < c$ decreases and the Li^+ concentration at locations $x > c$ increases. As the compensated region expands, the Li^+ concentration at $x < a$ continues to decrease while the Li^+ concentration at $x > b$ continues to increase. Note that the Li^+ concentration does not reduce below N_A for $x < c$ and does not exceed N_A for $x > c$. If it could, then

the space charge polarity would reverse in either region, causing Li^+ to drift towards the negative space charge until compensation was complete. The number of Li^+ ions per cm^2, the ion current density, moving across the junction boundary in time t is $\mathcal{E}\mu_{Li}N_A t$ and it is assumed the electric field is primarily in the compensated region where $N_D \simeq N_A$. Overall, the total number of Li^+ ions drifted is represented by the gray areas in Fig. 16.22. Near $t = 0$ at the beginning of the drift process, when $W \ll 2Dt_p/c$, Pell [1960b] approximates the amount of Li drifted over time t as

$$\int_0^t \mu_{\mathrm{Li}}\mathcal{E}N_A dt = \int_a^c N_D(x)\,dx - (c-a)N_A = (b-c)N_A - \int_c^b N_D(x)\,dx. \tag{16.46}$$

Insertion of Eq. (16.39) into Eq. (16.46) and use of

$$\int \mathrm{erfc}(az)\,dz = z\ \mathrm{erfc}(az) - \frac{1}{a\sqrt{\pi}}\exp(-a^2z^2), \tag{16.47}$$

which is obtained by integration by parts, yields

$$\begin{aligned}\int_0^t \mu_{\mathrm{Li}}\mathcal{E}N_A dt = \int_a^c N_D(x)\,dx - (c-a)N_A = -(c-a)N_A + cN_0\mathrm{erfc}\left[\frac{c}{\sqrt{4Dt_p}}\right] \\ -aN_0\mathrm{erfc}\left[\frac{a}{\sqrt{4Dt_p}}\right] + \frac{N_0}{\pi}\sqrt{4Dt_p}\left[\exp\left(\frac{-a^2}{4Dt_p}\right) - \exp\left(\frac{-c^2}{4Dt_p}\right)\right].\end{aligned} \tag{16.48}$$

A similar expression can be obtained in terms of a and c using the right-hand side of Eq. (16.46). A Taylor expansion of the erfc and exponential functions in Eq. (16.48) about c gives

$$\int \mu\mathcal{E}dt \simeq \frac{(c-a)^2}{2L} + \frac{(c-a)^3}{6L^2}, \tag{16.49}$$

where $L = 2Dt_p/c$. Pell [1960b] assumed that the compensated width $W = (b-a) \ll L$ if t_p is very small. If the slope of the Li concentration is assumed linear at point c in Fig. 16.22, then at $t_p \approx 0$ the distance $c - a \approx b - c$, such that the first expansion term of Eq. (16.49) yields

$$\int \mu_{\mathrm{Li}}\mathcal{E}dt \simeq \frac{W^2}{8L}. \tag{16.50}$$

As the drift process continues, it can be assumed that $(b-c) \gg (c-a)$ and $W \simeq (b-c)$, so that [Goulding 1966]

$$dW \simeq \mu_{\mathrm{Li}}\mathcal{E}dt. \tag{16.51}$$

For a planar device where $\mathcal{E} = V/W$, the solution for the compensated detector width is

$$W = \sqrt{2\mu_{\mathrm{Li}}Vt}. \tag{16.52}$$

By using both Eq. (16.45) and Eq. (16.52), Blankenship and Borowski [1962] develop a plot predicting the compensated width of a planar Si(Li) detector as a function of temperature, time, mobility, and voltage. The resulting devices usually have active regions with thicknesses between 3 and 5 mm; however, thicker widths are possible [Ristinen et al. 1967; Bertolini and Coche 1968]. Sharma and Divatia [1986] report a table of drift time and temperature that indicates a 5-mm compensated region takes 280 kilovolt hours at 110°C while raising the temperature to 130°C reduces the drifting duration to 115 kilovolt hours. Adequate

detail of a few drift procedures are provided in the literature [Blankenship and Borkowski 1962; Goulding 1965, 1966; Sharma and Divatia 1986].

The performance of Si(Li) detectors can be affected by detector volume and the initial distribution of background impurities. Although the analysis performed above is a common treatment for the Li drift process, there are many non-ideal situations that affect the outcome. Gibbons and Iredale [1967] and Lauber [1969] analyze numerous alternative solutions that include nonuniform distribution of acceptors, the affect of free charge carries, generation and recombination current, and the effect of trapping and detrapping on the drift process. Gibbons and Iredale [1967] also analyze the expected Li drift result for a detector with coaxial geometry. Contaminants in the Si can also cause problems with the process, further evidence that it is best to start with relatively pure Si material. Pell [1961] and Ammerlaan and Mulder [1963] report that oxygen contamination in the Si can adversely affect the drift process and drastically lower the Li^+ ion mobility from the formation of LiO^+-complex.

A second "clean up" drift at a lower temperature is usually performed after the primary drift process [Lauber 1969], although this drift procedure is still conducted at a temperature higher than the detector operating temperature. The second drift is conducted such that the thermally generated free charge carrier density is much lower, thereby lowering the total space charge concentration. Sharma and Divatia [1986] describe a "clean up" process in which the temperature is slowly reduced under bias as the drifting process continues. Overall, the second drift process produces a much more uniform and complete compensation as the Li^+ ions redistribute.

Unfortunately, even with the second drift, there are usually some residual uncompensated centers, resulting in a net space charge density [Gibbons and Ireland 1967]. These residual uncompensated defects alter the electric field, pulse shape, and performance of the detector [Moszyński et al. 1968; Moszyński and Przyborski 1968; Moroz and Moszyński 1969]. As explained in Sec. 15.3, space charge limits the depletion thickness, and from Sec. 16.2.4, ionized impurities reduce the charge carrier mobilities. If the residual space charge is uniform, then the electric field drops linearly, being lowest near the n-type contact. However, if the residual space charge varies over the detector width, the electric field can have a much more complicated distribution. The research of Mosziński and Przyborski [1968] indicates that the actual electric field distribution is parabolic in shape, a consequence of non-uniform compensation of the background impurities, which appears to have a linearly varying distribution of space charge. The pulse shapes are dependent on the radiation interaction location, and ultimately the operating voltage must be increased to sustain good performance.

Llacer [1964, 1966] determined that the surface conditions and the junction geometry affect the performance of a Si(Li) detector, noting that most of the surface current originates at the i-p junction where the electric field is highest. Further, it was observed that an inversion layer can form on the periphery of the Li-drifted region, where a n-type layer forms, thereby forming a junction around the device including atop the p-type region. The consequence is low-breakdown voltage and relatively high surface leakage current, both contributing to electronic noise. By changing the detector geometry, it was found that the surface breakdown voltage could be increased and the leakage current decreased [Goulding 1965; Llacer 1966]. The added advantage of a higher operating voltage is faster charge carrier collection times. Two popular Si(Li) detector geometries used to increase surface breakdown voltage are depicted in Fig. 16.23, both pin-type devices (discussed in Chap. 15). The inverted-T design includes a deeply etched trench surrounding the n-type contact, while the etched planar design isolates the n-type contact away from the bulk p-type region. Malm and Dinger [1976] and Goulding [1977] point out that the inverted-T design has regions with only partial collection of charge carriers, mainly near the boundary of the etched trench where charges can be collected at the trench. This charge becomes lost and consequently degrades the signal. An isolated guard ring around the n-type contact isolates the detector sensitive region from the trench and improves overall performance [Goulding 1977; Hau et al. 2003].

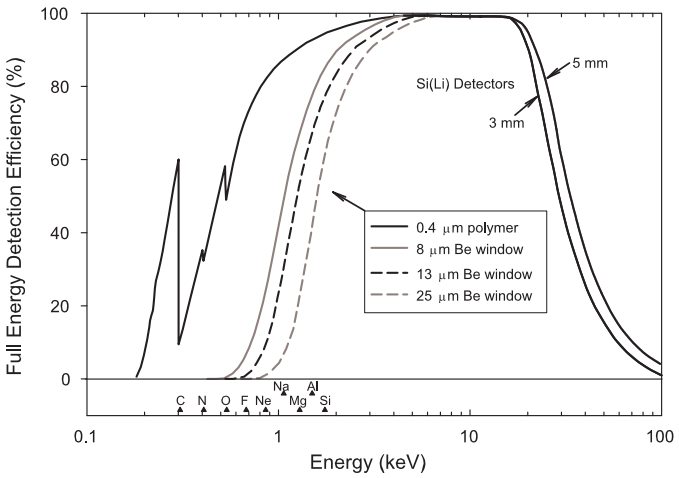

Figure 16.24. The absorption efficiency of a Si(Li) detector as a function of x-ray energy, depletion thickness, and entrance window. Data from Canberra Industries, Inc. 2003.

Unlike the lithium-drifted version of Ge detectors, or Ge(Li) detectors, the Li^+ ions remain locked into position at room temperature. Although Si(Li) detectors can be operated at room temperature, they perform best when cooled to low temperatures. Various Si(Li) detectors are available coupled to either liquid nitrogen (LN2) dewars or Peltier coolers.

The detectors are encapsulated in a protective container with a thin entrance window, typically constructed from Be. The entrance window of the detector affects the low energy sensitivity limit. Shown in Fig. 16.24 is the detection efficiency for various Si(Li) detectors with different thicknesses and different entrance windows. Note that thicker detectors increase the efficiency for higher energy x rays, and an appropriate choice of material for the entrance window can increase the detector efficiency for low-energy x rays.

Si(Li) detectors are best used for spectroscopy of low-energy gamma and x rays. When cooled to cryogenic temperatures (77 K), the resolution performance can be excellent. The energy resolution of a Si(Li) detector can be predicted from Eq. (16.38), as shown in Fig. 16.25. An example x-ray spectrum from a chilled Si(Li) detector is shown in Fig. 16.26.

Si(Li) detectors can be commercially acquired in a variety of segmented patterns, including strips, triangular, and square patterns. The detectors consist of *pin* diode structures individually fabricated into a

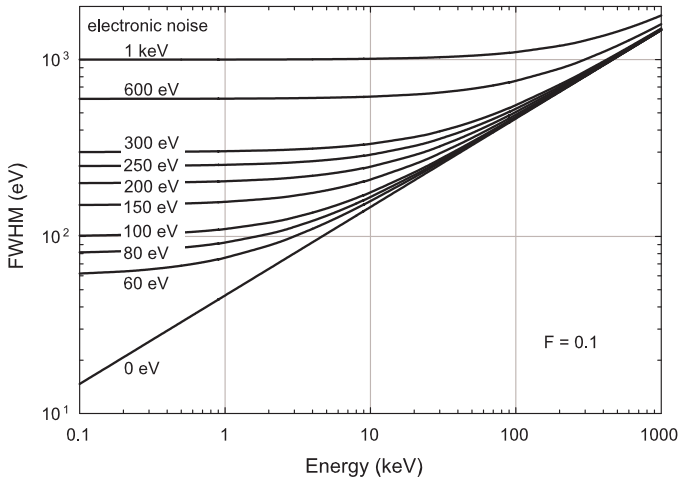

Figure 16.25. The theoretical energy resolution of a Si(Li) detector, which includes contributions from electronic noise. A Fano factor of 0.1 was used for the calculation. After Canberra Industries, Inc. 2003.

single Si substrate, thereby reducing "dead zones" between neighboring detectors. These detectors offer high x-ray energy resolution and spatial interaction information. Further, clever designs can actually improve count rate efficiency for ion probe instrumentation, such as PIXE, by surrounding the target region with multiple detectors. Used in conjunction with other γ-ray detectors, the segmented Si(Li) detectors can be used for Compton scatter γ-ray cameras. Properties of commercially available Si(Li) detectors are presented in Table 16.6.

Si(Li) β-Particle Detectors

At energies above 500 keV, the linear energy transfer (collisional) for fast electrons between 500 keV and 10 MeV is nearly constant (see Fig. 4.20). In Si the linear energy transfer ranges between 1.6 MeV cm^2g^{-1} ($\sim$ 3.8 MeV cm^{-1}) at 500 keV to 1.92 cm^2g^{-1} ($\sim$ 4.5 MeV cm^{-1}) at 100 MeV. Unfortunately, excessive reverse voltage is required to deplete surface barrier and *pn* junction Si diodes to thicknesses capable of recording

meaningful energy deposition exceeding a few hundred keV. For instance, a surface barrier detector with $N_b \simeq 10^{12}$ cm^{-3} biased at -100 volts has a depletion region 250 microns wide, yet is capable of absorbing the full energy of only about a 200 keV or lower energy electron (see also Table 16.7).[16] This problem of incomplete energy deposition is mitigated, somewhat, by using Si(Li) detectors, and indeed special planar Si(Li) detectors are designed specifically for the purpose of energetic particle detection.

Detectors with active region depths between 4 mm to 8 mm are commercially available and are capable of absorbing full electron energies ranging from 1.6 MeV to 3 MeV, respectively. Berger et al. [1969b] report lower electron energy limits for some Si detectors, ranging between 20 to 40 keV, depending on the thickness of dead layer which is the detector's front contact. Here the 20 keV limit is for a surface barrier detector and the 40 keV limit is for a Si(Li) detector. Should the detector width be less than the electron range, then the electrons can pass completely through the detector and deposit only a fraction of their energy [Berger et al. 1969a]. Consequently, a low energy tail, a consequence of partial energy deposition, forms in the pulse height spectrum accompanied by a diminished full energy peak (as discussed further in Sec. 20.9). Backscatter losses and bremsstrahlung energy losses can also add to the low energy tail [Frommhold et al. 1991]. Berger et al. [1969a] published tables of response functions that offer a method to determine the energy deposition as a function of detector thickness. Modern Monte Carlo programs can also be used to generate the same data.

Positrons deposit energy in the detector in much the same way as do electrons. However, when they come to rest, through annihilation, two 511-keV photons are released in opposite directions. If either photon undergoes Compton scattering in the device, then the total positron energy plus the added energy left by the scattered photon appear summed in the pulse height spectrum. Consequently, a high energy tail can appear with positron spectroscopy (discussed and shown later in Sec. 20.9). Because Si has a low Z number, the spectrum from a Si(Li) detector suffers less from Compton scattering effects than do detectors composed of higher Z materials.

[16] The maximum energy listed in Table 16.7 is the energy of the particle whose CSDA range is x. So heavy charged particles with $E < E_{\rm max}$, that mostly travel in straight lines as they slow, are completely stopped within a distance x. By contrast, the tortuous paths traveled by electrons allow some electrons with $E > E_{\rm max}$ to still deposit all their initial energy within a thickness x.

The electron backscatter coefficient for Si is relatively small, being approximately 0.14 at 100 keV (see Fig. 7.7). As discussed in Sec. 7.2.2, the backscatter coefficients in Fig. 7.7 are for the special case in which the particle enters perpendicular to the surface. However, backscattering becomes worse as the entrance angle decreases from 90°; hence the backscattering coefficients of Fig. 7.7 depict overly optimistic results. Regardless, Si is one of the best semiconductor materials for electron spectroscopy.[17] To improve the measured electron energy spectrum the source can be collimated so electrons are normally incident on the detector. In this manner, improved spectral features can be obtained without excessive backscattering adding to the low energy tail.

There are special precautionary measures that must be taken for charged particle spectroscopy. First, to eliminate energy loss from the environment, the particle source and detector should be in an evacuated vessel. Further, Si(Li) detectors can be operated at room temperature, but better energy resolution is obtained if the detector is cooled to some extent. Commercial spectrometers often come with an integrated method of cooling the detector. However, when chilling the detector, precaution should be taken to prevent condensation forming on the detector itself and, thereby attenuating the incident charged particles. The prevention of condensation is typically achieved by operating the detector in vacuum. Also, some commercial units may have a thin window protecting the entrance contact, but such windows add to the overall dead layer thickness. For spectroscopy of low-energy electrons, it is best to enclose both source and detector, without a window, in the evacuated chamber. In fact, some commercial vendors offer a Si(Li) detector with a mount that can be directly attached to a user's vacuum chamber. For special cases requiring transmission measurements, where the goal is to measure ΔE for a particle passing through the detector, transmission devices, sometimes called *sidelookers*, with thin contacts on front and back are available. Aligning several transmission Si(Li) detectors can be used to measure electron energies that have ranges beyond that of a single detector.

16.4.2 Detectors Based on Ge

Germanium (Ge) was first reported as a semiconductor detector by McKay in 1949. This initial Ge detector was manufactured from a point-contact Ge rectifier, and was reported as a particle counter.[18] Ge is a mature and commercially available semiconductor manufactured in many radiation detector configurations. With a density of 5.33 g cm^{-3} and atomic number of 32, it has modest gamma-ray absorption efficiency, but certainly superior to Si detectors. Ge has a narrow band-gap energy of 0.66 eV at room temperature, increasing to 0.72 eV at 77 K. Although a narrow band gap has the disadvantage of increasing the thermal leakage current, it has the advantage of decreasing the average ionization to only 2.98 eV/ e-h pair. Ge has a cubic FCC lattice formed as a diamond structure. Ge also has an indirect band gap, with a band minimum at L in the [111] direction (see Fig. 16.27), which helps to increase charge carrier lifetimes, often greater than 10^{-3} s for highly pure material. The room temperature charge carrier mobilities are μ_e of 3900 and μ_h of 1900 $cm^2\ V^{-1}s^{-1}$, which are relatively high. However, Ge detectors are usually operated at 77 K, and the mobilities are much higher at μ_e of 39000 and μ_h of 42000 $cm^2\ V^{-1}s^{-1}$. A Fano factor below 0.13 is commonly reported.

Germanium (Ge) Radiation Detectors

Presently, the most popular high resolution γ-ray spectrometers are constructed from high purity Ge (HPGe). The material is purified through zone refinement, resulting in a nearly intrinsic material. Although numerous detector configurations exist, including special order devices, a standard unit is a coaxial $p\pi n$ or $p\nu n$ design

[17] Although both SiC and diamond may have lower backscatter coefficients, these detectors presently do not have the required active region width for high energy electron spectroscopy.

[18] Although Si is the most commonly used semiconductor for electronic components, at one time Ge was widely used for diodes and transistors. Ge transistors are still preferred for some specialized electronics, such as electric guitar pedals.

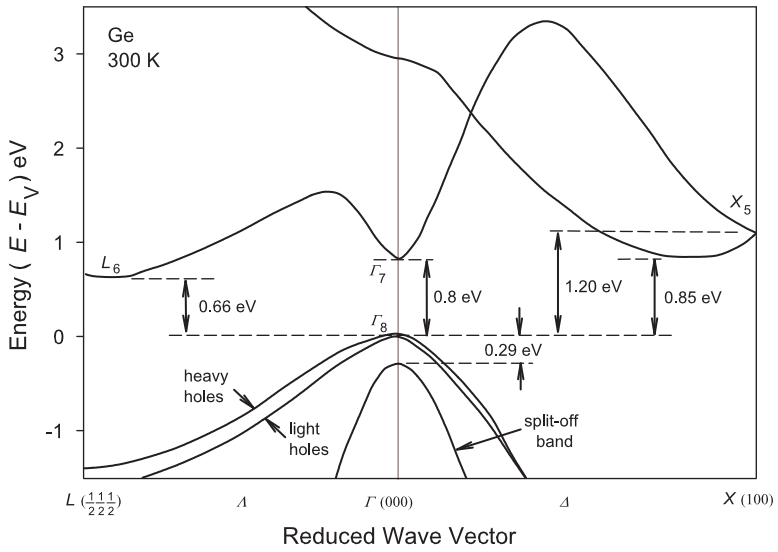

Figure 16.27. The theoretical energy bands of Ge at 300 K calculated with a pseudopotential method. Data are from Chelikowsky and Cohen [1976].

with the rectifying junction on the outer surface (see Fig. 16.36). The coaxial design permits large detectors to be fabricated while minimizing the detector capacitance. With the rectifying surface on the outer surface, rather than on the inner surface, the active volume is increased and detection efficiency for low energy γ-rays is improved.

One difficulty with HPGe detector operation is the need to chill the device during operation. Because of the small band-gap energy (0.66 eV at 300 K), the intrinsic carrier concentration of electrons and holes is much too high at room temperature and significant leakage current is produced when operated at high voltage, which can damage the detector. For this reason, HPGe detectors are typically attached to a dewar and cooled with LN2, or they are attached to a low noise refrigerator system. To ensure that damage does not occur from excessive leakage current should the LN2 be exhausted, most modern systems have a safety shut-off that disconnects the high voltage if the HPGe detector increases to a preset temperature. Portable survey detectors and laboratory units are available with either LN2 dewars or electrically cooled refrigerators. Hybrid LN2/electrical cryostats have become available, in which the main cooler is electrical, backed up with LN2 cooling in case of a power outage.

The usual standard for quality comparisons of HPGe detectors is to quote the energy resolution for 1.33 MeV γ rays from ^{60}Co. The expected energy resolution can be approximated by Eq. (16.37), in which the Fano factor is approximately 0.08. Efficiency, for historical reasons, is quoted most often as a comparison to a 3 in $\times$ 3 in (7.62 cm $\times$ 7.62 cm) right cylindrical NaI:Tl detector with the source placed 25 cm from the face of either detector. For instance, a relative 30% HPGe detector has 30% of the efficiency expected from a 3 in $\times$ 3 in NaI:Tl detector at 1.33 MeV. Although useful as an approximation of detector performance, due to differences in detector geometries and mounting apparatuses, such sweeping generalizations can be erroneous for accurate measurements. It is best to characterize the detector efficiency and resolution by using a method described by ANSI/IEEE 325-1996. A calibrated National Institute of Standards ^{60}Co check source is placed 25 cm from the front of the detector face. The number of counts appearing in the full energy peak for the 1.332 MeV γ ray are divided by the number of emissions over that same time interval, which

yields the absolute efficiency. The relative efficiency is found by dividing the absolute efficiency by 1.2×10^{-3}, which is the standard efficiency for a 3 in $\times$ 3 in NaI:Tl detector under the same irradiation conditions.

Li Drifted Ge [Ge(Li)] Detectors

Although Ge was first reported as a radiation detector in 1949 [McKay 1949], it was over ten years later that it became a serious contender as a radiation detector (spectrometer) [Freck and Wakefield 1962]. Impurity concentrations were still too high in processed Ge, even for zone-refined materials, in which the background impurities predetermined the depletion width of diodes and consequently also limited the overall detector volume. Even at low temperature, a significant density of background impurities would produce high leakage current. Processed Ge ingots were predominantly p-type from the background impurities. In 1960, Pell introduced the process of Li drifting, a method to electrically drift Li^+ ions through a semiconductor. Li behaves as an n-type dopant in Ge, and counterbalances the p-type contaminants [Tavendale and Ewan 1963; Tavendale 1966]. Further, Li^+ is a small ion and has high mobility in Ge crystals, which allows Li^+ ions to be driven deep into a Ge semiconductor block. Li may be applied to one end of a detector with a grease, oil, or with physical vapor deposition [Goulding 1965; IAEA 1966; Brownridge 1972]. A high voltage of approximately 500 volts is applied to the crystal by metallic clamps such that the positive Li^+ ions drift into the crystal. The Ge sample is heated to approximately 30-60°C, usually from the ohmic current, which can be controlled with thermoelectric coolers. The Li^+ ions drift through the lattice as interstitial ions, individually coming to rest as they neutralize the negative electric field formed by the impurity acceptors, such that $N_D^+ = N_A^-$ [Pell 1960a]. Concurrently, unmatched Li^+ ions continue to drift through the lattice while the voltage is applied. The Li^+ drifting proceeds provided that the drift velocity of the Li^+ ions is much greater than the diffusion force, or $\mu_{Li^+}\mathcal{E}N_D \gg D\nabla N_D$ [Pell 1960a]. Hence, Li^+ drifting produces a region of intrinsic behaving material. After the drift process is complete, the crystal is etched and mounted in a cryostat and evacuated down to at least 10 millitorr. The crystal is then cooled to 77 K, and this temperature must be maintained *at all times* whether in operation or not. The Li drifting process enabled sizeable Ge detectors to be realized, and Ge detectors became a standard for high-resolution gamma-ray spectroscopy. If the Ge(Li)[19] detector warms up, the Li diffuses away from the compensation sites and the crystal is ruined, no longer performing well as a spectrometer. Because of the problem of Ge(Li) becoming destroyed if allowed to become warm, which unfortunately happened too often, Ge(Li) detectors have been almost entirely replaced by high-purity Ge (HPGe) detectors.[20]

High-Purity Ge Production

If a Ge(Li) detector loses cooling, the Li becomes redistributed through diffusion and an expensive detector is ruined as a result. This Li redistribution was a serious problem. Although such a damaged crystal could be redrifted once, maybe twice, the redrifted detector inevitably had poorer energy resolution. Hence, around 1970 an active program began to purify Ge to such levels that intrinsic material was achieved solely through extreme purification. Two research groups sought to accomplish this purification task, one led by Robert N. Hall [1971] at the General Electric Company and another led by William L. Hansen [1971] at Lawrence Berkeley Laboratory [Haller 1996].

The process adopted to purify Ge was originally introduced by Pfann [1952; 1966], referred to as zone-refinement.[21] In zone refining, a series of molten zones are passed in one direction through an ingot. Depending on the segregation coefficient of the various impurities, they travel with, or opposite, the direction of the molten passes. The segregation coefficient is defined as the solute concentration in the *freezing solid*

[19] Pronounced "jelly".

[20] The Li-drifted Si(Li) detector, pronounced "silly" detector, is still in production because the Li ion is immobile at room temperature and, unlike Ge(Li) detectors, is not ruined if it accidently loses cooling.

[21] Sometimes referred to as zone melting or zone leveling, Pfann [1966] clearly distinguishes the differences between the methods.

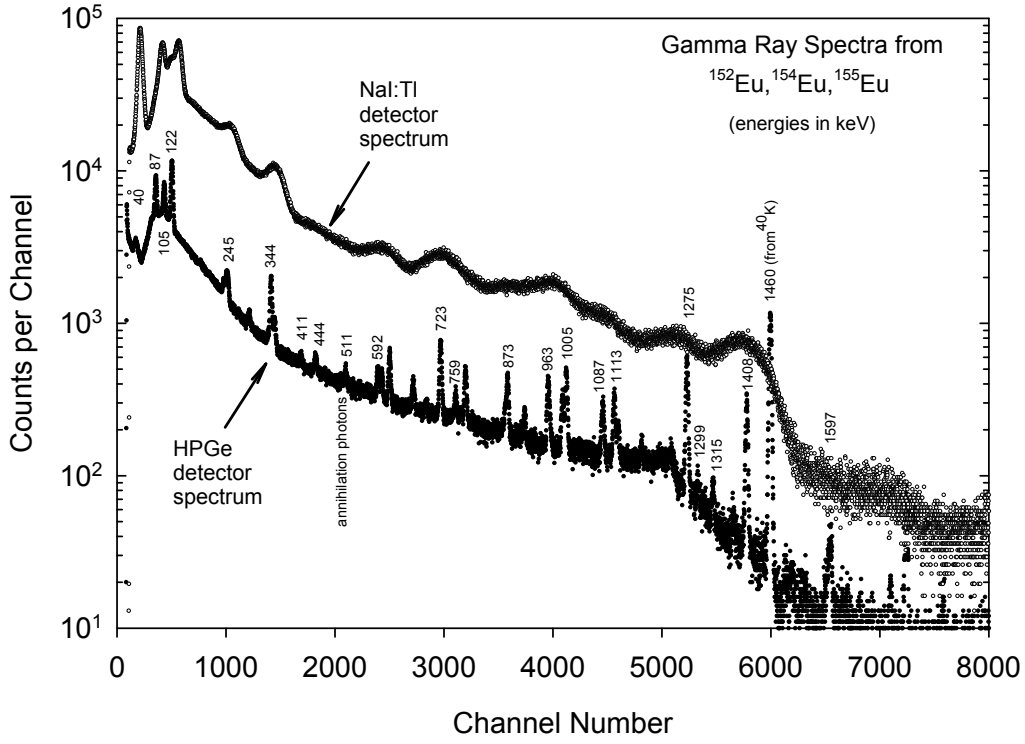

Figure 16.28. A comparison of HPGe detector performance to that of a 3×3 NaI:Tl scintillation detector. The gamma-ray source is a mixture of ^{152}Eu, ^{154}Eu, and ^{155}Eu.

to that of the concentration in the *molten liquid*. The segregation coefficient is greater than unity if the impurity raises the melting point of the material, and less than unity if it lowers the melting point. After numerous passes of the molten zones, the impurities collect at either end of the ingot, leaving a relatively pure substance in the middle.

The impure end regions are sliced from the ingot, and the remaining purified material is used to grow a single crystal of Ge (commonly through Czochralski methods). Impurity levels below 2×10^{10} cm^{-3} are common for zone-refined Ge. Although the purified material is nearly devoid of impurities, the finished product is usually slightly p-type (denoted π-type) or slightly n-type (denoted ν-type). The single crystals of high-purity Ge (HPGe) are then sliced into sections and ground to a desired shape, typically a cylinder. The grinding and slicing damage to the crystal is subsequently etched away and p and n junctions are applied to the sample to produce p-π-n or p-ν-n diodes.

The gamma-ray absorption efficiency for Ge (Z = 32) is much less than that for the iodine (Z = 53) in NaI:Tl. Due to the higher atomic number and generally larger size, NaI:Tl detectors often have higher detection efficiency for high-energy gamma rays than do HPGe detectors, but much poorer energy resolution, as shown in Fig. 16.28. When first introduced, Ge detector efficiency was commonly compared to that of a 3 inch diameter $\times$ 3 inch long (3×3) right circular cylinder of NaI:Tl for 1332-keV gamma rays from ^{60}Co. Even today, efficiency of a Ge detector is quoted in terms of a 3×3 NaI:Tl detector (Fairstein et al. 1996). For instance, an HPGe detector denoted as 60% relative efficiency has 60% of the efficiency that a 3×3 NaI:Tl detector would have for 1332-keV gamma rays from ^{60}Co. HPGe detectors are much more expensive than NaI:Tl detectors, hence are best used when gamma-ray energy resolution is most important

for measurements. If efficiency is of greatest concern, it is often wiser to use a NaI:Tl detector. Comparison spectra between a 20% HPGe detector and a 3 × 3 NaI:Tl detector are shown in Fig. 16.28. Although very expensive, modern manufacturers do produce larger HPGe detectors with 200% relative efficiency.

Various Designs

HPGe detectors are manufactured in various shapes, although most conform to either a planar or coaxial design. Small detectors are commonly manufactured as planar detectors. Relatively large HPGe detectors are manufactured as coaxial devices mainly to keep detector capacitance low. Small HPGe detectors usually have better energy resolution than larger devices, and the larger detectors have better γ-ray detection efficiency.

Planar HPGe planar detectors are typically fabricated by applying a doped region upon a highly pure slab of Ge so that the abrupt junction approximation is valid. The solutions for the electric field and the width of the depletion region were derived in Sec. 15.3. The electric field was determined to be

$$\mathcal{E}(x) = -\frac{|q_e|N_b}{\kappa\epsilon_0}(W - x),\ 0 \le x \le W, \tag{16.53}$$

where W is the depletion region width, N_b is the net background doping concentration, κ is the semiconductor dielectric constant, and ϵ_0 is the permittivity of free space. The depletion width, as a function of applied voltage, is

$$W \simeq \left[\frac{2\kappa\epsilon_0(V_{bi} - V)}{|q_e|N_b}\right]^{1/2}, \tag{16.54}$$

where V_{bi} is the junction built-in potential. The full depletion voltage is obtained by setting $W = W_D$,

$$V_D = V_{bi} - \frac{|q_e|N_b W_D^2}{2\kappa\epsilon_0}. \tag{16.55}$$

Remember that V_D is a reverse (negative) voltage by convention. If the applied reverse voltage is higher than the required depletion voltage, then the electric field becomes

$$\mathcal{E}(x) = -\frac{|q_e|N_b}{\kappa\epsilon_0}(W_D - x) - \frac{|V - V_D|}{W_D},\ V > V_D. \tag{16.56}$$

Coaxial The electric field in a coaxial detector can be found by solving Poisson's equation for a cylinder with space charge

$$\nabla^2 V = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 V}{\partial \phi^2} + \frac{\partial^2 V}{\partial z^2} = \frac{-q_e(N_A^- + N_D^+ + n + p)}{\kappa\epsilon_0}, \tag{16.57}$$

where κ is the semiconductor dielectric constant, ϵ_0 is the permittivity of free space. For the following analysis, assume that the detector is a straight coaxial cylinder, thereby eliminating the angular and longitudinal dependences of ϕ and z. Under operation, it is assumed that the device is fully depleted of charges, leaving behind a net space charge, denoted here as ρ_c. Eq. (16.57) reduces to

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{dV(r)}{dr}\right) = \frac{d^2V(r)}{dr^2} + \frac{1}{r}\frac{dV(r)}{dr} = -\frac{\rho_c}{\kappa\epsilon_0}, \tag{16.58}$$

The rectifying contact is usually fabricated on the outer surface of a coaxial detector, although it could also be formed on the inner surface. The choice of placing the pn junction on the outer surface allows the depletion region to increase from the largest geometric volume, easily understood by approximating

$$\Delta v \simeq 2l\pi r\Delta r \tag{16.59}$$

where Δv is an incremental change in volume, l is the coaxial length, Δr is a incremental increase in radius, and r is a radial distance located between r_1 and r_2. Here r_1 is the coaxial inner radius and r_2 is the outer radius. The volume incrementally increases the most where r is the largest, *i.e.*, at r_2.

HPGe coaxial detectors are usually operated with the high voltage applied to the outer contact, with the inner contact held at ground potential. For gas-filled coaxial detectors, the high voltage is almost always applied to the central wire with the outer cylinder wall held at ground potential. However, because the actual Ge crystal is contained in a vacuum sealed protective housing, the high potential is not accessible to the user. Hence, the high voltage is applied to the outer contact at r_2, with the electronic readout connected to the contact at r_1. This bias configuration reduces electronic noise introduced into the input FET (at r_1).

To solve Eq. (16.58) first use the change of variable $r = e^y$, from which

$$\frac{dV}{dr} = \frac{dV}{dy}\frac{dy}{dr} = \frac{dV}{dy}e^{-y}, \tag{16.60}$$

and

$$\frac{d^2V}{dr^2} = e^{-2y}\left(\frac{d^2V}{dy^2} - \frac{dV}{dy}\right). \tag{16.61}$$

Substitution of Eq. (16.60) and Eq. (16.61) into Eq. (16.58) then yields the equation

$$\frac{d^2V}{dy^2} = -\frac{\rho_c}{\kappa\epsilon_0}e^{2y}, \tag{16.62}$$

whose general solution is

$$V(y) = \frac{-\rho_c e^{-2y}}{4\kappa\epsilon_0} + C_1 y + C_2. \tag{16.63}$$

Substitution of $r = e^y$ back into Eq. (16.63) yields

$$V(r) = \frac{-\rho_c r^2}{4\kappa\epsilon_0} + C_1 \ln(r) + C_2, \tag{16.64}$$

where C_1 and C_2 are arbitrary constants.

The values of C_1 and C_2 can be found in terms of the boundary voltages $V(r_1)$ and $V(r_2)$. In terms of $V_0 = V(r_2) - V(r_1)$, C_1 is found to be

$$C_1 = \frac{V_0 - \dfrac{\rho_c}{\kappa\epsilon_0}\left[\dfrac{r_2^2 - r_1^2}{4}\right]}{\ln\left[\dfrac{r_2}{r_1}\right]}, \tag{16.65}$$

and C_2 is

$$C_2 = \frac{\rho_c r_1^2}{4\kappa\epsilon_0} - \frac{V_0 - \dfrac{\rho_c}{\kappa\epsilon_0}\left[\dfrac{r_2^2 - r_1^2}{4}\right]}{\ln\left[\dfrac{r_2}{r_1}\right]}\ln(r_1). \tag{16.66}$$

Hence, at full depletion of the HPGe volume, the voltage distribution in the HPGe crystal is

$$V(r) = \frac{-\rho_c r^2}{4\kappa\epsilon_0} + \frac{V_0 - \dfrac{\rho_c}{\kappa\epsilon_0}\left[\dfrac{r_2^2 - r_1^2}{4}\right]}{\ln\left[\dfrac{r_2}{r_1}\right]}\ln\left[\frac{r}{r_1}\right] \tag{16.67}$$

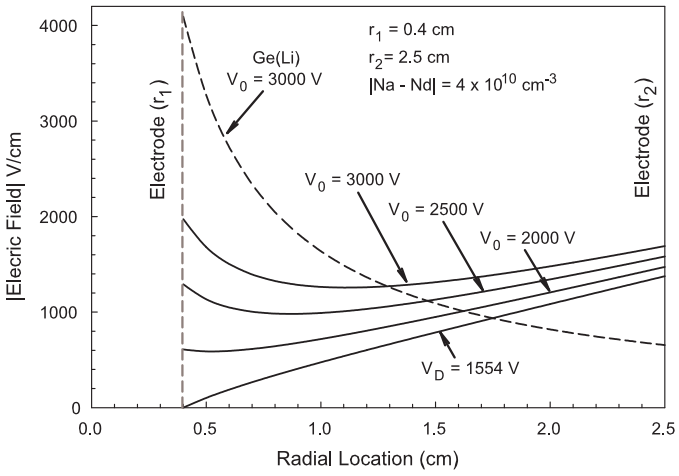

Figure 16.29. Calculated electric field profiles for a HPGe detector with $r_1 = 0.4$ cm and $r_2 = 2.5$ cm. The background impurity concentration is $|N_A - N_D| = 10^{10}$ cm^{-3}. The calculated minimum full depletion voltage is 1554 volts. Also shown is a comparison to the calculated electric field within a Ge(Li) detector of the same size.

and the corresponding electric field is

$$\mathcal{E}(r) = -\frac{dV}{dr} = \frac{\dfrac{\rho_c}{\kappa\epsilon_0}\left[\dfrac{r_2^2 - r_1^2}{4}\right] - V_0}{r \ln\left[\dfrac{r_2}{r_1}\right]} - \frac{\rho_c r}{2\kappa\epsilon_0}. \tag{16.68}$$

If the electric field just barely reaches the contact at r_1, then the device is said to be fully depleted. Hence, with the condition $\mathcal{E}(r_1) = 0$, the voltage required for full depletion is,

$$V_D = \frac{\rho_c}{\kappa\epsilon_0}\left(\left[\frac{r_2^2 - r_1^2}{4}\right] - \frac{r_1^2}{2}\ln\left[\frac{r_2}{r_1}\right]\right). \tag{16.69}$$

An example of the electric field expected in an HPGe detector of average dimensions is shown in Fig. 16.29 compared to that expected from a Ge(Li) detector of the same size and dimensions. Note that the weighting potential for both the HPGe and Ge(Li) detectors is the normalized field distribution of the Ge(Li) detector.

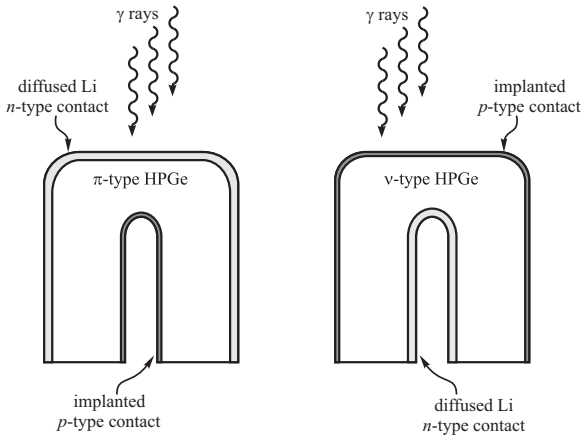

Figure 16.30. Typical configurations for π-type and ν-type coaxial HPGe detectors.

Coaxial detectors are usually fabricated as blind right cylinders, in which the coaxial center hole is not drilled completely through the cylinder. The blind section of the detector is used as the entrance window, a geometry that serves to increase the gamma-ray absorption efficiency. However, for a right circular cylinder, the electric field strength around the detector edge perimeter is weak and causes reduced charge carrier velocity, usually observed as longer pulse rise times.

To remedy the problem, blind coaxial detectors are bulletized (end is rounded) to even out and increase the electric field strength around the edge (see Fig. 16.30).

The capacitance of a straight coaxial HPGe detector can be determined from the depletion depth. For a simple coaxial capacitor, the difference in potential from the inner conductor to the outer conductor can be found from

$$V = \int_{r_1'}^{r_2} \frac{V_0}{r} dr = V_0 \ln\left(\frac{r_2}{r_1'}\right), \tag{16.70}$$

where the undepleted region may be too conductive to behave as a dielectric; hence, r_1' is the depletion region boundary. The total charge at the depletion boundary is

$$Q = \int_0^L dz \int_0^{2\pi} r_1' d\phi \frac{\kappa\epsilon_0 V_0}{r_1'} = 2\pi L \kappa \epsilon_0 V_0, \tag{16.71}$$

where L is the cylinder length. Capacitance is defined as $C = Q/V_0$, hence, at full depletion, it is obvious that the capacitance per unit length becomes,

$$\frac{C}{L} = \frac{2\pi\kappa\epsilon_0}{\ln(r_2/r_1)}. \tag{16.72}$$

Pulse Shape

Determining the pulse shape for planar detectors is relatively straightforward. At 77 K, the hole mobility is higher than the electron mobility, with $\mu_e = 36000$ cm^2 V^{-1} s^{-1} and $\mu_h = 42000$ cm^2 V^{-1} s^{-1}, giving a μ_e/μ_h ratio of 0.875. Consequently, it takes 1.143 times longer to collect electrons over the same distance as holes. It is expected that holes are collected faster than electrons, linearly, with electric field. From Eq. (8.44) the charge induction, without trapping, for a planar detector is

$$\frac{dQ}{dt} = \frac{q_e}{W}[v_e + v_h] = \frac{q_e\mathcal{E}}{W}[\mu_e + \mu_h] \tag{16.73}$$

while both types of charge carriers are in motion. Otherwise, as one charge carrier is collected, and the other is in motion, only one charge carrier type contributes to the induced current. If only electrons are in motion,

$$\frac{dQ}{dt} = \frac{q_e\mu_e\mathcal{E}}{W}, \tag{16.74}$$

and if only holes are in motion,

$$\frac{dQ}{dt} = \frac{q_e\mu_h\mathcal{E}}{W}. \tag{16.75}$$

Normalized to the total current

$$\left(\frac{W}{q_e\mathcal{E}(\mu_e + \mu_h)}\right)\frac{dQ}{dt} = \frac{\mu_e}{\mu_e + \mu_h}\Bigg|_0^{t_e'} + \frac{\mu_h}{\mu_e + \mu_h}\Bigg|_0^{t_h'}, \tag{16.76}$$

where t_e' is the electron collection time and t_h' is the collection time for holes. Substitution of the 77 K mobilities for Ge, the normalized pulse increases as

$$\left(\frac{W}{q_e\mathcal{E}(\mu_e + \mu_h)}\right)\frac{dQ}{dt} = 0.4615\Bigg|_0^{t_e'} + 0.5385\Bigg|_0^{t_h'}. \tag{16.77}$$

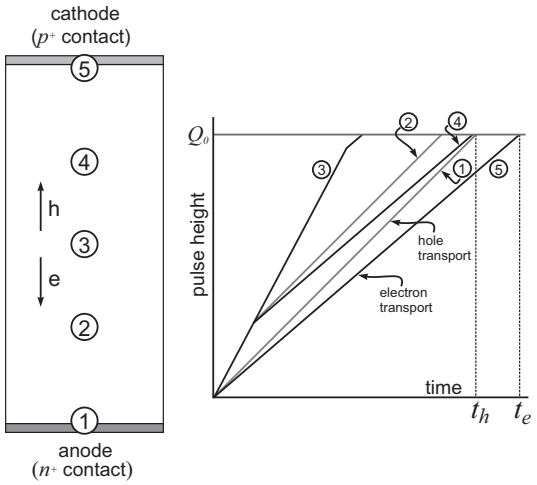

Figure 16.31. The expected position-dependent pulse shapes from a planar HPGe detector operated at 77 K.

Ballistic deficit from the RC time constant notwithstanding, the position dependent pulse shape is depicted in Fig. 16.31. If the event occurs at the anode, then the entire pulse is dependent upon hole collection, extending to the maximum hole collection time of t_h. Similarly, if the event occurs at the cathode, then the entire pulse is dependent upon electron collection, extending to the maximum electron collection time of t_e.

The pulse shape of a coaxial HPGe detector is much more complicated, a consequence of both the non-uniform electric field and the non-uniform weighting potential. If the electric field through the device is high enough to reach velocities near saturation, the pulse shapes can be predicted primarily from the weighting potential, assuming no trapping complications. The normalized induced charge for a coaxial detector is given by Eq. (8.80), namely

$$\frac{Q(t)}{Q_0} = \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \ln\left(\frac{r_2'}{r_1'}\right). \tag{16.78}$$

where r_1' and r_2' are the free charge carrier locations after moving from the initial starting location at r_0. By substitution of $r' - r_0 = vt$ into Eq. (16.78), the pulse shape of a $p^+\pi n^+$ detector, where electrons are collected at the outer contact, is described by

$$\frac{Q(t)}{Q_0} = \left[\ln\left(\frac{r_2}{r_1}\right)\right]^{-1} \left[\ln\left(1 + \frac{v_e t}{r_0}\right)\Bigg|_0^{t_e'} - \ln\left(1 - \frac{v_h t}{r_0}\right)\Bigg|_0^{t_h'}\right], \tag{16.79}$$

where t_e' and t_h' are the electron and hole collection times, respectively. An example of the expected pulse shapes, as calculated from Eq. (16.79), is shown in Fig. 16.32 for a $p^+\pi n^+$ HPGe detector operated at saturation velocity (10^7 cm s^{-1}). For a $p^+\nu n^+$ HPGe detector, the roles of electrons and holes are switched in Eq. (16.79).

Cryogenics and Cooling

HPGe detectors no longer need to be constantly chilled to low temperature as did the older Ge(Li) detectors. However, they still must be chilled to cryogenic temperatures during operation to suppress thermal leakage current. Otherwise, the energy resolution is poor and the detector may suffer severe damage from excessive thermal leakage current. Modern HPGe detector units have a thermal sensor that turns off the detector voltage if the detector temperature rises too high, which can happen if the coolant is allowed to expire or

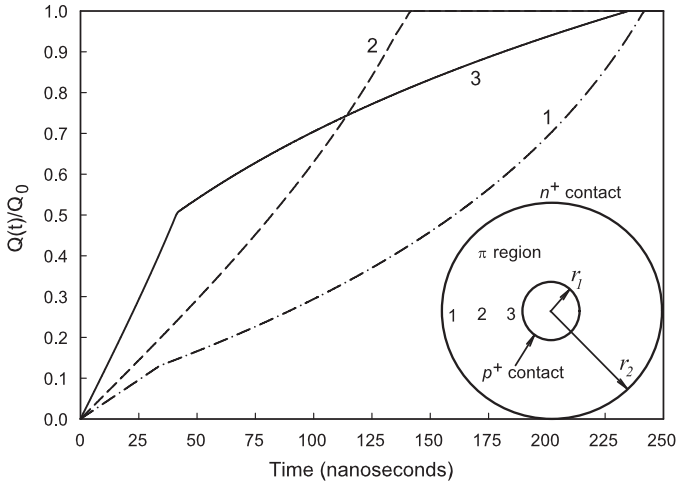

Figure 16.32. The expected position-dependent pulse shapes from a coaxial HPGe detector operated at 77 K, determined from Eq. (16.79). The calculation was performed for a $p^+\pi n^+$ detector with $r_1 = 5.85$ mm and $r_2 = 33.5$ mm. The start locations are identified as $r_0 = 30$ mm, 20 mm, and 10 mm for locations 1, 2, and 3, respectively.

prematurely boils off from vacuum failure in the dewar/stem assembly. This thermal sensor precaution is added to prevent severe damage to the preamplifier circuit. Cooling is achieved by two common methods. The first is the incorporation of a cryogenic dewar filled with liquid nitrogen (LN2). The second is a mechanical refrigerator unit operating on a modified Stirling cycle.

The HPGe detector crystal is mounted inside a mounting cup with standoffs to hold it in place. Usually the mounting cup is electrically attached as an outer contact to the crystal and a conductive pin is used as the inner contact within the hollow penetration. The mounted crystal is placed inside a housing, hermetically sealed, and evacuated. Older designs had the entire stem and housing evacuated; newer designs use a modular approach, in which only the detector compartment is evacuated. In the newer designs, an insulator plug partitions the electronics from the evacuated detector chamber. In either case, the detector crystal is shielded by the mounting cup and the housing, which unfortunately reduce efficiency for low-energy gamma rays. It is common to include a package of molecular sieve in the evacuated chamber to absorb residual gas molecules when the chamber temperature is lowered. The mounted detector is attached to a cold stem that is inserted into an LN2-filled dewar. The dewar is lined with "superinsulation", made of multiple thin sheets of aluminized Mylar®, to reduce LN2 losses and lengthen the time between periodic refills. The cold finger is usually made of copper, and is axially located inside a vacuum-tight jacket. This jacket is also partially filled with molecular sieve, used to getter residual gas molecules at low temperature. The preamplifier electronics are stationed close to the detector to reduce line capacitance. In many models, the preamplifer is situated adjacent to the detector house. In modern modular models, the entire preamplifier is situated next to the detector within the housing (see Figs. 16.33 and 16.34).

The actual detector is much smaller in size than the housing, and often not exactly a perfect cylinder. From experience, some detectors may have a small section sliced from the crystal (to remove a twin or bad region). The actual spectroscopic performance is within the vendors specification, as is the quoted efficiency. However, casual solid angle calculations without taking into account possible geometry differences produces measurement error. The accepted method of calibrating a HPGe detector is documented in IEEE 325-1996 [Fairstein et al. 1996], which mostly negates problems with detector shape and size.

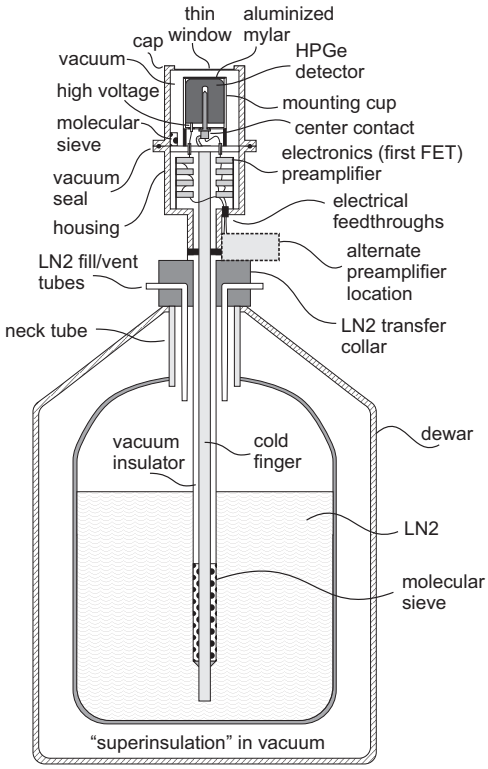

Figure 16.33. A common configuration for an HPGe detector is the vertical dipstick.

LN2 loss of about 15 to 45 ml per hour is expected, although the loss rate can change with environment. Common 30 liter laboratory dewars are refilled at least every two weeks to avoid accidents or other problems. Measurements should not be conducted during refills to avoid microphonics noise that could ruin the results. If the dewar becomes damaged, such that the insulation is compromised, unusually fast boil-off may occur. A cross section diagram of a common HPGe dewar system in the vertical dipstick configuration is shown in Fig. 16.33. Alternative configurations include the horizontal dipstick ("side looker"), downlooking device with the detector pointing down positioned under the dewar, the sidelooking detector attached near the bottom of the dewar, and the "J" type detector with detector attached near the dewar bottom, but the detector and housing positioned to point upwards. There are smaller dewars for portable units, usually rated for approximately 24 hours of use. Some modern dewar systems use a combined system between a refrigerator and conventional LN2 cooling. These units have a refrigerator that recycles the LN2 boil-off back into the LN2 dewar. In the case of a power outage, the LN2 keeps the system cool for up to a week. Because of the recycling of the LN2 in the chamber, these detectors can go without refilling for over a year.

In the last decade, major improvement with mechanical coolers have allowed modern HPGe detectors to operate without LN2, a convenience for locations where LN2 is hard to come by. Originally, these mechanical coolers were used to bring the HPGe detector down to operating temperature ($\sim$ 77 K), and then switched off during a measurement, a procedure requirement because vibrations would cause excessive microphonic noise that would compromise the spectrum. However, vast improvements in refrigerator design now allow these systems to continue operation during a spectroscopic measurement. Some laboratory systems have a large compressor with an umbilical cooler attachment that couples to a modular HPGe detector. Portable

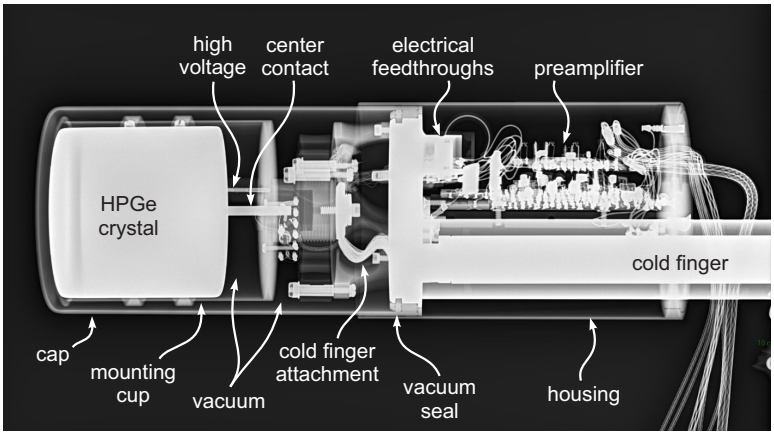

Figure 16.34. X-ray image of an HPGe detector mounting and electronics configuration for a side-looking detector.

units have either modified Stirling cycle refrigerators or pulse tube refrigerators. In either case, the modern units have negligible vibrations and can operate without LN2.

Detection Efficiency, Absorption Losses, and Dead Layers

The response functions for ν-type and π-type HPGe detectors are quite different at low energies. High purity π-type detectors are fabricated with Li, an n-type dopant, as the rectifying contact diffused at a depth of approximately 700 μm thick around the outer surface. A much thinner implanted junction of p-type dopant (typically boron), approximately 300 nm deep, is formed as the ohmic contact on the inner surface. Consequently, the relatively thick "dead" layer formed by the outer contact significantly reduces the detector sensitivity to low energy photons (typically below 40 keV). From Eqs. (16.78) and (16.79), the reverse bias configuration and geometry of $p\pi n$ HPGe detectors cause the average output pulse to be dominated by hole motion. These $p\pi n$ HPGe detectors typically have slightly better energy resolution at high γ-ray energies than $p\nu n$ HPGe detectors.

High purity ν-type detectors are fabricated with p-type dopants implanted and activated at a depth of approximately 300 nm for the outer rectifying contact. A much thicker diffused Li junction up to 700 μm thick is fabricated as the ohmic contact. As a result, low energy γ rays and x rays encounter less "dead" layer in the outer contact, thereby increasing the efficiency for these low energy photons. To take further advantage of the thin surface contact, these ν-type detectors are typically packaged in a can that has a thin Be window, thereby minimizing γ-ray and x-ray attenuation through the detector container. An additional advantage with ν-type HPGe detectors is their increased radiation hardness to neutron radiation. Neutron damage tends to form hole trapping sites, hence the electron dominated pulses from ν-type HPGe detectors are somewhat less affected.

In order to reduce absorption losses from low-energy gamma rays, the front window of the detector cap is fabricated from thin low-density material, commonly aluminum approximately 1.5 mm thick. Aluminum windows are used for efficient transmission of energies above 30 keV. However, detectors with special composite carbon windows or beryllium windows can be purchased that allow transmission for low-energy gamma rays and x rays down to 10 keV and 3 keV, respectively. Depending on the vendor and the design, the detector mounting cup may have an open end design, or instead may have a thin aluminized Mylar® window, apparently in place to reduce infrared absorption. The HPGe crystal is kept in vacuum, which insulates the cryogenically cooled crystal from the external environment. Otherwise, ice crystals can form on

Table 16.8. Typical gamma-ray energy resolution of a few representative commercially available HPGe semiconductor detectors. Many other sizes are offered by the different vendors.

HPGe detector	relative eff. (%)	energy (keV)	FWHM (keV)	comments	source*

the cap, and in the worst case, inside the cap on the actual detector. The vacuum is also necessary to reduce the accumulation of contaminants on the Ge crystal surface. Over time, an accumulation of contaminants adhering to the Ge surface can increase the detector leakage current, a value that must be maintained below 20 pA during operation. Because the detector windows are thinned at the front entrance, these detectors are designed for irradiation from the front. Note that gamma rays may enter from the sides with relatively good efficiency for moderately high energy gamma rays, yet the user should be aware that detection efficiency changes between front irradiation and alternative orientations.

Detectors to be used primarily for low energy measurements need not have a large block of germanium to accomplish the task, nor is the coaxial configuration required. Instead, the planar design is used, with effective diameters available between 6 mm to 70 mm and ranging between 6 mm to 20 mm thick. The planar detectors are $p\nu n$ devices, with an outer p-type implanted contact to reduce the dead layer. The edges are not bulletized, but instead maintain 90° edges, which improves the efficiency of gamma-ray measurements for sources placed close to the detector face. These detectors have better overall absorption efficiency than a Si(Li) detector because of the higher Z (32 opposed to 14); however, they suffer a noticeable decrease in absorption efficiency at 11.1 keV from the Ge K-edge, a fact that should be taken into consideration when deciding on a type of detector for low energy gamma-ray measurements.

As previously stated, the standard reporting procedure for efficiency calibration is outlined in IEEE Standard 325-1996, and efficiency is reported for 1.33 MeV gamma rays from ^{60}Co as a comparative ratio to that of a 3 in × 3 in right circular cylinder NaI:Tl detector [see Fairstein et al. 1996]. HPGe detectors can be obtained commercially with efficiencies ranging from 10% up to 200% [Sangsingkeow et al. 2003], with expense significantly increasing with efficiency. Energy resolutions for some commercially available HPGe detectors are listed in Table 16.8.

Efficiency response examples for a few HPGe variations are shown in Fig. 16.35. Notice in Fig. 16.35 the dip in efficiency at the Ge K absorption edge (11.1 keV). Also note the efficiency reduction below 100 keV for the p-type HPGe detector, which becomes only an issue for the n-type devices represented in Fig. 16.35

at energies below 10 keV. The drop in efficiency is due to a combination of photon absorption in the detector contact dead region and the container holding the detector. Detectors specifically designed for low energy γ-ray spectroscopy typically have thin Be windows that do not appreciably attenuate γ rays entering the device. Overall, the decision regarding which HPGe detector is best for an application requires some knowledge of the preferred energy resolution, necessary detection efficiency, and the photon energy range of interest.

Radiation Damage

Radiation interactions in Ge can cause displacement damage. Under common use, charged particles typically cannot penetrate the detector housing, and gamma-ray damage is minimal. It is damage from fast neutrons that can cause degradation in detector performance by producing Frenkel defects that give rise to charge carrier trapping. Consequently, HPGe detectors operated in radiation fields with appreciable fast neutron exposure suffers, over time, from performance degradation, manifested as a trapping tail (Sec. 15.5.1) and broadening of the energy resolution.

These damage induced defect sites preferentially trap holes over electrons. Consequently, coaxial ν-type detectors are less susceptible to radiation damage effects than coaxial π-type detectors. This difference can be understood by inspecting the geometric weighting and the weighting potential of the detectors. Recall from Eq. (16.59) that the outer detector volume has a higher probability of gamma-ray interactions than inner portions, obvious from volumetric arguments. A π-type detector has the rectifying barrier on the outside perimeter, and holes are drifted in the direction of $r_2 \rightarrow r_1$. With a linear dependence of r, the geometrical dependence indicates that more hole dominated pulses appear than electron dominated pulses.

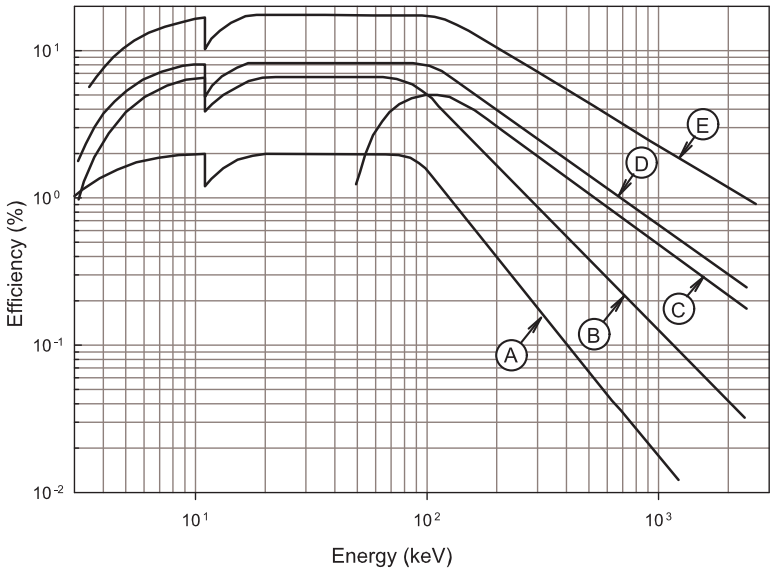

Figure 16.35. The absolute detection efficiency for several HPGe detector configurations with a 2.5 cm source to end cap spacing, showing a (A) 200 $mm^2 \times 10$ mm thick low energy ν-type nominally planar HPGe detector, (B) 10 $cm^2 \times 15$ mm thick low energy ν-type nominally planar HPGe detector, (C) coaxial π-type HPGe detector with 10% relative efficiency, (D) coaxial thin window ν-type 15% relative efficiency HPGe detector, and a (E) broad energy range π-type 5000 $mm^2 \times 30$ mm thick nominally planar HPGe detector. After Canberra, Incorporated [2016].

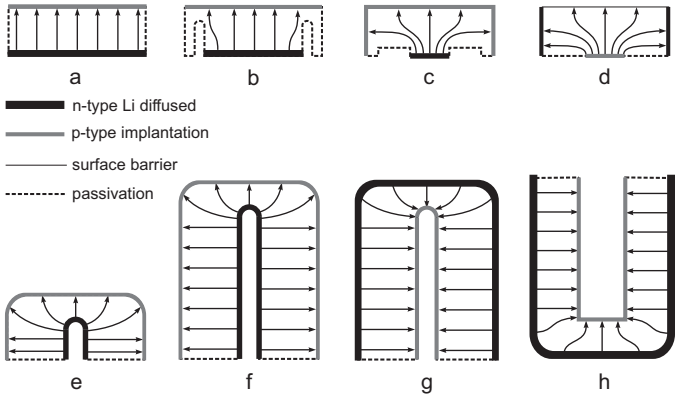

Figure 16.36. Different commercially available HPGe detector structures with electric field lines depicted: (a) basic planar detector, (b) grooved planar, (c) low capacitance planar, (d) surface barrier planar, (e) truncated $p\nu n$ blind coaxial, (f) $p\nu n$ blind coaxial, (g) $n\pi p$ blind coaxial, (h) $p\pi n$ well configuration. After Darken and Cox [1995], Canberra [2016] and Ortec [2016].

From the coaxial design, the induced current is highest as charge carriers drift in the vicinity of r_1 (see Sec. 8.7). Under severe hole trapping, holes originating from the outer regions near r_2 may not reach r_1, and consequently, the pulse output is compromised and lower than expected, producing low energy tails for energy peaks in pulse height spectra.

The opposite case is true for ν-type detectors, for which the majority of pulses are electron dominated. Because the neutron induced defects are primarily hole traps, electron transport from r_2 to r_1 is less affected by charge carrier losses. Holes drifting from r_1 towards r_2 may suffer from trapping, but most of their induced charge is produced in the region nearest r_1. Hence, holes can still contribute a significant amount to the induced current before they are lost to traps.

Both devices can be heated and annealed to remove neutron radiation damage. Detectors manufactured from ν-type Ge can be annealed at approximately 100°C for one day to effectively remove defects. However, π-type HPGe detectors must be annealed at slightly higher temperature ($\sim$ 120°C) for up to a week to effectively remove neutron induced defects. Unfortunately, because Li is used as the n-type dopant on the outer surface of π-type HPGe detectors, the high diffusivity of Li allows it to drive deeper into the detector and increase the outer surface dead region. Consequently, the low energy sensitivity of π-type detectors reduces with the annealing procedure. However, the implanted p-type contact on the outer surface of ν-type detectors is not affected by diffusion at the relatively low annealing temperatures, and consequently does not suffer a reduction in low energy efficiency. In short, ν-type HPGe detectors are better suited for operation in a fast neutron environment than are π-type HPGe detectors.

Detector Structures

There are several types of HPGe detector structures available for specific uses. These structures include detectors optimized for low energy gamma-ray measurements, specifically designed with thin dead regions and thin entrance windows. Other detectors are optimized for best energy resolution, increased radiation hardness, or high detection efficiency. Some of the more popular structures are depicted in Fig. 16.36 and discussed in the following sections.

Although detection efficiency is mostly determined by the detector volume, the energy resolution is a function of the statistical fluctuations in the production of electron-hole pairs, charge carrier losses during

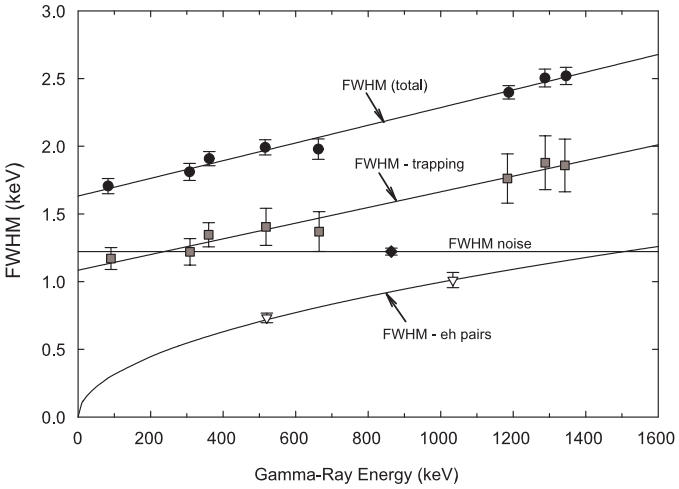

Figure 16.37. Example of energy resolution dependence on gamma-ray energy, electronic noise, and trapping. The curves for the total and the trapping FWHMs were found with a linear least squares fit and the curve for the eh pairs FWHM was modeled with $F = 0.06$ in Eq. (16.83). Data are from Owens [1985].

transport, and signal fluctuations from electronic noise, so that

$$\mathrm{FWHM} = \left[(\mathrm{FWHM}_{\mathrm{noise}})^2 + (\mathrm{FWHM}_{\mathrm{trap}})^2 + (\mathrm{FWHM}_{\mathrm{eh}})^2 \right]^{1/2}. \tag{16.80}$$

The contribution from statistical fluctuations in excited charge carriers is presumed Gaussian in nature, the variance in number of charge carriers produced is

$$\sigma_{eh}^2 = \frac{FE_\gamma}{w} = F\bar{N}, \tag{16.81}$$

where E_γ is the gamma-ray energy, w is the average excitation energy, F is the Fano factor correction constant, and $\bar{N}$ is the average number of charge carriers produced. The fractional standard deviation is

$$\sigma_{eh(f)} = \sqrt{\frac{FE_\gamma}{w}} \frac{1}{\bar{N}} = \sqrt{\frac{wF}{E_\gamma}}, \tag{16.82}$$

and by multiplying this fraction by the original gamma-ray energy, the contribution of the excited charges to the energy resolution is found as

$$\mathrm{FWHM}_{\mathrm{eh}} = 2\sqrt{2\ln(2)}\sigma_{eh(f)}E_\gamma = 2.355\sqrt{wFE_\gamma}. \tag{16.83}$$

Contributions from electronic noise can generally be measured with a pulser added into the circuit under normal detector operation, usually through a connection port provided on the preamplifier. The value of $\mathrm{FWHM}_{\mathrm{noise}}$ can be measured from the resulting pulse height spectrum of the pulser input. Sources include the detector and line capacitance, possible ground loops, and impedance mismatch of connectors.

As seen in Sec. 15.5.1, the pulse height spectrum is skewed towards a lower energy tail, an effect that is important for high trapping losses. Hence, the FWHM is not strictly Gaussian in nature.[22] Further, the contribution from charge carrier trapping changes with detector voltage and size. Larger detectors suffer more trapping, and consequently a higher variance contribution. Increasing the voltage can reduce the effect of trapping, but with limited results. Ultimately, charge carriers reach a saturation velocity (see Fig. 16.5), and increasing the voltage actually has an adverse effect if electronic noise increases. Further, at high enough voltages the diode can reach a voltage breakdown condition. Manufacturers usually have a suggested optimum voltage that produces the best overall energy resolution.

Overall, the total energy resolution FWHM of HPGe detectors, in units of energy, increases with gamma-ray energy. This dependence becomes obvious from Eq. (16.83) for the FWHM in electron-hole pairs produced, but should also be intuitive from the trapping consequences described in Sec. 15.5.1. As the gamma-ray energy increases, the photon absorption becomes more uniform, which decreases the energy resolution in the presence of trapping. Note also from Fig. 16.37 that electronic noise has more effect on resolution for low-energy gamma rays than with high-energy gamma rays.

Planar Detectors The physical attributes of planar semiconductor detectors have been presented in Chapter 15 and in prior sections of this chapter. Of particular note is that planar structures are much easier to fabricate than coaxial detectors. However, the linear weighting potential of a planar detector is more susceptible to resolution degradation from charge carrier trapping. Fortunately, HPGe detectors have low trap densities, long charge carrier lifetimes, and high charge carrier mobilities at low temperature. It is found that smaller planar HPGe detectors yield better energy resolution, with many quoted as having a resolution of less than 200 eV FWHM at 10 keV. HPGe detectors designed for low energy gamma-ray spectroscopy do not need large active volumes, and hence, do not need to be configured in a coaxial structure. Planar HPGe detectors have special use as low energy gamma-ray spectrometers; however, because of their reduced mass, they are considerably less efficient than coaxial detectors at high gamma-ray energies. Shown in Fig. 16.36 are three common planar structures, the simple planar, the grooved planar and the low capacitance planar structures. The grooved structure (Fig. 16.36(b)) suppresses the surface leakage current and thus reduces electronic noise. The small electrical contact design shown in Fig. 16.36(c) takes advantage of a reduced detector capacitance, non-linear weighting potential, and high energy-resolution typical of a small detector to improve performance at low energies. All of the shown planar configurations have a shallow p-type implanted region on ν-type material which serves as the rectifying contact and entrance surface. Coupled with a low Z thin cap window, these detectors can be used for gamma-ray and x-ray energies down to 3 keV. With low Z polymer window materials [Moxtek 2017] as replacements for beryllium windows, it is possible to detect photons with energies below 1 keV. A relatively new configuration fabricated from π-type material has a Schottky barrier front contact, a Li diffused n-type contact around the periphery, and a small p-type contact at the collection electrode. This detector type can have outstanding efficiency and energy resolution performance at energies ranging from 3 keV up into the higher energy range generally relegated to coaxial devices (see Figs. 16.36 and 16.38).

Coaxial Detectors By far the most popular geometry in current use, the coaxial detector design offers outstanding energy resolution and gamma-ray detection efficiency. Capacitance is reduced from common planar detectors, as already mentioned. Coaxial detectors are fabricated from either ν-type or π-type materials, both having advantages. Coaxial $p\pi n$ detectors generally have better energy resolution performance than coaxial $p\nu n$ detectors of similar size, but the thick dead region formed by the Li-diffused junction limits

[22] Owens [1985] argues that HPGe coaxial detectors have nearly Gaussian features even in the presence of trapping provided that the applied electric field is high. This observation is perhaps true, but takes advantage of the coaxial geometry with the non-linear weighting potential, for which the charge carriers suffering higher trapping are collected on the outer electrode.

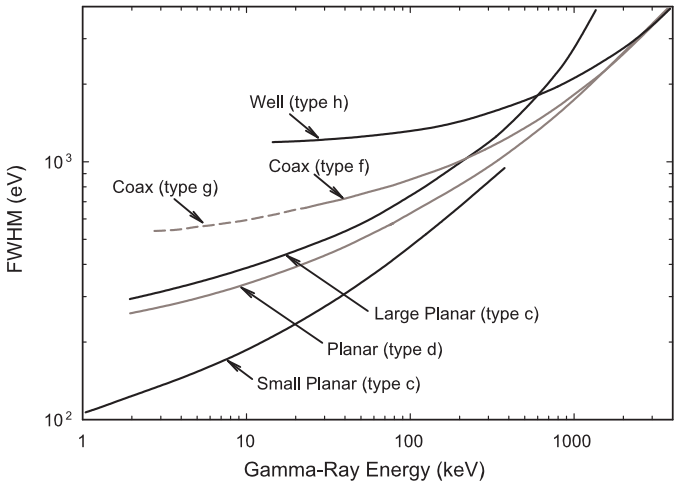

Figure 16.38. Energy resolution at FWHM as a function of gamma-ray energy for several commercial HPGe detector types identified in Fig. 16.36. Data are from Canberra [2016].

detection to gamma-rays above 40 keV. Coaxial $p\nu n$ detectors can be used for lower energy gamma-ray detection, down to 3 keV, and they are much more radiation hard to neutrons than their $n\pi p$ counterparts. The configuration is harder to manufacture than a common planar detector. Straight coaxial detectors have a hole, usually 8 mm to 10 mm diameter, drilled and etched straight through a right circular cylinder. Blind coaxial detectors have the hole drilled nearly through, but with approximately 5 mm of mass left at the detector end. Recall that blind coaxial detectors have the end bulletized to help produce a uniform electric field in the device. The detectors are designed for front side irradiation, and can be acquired in a number of different dewar/detector configurations, the most popular are the dipstick and the top side-looker. Shallow coaxial detectors (Fig. 16.36 (e)) have lower capacitance from the smaller size and are generally thicker than most planar designs. These shallow coaxial detectors are fabricated as $p\nu n$ devices, allowing their use for low-energy gamma-ray spectroscopy with better energy resolution than their larger coaxial counterparts. Unfortunately, because of their smaller size, truncated coaxial detectors have reduced efficiency at higher gamma-ray energies.

Well Detectors The well detector, shown in Fig. 16.36 (g), is a device that nominally produces a 4π counting geometry, in which the radiation source is placed inside the well structure. To achieve highest performance at low energies, the well hole is doped with p-type implants in a π-type blind coaxial device. The outer surface is doped with diffused Li to produce a n-type contact. For this configuration, it must be fully depleted to take advantage of the thin p-type implanted ohmic junction. The construct of the well cap is thin aluminum, usually thin enough to allow detection down to 10 keV. Because of the geometry, well detectors suffer compromised energy resolution compared to other geometries, but can still achieve FWHM near 3 keV for 1332-keV gamma rays. There have been some commercial well hole units in the past that were true coaxial detectors, with the hole drilled completely through the detector. The configuration of the blind hole well requires a longer lead to the first amplifier stage which is manifested in microphonic noise [Gilmore 2008]. The lead on a through-well structure can be shorter, thereby reducing the electronic noise problem. Although the loss of mass at the bottom of the well may reduce efficiency, this problem can be mitigated by making the coaxial detector longer.

Special HPGe Detectors HPGe detectors can be fashioned into numerous different geometries for application-specific measurements. For instance, special instruments for high energy physics [Eberth and Simpson 2008], Compton scatter studies [Choong et al. 2008], gamma-ray tracking [Wieland et al. 2003], and gamma-ray imaging [Niedermayr et al. 2005] have been built for these various applications. In some cases, an array of common coaxial HPGe detectors may be adequate, although the geometry of the array may require innovative electronics arrangements. These arrays improve efficiency and reduce Compton scattered photon losses while yielding information of the gamma-ray trajectories. Eberth and Simpson [2008] provide a good review of several detector array projects and results for assemblies of commercial HPGe detectors.

The maturity of germanium crystals enables the production of segmented arrays of detectors that come in many forms. The most basic are large crystal volumes snuggly fit into a single package and interconnected to form a single device. For instance, the CLOVER device introduced by Canberra Industries [Canberra 2012] has four detectors that when connected provide over 130% efficiency at 1.33 MeV by using a coincidence counting method to sum the full energies of Compton scattered and pair production events. Other segmented detectors have been fashioned by defined sections on either planar and coaxial detectors through photolithography methods [Sandsingkeow et al. 2003], or by directly cutting grooves with a wire saw [King et al. 2008]. In either case, the end result is an array of rectifying contacts individually isolated on the outer surface regions. Cylindrical detectors are divided into zones, and individual preamplifiers attached to these zones are used to sense independent signals originating from these zones. By doing so, Compton scatter imaging and gamma-ray tracking can be performed. Commercial manufacturers offer segmented detectors in either planar or coaxial geometries, some with over 30 segments to a single coaxial device. Segmented detectors can also be arranged in complex arrays to increase the total volume of a detection system.

16.4.3 Diamond Detectors

Another single element group IV semiconductor used occasionally as a radiation detector is carbon in the form of diamond. Diamond was the first semiconductor investigated, successfully, as a radiation detector [Stetter 1941], although it went largely unnoticed at the time. Diamond forms as an FCC lattice,[23] has an indirect band gap of 5.47 eV, and requires on average 13.25 eV to produce an electron-hole pair. Overall, the high ionization energy results in fewer charge pairs produced per unit energy than either Si or Ge. Consequently, there is a reduction in relative pulse height for diamond detectors compared to other semiconductors, yet the average ionization energy is still approximately two to three times less than most gases used in proportional counters. With a Z of only 6, it is the lightest of the group IV semiconductors. The dielectric constant of diamond is relatively low at 5.7 and the index of refraction is 2.424 at a wavelength 546 nm, reducing to 2.418 at 500 nm. The atomic density is 1.763×10^{23} cm^{-3} and the mass density is 3.52 g cm^{-3}.

Diamond has a thermal conductivity coefficient of 25 W cm^{-1} K^{-1}, which is nearly 17 times greater than silicon. The room-temperature electron and hole mobilities for natural diamond reach 2800 and 2000 cm^{2}V^{-1}s^{-1}, respectively. Shown in Figure 16.39 are variations of charge carrier mobilities with temperature and impurity concentration. Near 300 K, these mobilities are only slightly altered with changing temperature. From the literature, highly doped diamond suffers reduction in mobility at low temperature, not an intuitive result [Nebel 2003].

The room-temperature charge carrier saturation velocities are higher than most semiconductors, reaching velocities greater than 1.6×10^7 cm s^{-1} for electrons and greater than 10^7 cm s^{-1} for holes (see Fig. 16.40). Because of its low Z, it is impractical as a gamma-ray spectrometer; however, it has found use on occasion as a particle detector, especially for high-temperature applications. Having a Mohs hardness of 10, it is also more radiation resistant than all other semiconductors. Diamond has a displacement energy ranging between

[23] It is often classified as a diamond lattice, but this is actually incorrect terminology. Instead it is the FCC Bravais lattice with two atoms arranged at each lattice point.

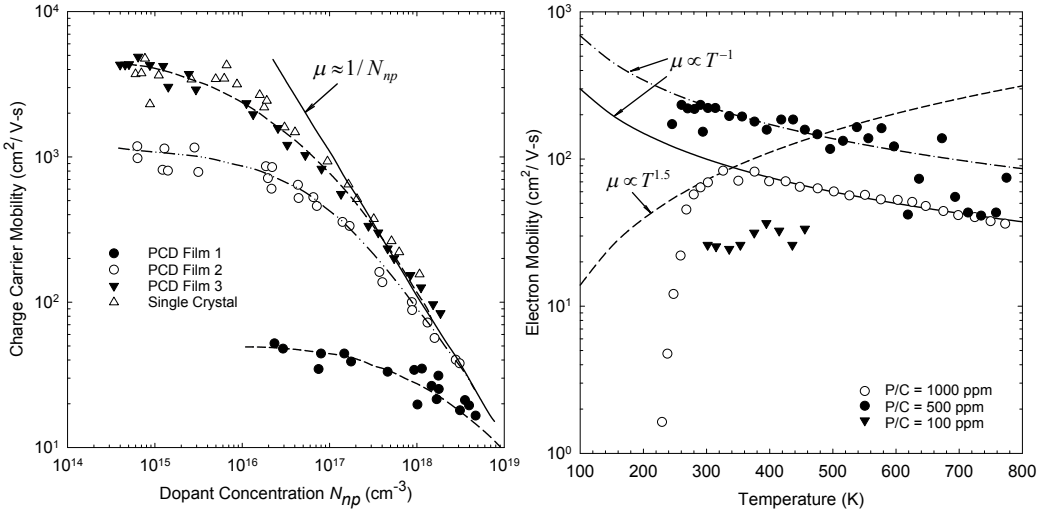

Figure 16.39. The charge carrier mobility in diamond as a function of (left) impurity concentration and (right) temperature. Data are from Nebel [2003].

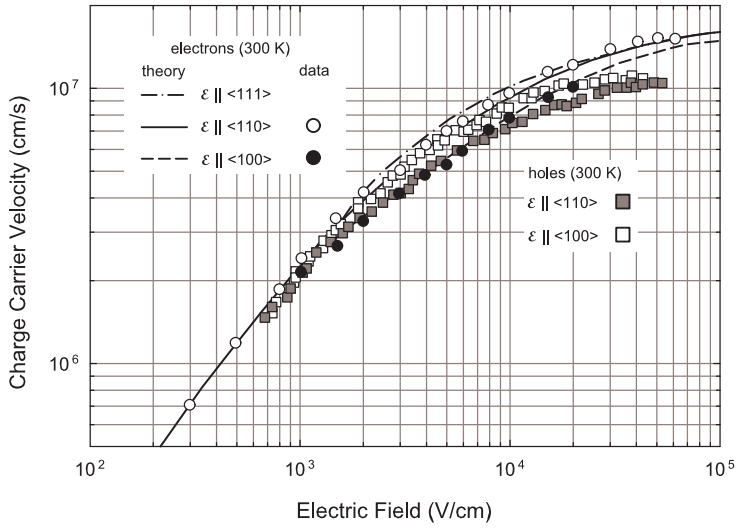

Figure 16.40. The charge carrier velocity in pure natural diamond as a function of electric field and crystal orientation. Data are from Nava et al. [1980] and Reggiani et al. [1981].

35 and 48 eV per atom depending on the irradiation direction in the crystal [Bourgoin and Massarani 1976; Koike et al. 1992], higher than common semiconductors used for radiation detection. The displacement energies for most semiconductors generally range between 6 to 25 eV per atom [for examples, see Loferski and Rappaport 1959; Larin 1968; Bryant and Cox 1968]. This radiation resistance should not be interpreted as being radiation proof, because diamond also accumulates displacement damage from charged-particle and neutron interactions. Consequently diamond detectors also suffer eventual catastrophic failure in a harsh

radiation environment. However, the onset of failure from charged particle damage is usually at a much higher fluence, approximately an order of magnitude greater than observed with either Si or Ge.

Diamond is synthetically produced by chemical vapor deposition (CVD) in a microwave chamber, generally limited to a thickness of 1 mm or less [Hemley et al. 2005]. The process requires a reaction between hydrogen and methane gases at low pressure and at a relatively high temperature, typically above 700°C [Schwartz et al. 2004; Wolfer et al. 2009]. The concentration of methane is much lower than the hydrogen, usually only 1-2% of the total gas mixture [Liang et al. 2009]. The organic gas molecules decompose in the microwave field and deposit the carbon in layers on a prepared substrate, after which a post-growth anneal at higher temperatures (> 2000°C) eliminates graphite structures that may have formed [Liang et al. 2009]. Growth rates increase with temperature, and apparently growth rates also increase with the introduction of nitrogen [Yan et al. 2002]. Including a small amount of oxygen in the CVD plasma also increases the growth rate of diamond, improves crystallinity, and suppresses the formation of graphite [Tapper 2000]. CVD-grown diamond reportedly has higher mobilities than natural diamond, reaching up to 4500 $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$ for electrons and 3800 $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$ for holes [Wort and Balmer 2008]. Effective doping of diamond is difficult, but can be performed. The ionization energies of traditional dopants in group IV materials are relatively large. For instance, the ionization energy of boron (p-type dopant) is 0.37 eV and the ionization energy of arsenic and phosphorus (n-type dopants) are 0.41 eV and 0.59 eV, respectively. Regardless, *pn* junction diodes have been successfully produced with diamond. Except for impure materials, a rectifying junction is probably unnecessary for diamond detectors because the intrinsic resistivity is greater than 10^{13} Ω cm.

The construction of diamond detectors is simple, usually consisting of a parallel plate design with metal contacts on opposing surfaces. Alternative designs have a pair of interdigitated electrodes on a single surface [Mainwood 2000]. One of the major advantages of diamond is its relatively higher radiation hardness to other semiconductors. Because the band gap is wide and also indirect, the probability of band-to-band radiative transitions is low. Instead, performance is strongly dependent on the trap density, and Shockley-Read-Hall recombination dominates. The radiation hardness of diamond is usually measured by the degradation in charge collection efficiency, defined by a comparative decrease in the combined charge carrier drift lengths,

$$\lambda_e + \lambda_h = (\mu_e \tau_e^* + \mu_h \tau_h^*)\mathcal{E} = v_e \tau_e^* + v_h \tau_h^*. \tag{16.84}$$

In other words, as defects are introduced through radiation absorption events, the trap density increases and the mean free drift time (τ^*) decreases. The overall induced charge loss is also a function of detector thickness. Hence, it is expected that as the thickness of a diamond detector is increased, the relative radiation hardness decreases. Damage tends to become severe for charged particle fluences exceeding 10^{15} cm^{-2} [Mainwood 2000], an order of magnitude higher than observed for Si [Adam et al. 2000] and bulk GaAs [Gersch 2002].

16.5 Compound Semiconductor Detectors

Compound semiconductors have been under investigation since 1945 when Van Heerden first explored the use of AgCl as a radiation counter. Unfortunately, compound semiconductors have been substantially less successful than group IV semiconductors. One main reason for the lower success is because of increased number of possible defects that can form with compound semiconductors, commonly arising from antisite defects and non-stoichiometric effects, neither of which is a problem with common group IV semiconductors such as Si and Ge. Added to the complications with purification, these multiple defects can increase charge carrier trapping and affect the electric field profile. However, there are a few compound semiconductors that are useful for special applications, a few of which are described in the following sections.

Compound semiconductor detectors have become more important in recent years, with commercial units now available. Typically these detectors are somewhat smaller than Si- and Ge-based detectors, mainly due to material imperfections. Regardless, a few materials, namely CdTe, CdZnTe, and HgI_2, have desirable

properties for room-temperature operated devices, an advantage not shared by Si(Li) or HPGe detectors. The reason for this advantageous property is that, at 300 K, their larger band gap energies reduce their intrinsic carrier concentrations and substantially increase their resistivities. Further, CdTe, CdZnTe, and HgI_2 all have relatively high Z atomic constituents, hence have larger gamma-ray absorption coefficients over those of Si and Ge. Still, because of their typical smaller size, energy resolution for these compound semiconductor detectors are usually reported relative to 662-keV gamma rays of ^{137}Cs instead of 1.33 MeV. Because of the importance of these properties, lengthy reviews have been periodically published that are devoted entirely to the status of compound semiconductors as radiation detectors, notably Hofstadter [1949a; 1949b], Chynoweth [1952], Mayer [1966], Sakai [1982], Cuzin [1987], Squillante and Shah [1995], McGregor and Hermon [1997], and Owens and Peacock [2004]. Further, a few technical books have devoted much material to discussions on compound semiconductor radiation detectors, such as Bertolini and Coche [1968], Schlesinger and James [1995], and Owens [2012]. In the present text, the authors attempt to condense that vast amount of information on compound semiconductor radiation detectors to a manageable level, incorporating some of the more important developments and findings.

The total charge collected is usually affected by crystalline imperfections that serve as *trapping* sites, which are energy states that remove free charge carriers from the conduction and valence bands. Charge is induced as long as these charge carriers are in motion; hence, their removal diminishes the output voltage. Although the actual trapping process is complicated, it is typical to describe the relative charge collection efficiency as a simplified function of trapping. The induced charge for planar detectors is given by Eq. (15.240), which is written here as

$$\frac{Q(x)}{Q_0} = \varrho_e \left(1 - \exp\left[\frac{x - W}{\varrho_e W}\right]\right) + \varrho_h \left(1 - \exp\left[\frac{-x}{\varrho_h W}\right]\right), \tag{16.85}$$

where W is the detector active region width, Q_0 is the initial excited charge magnitude, x is the event location in the detector, and

$$\varrho_{e,h} = \left(\frac{\tau_{e,h} v_{e,h}}{W}\right) = \left(\frac{\mu_{e,h} \tau_{e,h} V}{W^2}\right) \quad , \tag{16.86}$$

where τ is the charge carrier lifetime, v is the charge carrier velocity, and V is the applied operating voltage. Note, that the relative charge collection is dependent upon the interaction location x, and for low values of ϱ, the energy resolution can be poor. Good energy resolution is achieved if $\varrho > 50$ for both electrons and holes, for which Q/Q_0 has little deviation over the detector width W. In some cases, even if the value of ϱ is low for one charge carrier (holes, for instance), energy resolution can often be preserved by irradiating the cathode side of the detector provided that the gamma-ray energy is relatively low, below the energy at which the cross sections for Compton scattering and photoelectric effect are equal. The reason for the preserved energy resolution is because electron-hole pairs are predominantly produced near the cathode, thereby most of the induced charge is from electron motion.[24] For more penetrating gamma rays, the effect diminishes as electron-hole pairs are produced more uniformly over the detector bulk.

The value of ϱ can be increased by decreasing the detector size (W), increasing carrier lifetimes (τ) through material improvement, or increasing the applied voltage V. Due to practical voltage limitations and the fundamental difficulty with improving materials, most compound semiconductor detectors are manufactured with small active widths to improve detector energy resolution, and, hence, the devices are relatively small. The $\mu\tau$ values for electrons and holes are often quoted measures of quality for compound semiconductors used as γ-ray spectrometers.

Several other methods have been employed to improve the performance of compound semiconductor radiation spectrometers. Electronic correction methods aimed at addressing charge loss have been used,

[24] If $\varrho_h \gg \varrho_e$, seldom the case, then one should obviously irradiate the anode instead of the cathode.

which include pulse-height *rejection* and pulse-height *correction* methods. Advanced detector designs that manipulate the weighting potential to effectively turn the detectors into "single carrier devices" have also been used to improve energy resolution. In more complex systems, a combination of weighting potential manipulation combined with pulse height correction have been used to produce excellent results. Examples of these methods are described in the following sections.

16.5.1 SiC Detectors

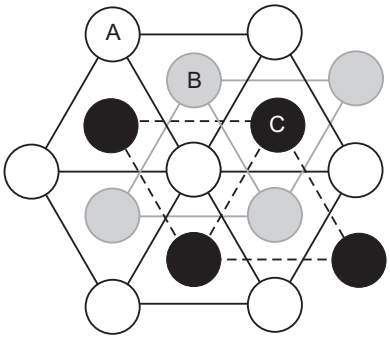

Figure 16.41. In a close pack lattice, layers can stack in positions A, B, or C. The sequence by which atoms stack upon these locations determines the polymorph.

SiC is a group IV compound semiconductor that has long been investigated as a potential radiation detector. SiC has a density of 3.21 g cm^{-3} with atomic numbers 14 and 6. SiC can form in over 200 different polymorphs, and the first identified polytype was a rhombohedral lattice (15R) [Ott 1925; Thibault 1944a, 1944b]. The three most common commercial forms of SiC are 4H, 6H, and 3C. The number indicates the repetitive layering sequence and the letter indicates the Bravais lattice, H for hexagonal, R for rhombohedral, and C for cubic.[25] The structural unit of SiC is a tetrahedron with four carbon atoms about a Si atom, although the basis can be considered the Si-C pair. Each of these pairs is located at a lattice point. A layer of the basis type can be formed in a two-dimensional hexagonal close pack lattice, such as a rack of billiard balls (see Fig. 16.41), which can serve for reference as the basal plane labeled A. A second layer can be laid atop the depressions of the first layer, of which there are two possibilities, labeled B and C. Essentially all of the SiC polytypes can be assembled by arranging these three possible layering structures in a proper sequence.

From Fig. 16.41, a 2H SiC polytype has stacking sequence ABAB where AB is the repetitive sequence. In similar fashion, the 4H polytype has sequence ABCB, the 6H polytype has sequence ABCACB, and the 3C polytype has sequence ABC (zinc blende) [Iwami 2001]. Although the mass densities are the same for these polytypes, the band-gap energies are not: the band gap for 3C is 2.36 eV, for 6H is 3.05 eV, and for 4H is 3.23 eV. SiC is also extremely hard with a Mohs hardness of 9. At 9.66, SiC has a slightly lower dielectric constant than most semiconductors. The intrinsic resistivity of 4H SiC is greater than 10^{15} Ω cm. SiC has a high melting point (decomposition point) of 2830°C (3100 K), a temperature that precludes traditional melt growth methods of production. Instead, SiC bulk crystals are grown by vapor phase transport (VPT), chemical vapor deposition (CVD), or liquid phase epitaxy (LPE) [Dmitriev and Spencer 1998; Sudarshan et al. 2005]. Vapor epitaxial methods are used to grow high quality SiC layers, usually on a bulk SiC substrate. With any of these methods, the production costs are relatively high, thereby making SiC wafers expensive by comparison to most other semiconductors.

Because SiC has such low Z numbers, it is relatively uninteresting as a gamma-ray detector. With the wider band gap, 4H SiC has an average ionization energy of approximately 7.8 eV per electron-hole pair, much larger than the average ionization energy of Si at 3.6 eV per electron hole pair. Further, the high temperature properties and the chemical resistance of SiC make *pn* junction formation a challenge, requiring much higher temperatures (greater than 2000°C) than that needed for common Si diode fabrication [Saxena and Steckl

[25] Ramsdell [1947] suggested this classification method rather than the previous arbitrary method of designating SiC types in sequential order of discovery. Instead, the number represents the number of layers per unit cell and the letter designates the Bravais lattice; H for hexagonal and R for rhombohedral. Thibault [1944a] named the cubic polytype β-SiC and named all other polytypes α-SiC with Roman numeral designations. Because there is only one cubic form, Ramsdell kept the identification β-SiC, yet even this was eventually changed to C for cubic. Hence, Type I became 15R, Type II became 6H, Type III became 4H, Type IV became 3C, etc.

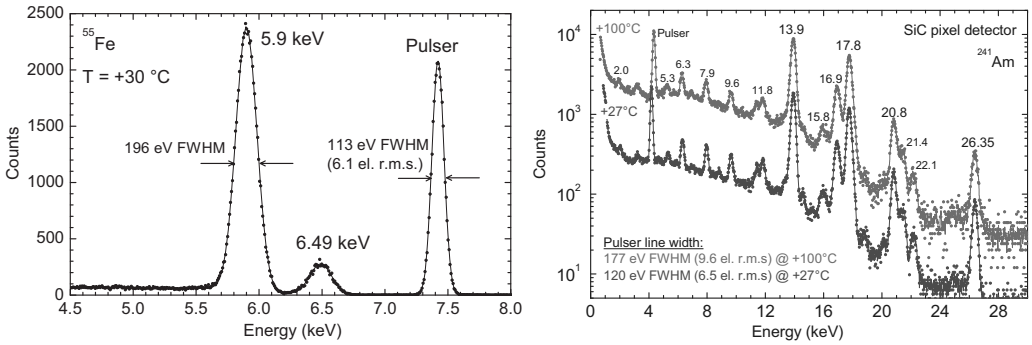

Figure 16.42. (left) Spectrum of ^{55}Fe acquired at 100°C with a SiC pixel detector. An 8 μs triangular pulse shaping was used and the electronic noise was 8.9 electrons r.m.s. (right) Comparison spectra of ^{241}Am acquired at 27°C and 100°C with a SiC pixel detector. From Bertuccio et al. [2011]; copyright Elsevier (2011), reproduced with permission.

1998]. Junction devices can be formed with CVD epitaxial growth of doped layers or with ion implantation of dopant species. Because *pn* junction formation introduces fabrication complications, Schottky contacts are a common method of producing rectifying junctions on SiC substrates. Ohmic contacts generally require a doped sublayer of material, produced by CVD or implantation, before the ohmic metal is applied. The hardness of SiC also presents a challenge for chemical and plasma-based etching. Surfaces that terminate with either C or Si atoms have different chemical properties.[26]

Regardless, there are several attributes to SiC that are of interest for radiation detection. First, because of the high melting point and the wide band gap, SiC detectors can be operated at high temperatures (greater than 700°C) with negligible leakage current [Babcock et al. 1963]. Second, it is relatively radiation hard by comparison to most other semiconductors [Babcock 1965; Barry et al. 1991; Kinoshita et al. 2005; Ruddy et al. 2007; Lefévre et al. 2009]. Hence, a thrust for SiC detector research is for high temperature radiation environments, such as those found in the vicinity of a nuclear reactor [Dulloo et al. 1999]. Third, SiC has a high thermal conductivity coefficient 4.9 W cm^{-1} K^{-1} at room temperature. Fourth, SiC has a saturation velocity of 2×10^7 cm s^{-1}, nearly twice that of Si. Finally, SiC has a high breakdown electric field, 2.2×10^6 V cm^{-1} for 4H material and 2.5×10^6 V cm^{-1} for 6H material so that high voltages can be applied to the detectors. Of the commercially popular SiC polytypes, 4H has emerged as the favored material for radiation detectors mainly because it has higher charge carrier mobilities than 6H and much higher resistivity than 3C. SiC wafers up to 150 mm diameter can be acquired commercially.[27] Because epitaxial SiC is generally of higher quality than bulk SiC, it is common that a high-quality epitaxial layer, grown upon a bulk grown SiC substrate, serves as the detection volume.

SiC has been studied as a neutron detector since the early 1960s [Brussels 1960; Weisman 1960, 1962; Belgium 1962; Babcock et al. 1963]. The primary reason for interest in SiC is because it has unique properties that permit their operation at high temperatures in a harsh radiation environment [Canepa et al. 1964; Seshadri et al. 1999; Nava et al. 2008; Ha 2009]. Detectors for slow neutron detection are usually fashioned as *pn* or Schottky junction diodes coated with a converter material [Dulloo et al. 2003; Manfredotti et al. 2005; Ha et al. 2009]. A type of SiC fast neutron detector relies on fast ^{12}C(n,n′)^{12}C and ^{28}Si(n,n′)^{28}Si elastic and inelastic collisions, along with numerous possible threshold reactions, as the detection mechanisms [Ruddy et al. 2006a; Ha et al. 2011]. Ruddy et al. [2006a] show spectral features for several fast reactions in a 4H SiC *pin* structure, and also demonstrate different pulse height spectra from three different fast neutron

[26] This trait is common to compound semiconductors.
[27] Cree, Inc.

sources, ^{252}Cf, AmBe, and a D-T generator. An alternative fast neutron detection method is to cover the SiC diode with a hydrogenous material such as HDPE and use the (n,p) recoil reactions as the detection method [Flammang et al. 2007]. A more detailed discussion about these neutron detectors is reserved for Chapters 17 and 18. Ruddy et al. [2006b] report on the performance of 4H SiC material as an alpha particle detector. These detectors were fabricated from a 100 micron thick high purity SiC epitaxial layer grown upon a 300 micron thick n-type SiC substrate. Ruddy et al. [2006b] report room temperature energy resolution of 41.5 keV FWHM at 3.18 MeV and 55.4 keV at 8.38 MeV. SiC has also been studied for low-energy x-ray detectors [Bertuccio et al. 2004a, 2004b, 2011; Moscatelli 2007; Nava et al. 2008]. Although these detectors are not suitable for high energy gamma-ray detectors, they performed well for photon energies below 60 keV. Bertuccio et al. [2004a, 2004b, 2011] report on photon detectors fabricated from SiC epitaxial layers, nominally 70 microns thick, grown upon SiC substrates. Operated at 373 K, energy resolution of 233 eV FWHM has been reported for 5.9-keV gamma rays for a pixel detector with a 200 micron diameter Schottky junction (Fig. 16.42) [Bertuccio et al. 2011].

16.5.2 Detectors Based on Group III-V Materials

Group III-V semiconductors are produced from elements in group III and group V of the periodic table. These materials include binary compounds such as GaAs, GaP, InP, and AlSb, ternary compounds such as InGaAs and InGaP, and quaternary compounds such as InGaAsP. For ionizing radiation detector applications, the binary compounds have been investigated the most, although some ternary and quaternary materials have been explored, primarily as contact materials. Both GaAs and InP are relatively mature semiconductors that are in common use within the VLSI industry. Both of these important semiconductors have direct band gaps and show negative differential resistance at high electric fields. Because of their direct band gaps, these two semiconductors have been used most commonly for photonic emission devices such as LEDs and laser diodes. The relatively wide band-gap energies of many III-V semiconductors have motivated researchers to investigate their potential use as room temperature semiconductor radiation detectors.

GaAs

Gallium arsenide (GaAs) was first reported as a semiconductor detector by Harding et al. in 1960. It is a relatively mature and commercially available semiconductor with some properties that make it attractive as a radiation detector [McGregor and Kammeraad 1995]. With a density of 5.32 g cm^{-3} and atomic numbers 31 and 33, it has similar gamma-ray absorption properties as Ge. It has a band gap of 1.42 eV and, thus, allows room temperature operation for moderate size detectors. GaAs has a direct band gap, which is beneficial for photonic emission devices, but also decreases the charge carrier lifetime. Electrons confined in the direct Γ valley have a high mobility, theoretically up to 8500 cm^2 V^{-1} s^{-1} and, thus, generate high electron velocities. The indirect L valley of GaAs is 1.71 eV, as shown in Fig. 16.43, which produces negative differential resistance as electrons transfer from the Γ valley to the L valley for electric fields exceeding 3×10^3 V cm^{-1} (see Fig. 16.6).

The intrinsic resistivity of GaAs is approximately 10^8 Ω cm, but GaAs detectors still must have blocking contacts to reduce leakage current to manageable levels. Detectors are most often produced with Schottky blocking contacts, generally composed of varied thicknesses and combinations of Au, Ti, and Pt [Williams 1990]. Almost all radiation detectors reported were fabricated with $\langle 100 \rangle$ GaAs substrates. Consequently, the $\langle 100 \rangle$ surface states typically "pin" the Fermi energy level near mid-gap, thereby largely decoupling the work function of the metal from the resulting Schottky barrier height. Regardless, there is some experimental evidence that modest alterations in the energy barrier can be achieved with appropriate surface treatments and choice of metal contact [Williams 1990]. The alternative to Schottky barrier blocking contacts is the application of p and n junctions. However, these junctions are not easily achieved with GaAs.

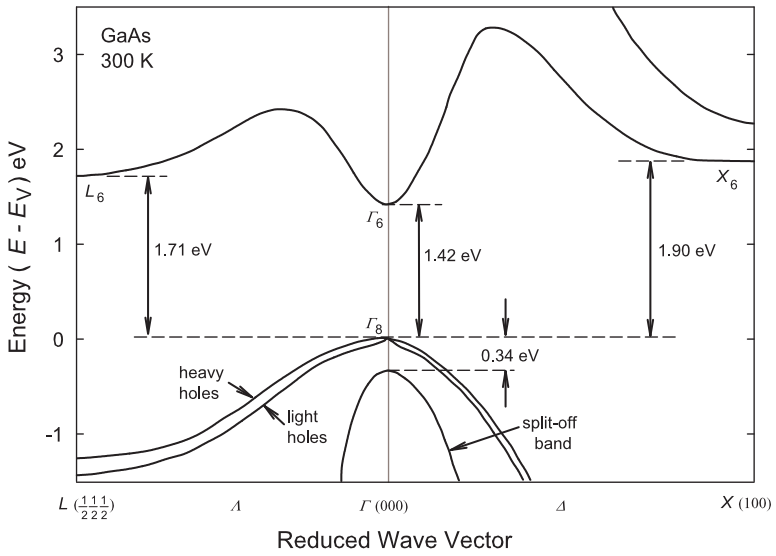

Figure 16.43. The theoretical energy bands of GaAs at 300 K calculated with a pseudopotential method. After Blakemore [1982].

Purification through traditional methods, such as zone refinement or zone leveling, are rendered difficult because arsenic outstreams from GaAs when heated above 400°C for prolonged periods of time, increasing in rate with temperature, thereby ruining the material.[28] Consequently, impurity purification is performed on starting materials (Ga and As) before crystal growth, with purity levels exceeding 7N being commercially available.[29] However, high resistivity is usually achieved by deep level compensation rather than intrinsic properties through purity. Deep level compensation is commonly achieved in bulk GaAs with the antisite As_{Ga} with As located on a Ga lattice location. This antisite defect produces a double deep donor with energies, measured at 0.75 eV and 1.0 eV below the conduction band edge, label EL2 [Martin et al. 1980; Thomas et al. 1984; Bourgoin et al. 1988; Martin and Makram-Ebeid 1992; Baraff 1992].

Historically, GaAs was the first compound semiconductor to demonstrate high energy resolution at room temperature (295 K) for gamma rays [Eberhardt et al. 1970, 1971]. Those detectors were fabricated with GaAs crystals grown by liquid phase epitaxy (LPE), a crystal growth method that intrinsically purifies materials through thermal migration of impurities. Unfortunately, the detectors were also limited to thicknesses of approximately 130 microns and, thus, severely limiting the gamma-ray detection efficiency. A typical pulse height spectrum from such a detector at room temperature is shown in Fig. 16.44. The LPE method of crystal growth is relatively expensive and impractical as a production method for large volume detectors. Epitaxially grown GaAs detectors have demonstrated excellent energy resolution [Owens et al. 1999], some with thicknesses up to 200 microns [Alexiev and Butcher 1992]. Attempts to manufacture thicker epitaxial GaAs have been explored (up to 600 microns), but the authors state that quality was compromised as the thickness increased [Hesse et al. 1972]. Unfortunately, thin devices combined with the relatively low atomic numbers of GaAs offer little advantage over alternative higher Z compound semiconductors, such as CdZnTe and HgI_2.

[28] If performed within a sealed ampoule backfilled with As gas, GaAs can be annealed at elevated temperatures. The cooling method can greatly alter the electrical resistivity of the material [Lagowski et al. 1986].

[29] In the usual jargon for purity, an 'N' represents a '9' in purity. Hence, 5N (or five nines) pure is 99.999% pure.

GaAs produced by bulk crystal growth methods was also studied during the 1980s and 1990s, also with limited success [McGregor and Kammeraad 1995]. Motivation for studying GaAs as a radiation detector included application as room-temperature operated gamma-ray spectrometers and as a radiation-hard particle detectors for high-energy colliders [Beaumont et al. 1992, 1993, 1994]. High resistivity GaAs is generally compensated with either Cr [Cronin and Haisty 1964; Lin and Bube 1976] or with the native EL2 defect [Martin et al. 1980; Kaminska 1987; Bourgoin et al. 1988]. In either case, the charge carrier lifetimes are relatively short, on the order of nanoseconds, thereby drastically reducing the useful size of these detectors. For a bulk GaAs device 130 microns thick, an acceptable energy resolution of 8.83 keV FWHM was achieved for 122 keV gamma rays [McGregor and Hermon 1997]. Energy spectra from a bulk GaAs spectrometer is shown in Fig. 16.45. A modest amount of cooling below room temperature produces a dramatic improvement in performance, as demonstrated by Bertuccio et al. [1997], namely an energy resolution for 60-keV gamma rays measured with 100-micron-thick bulk-grown GaAs detectors reduced from 15.5 keV FWHM at 295 K to 2.4 keV FWHM at 243 K. Yet, the small size also rendered these devices useful only for low energy gamma rays. The problem with compensated bulk GaAs is that the field dependent capture cross section of EL2 [Panousis et al. 1969; Prints and Bobylev 1981; Prinz and Rechkunov 1983] alters the electric field within the detectors and causes the electric field to increase with a non-traditional voltage dependence [McGregor et al. 1994a].

The deep level EL2 is an intrinsic antisite defect As_{Ga} that naturally produces a double deep donor with energy levels approximately 0.75 eV and 1.0 eV below the conduction band edge E_C. EL2 levels are neutral when filled with an electron and positively charged when empty. This antisite defect is purposely produced in concentrations of about 10^{16} cm^{-3} by introducing additional As into the GaAs melt source [Holmes et al. 1982]. A careful balance of the EL2 concentration with that of the residual carbon acceptor concentration (usually near 10^{15} cm^{-3}), and possibly other acceptor impurities, produces semi-insulating (SI) material with resistivities of about 10^8 Ω cm. This relatively high resistivity is still inadequate to produce resistive devices, and instead SI GaAs detectors are fabricated as rectifying diodes operated under reverse bias. Under equilibrium conditions, only a fraction of the EL2 deep donors are ionized and the Fermi level is pinned near midgap, as explained by the three-level model of Sec. 12.5.4. However, as the detector is reverse biased, the EL2 deep donor becomes fully ionized, and produces excess positive space charge near the reverse biased junction as shown in Fig. 16.46. Consequently, the non-uniform ionization distribution promotes the appearance of a two-zone electric field distribution [McGregor and Kammeraad 1995].

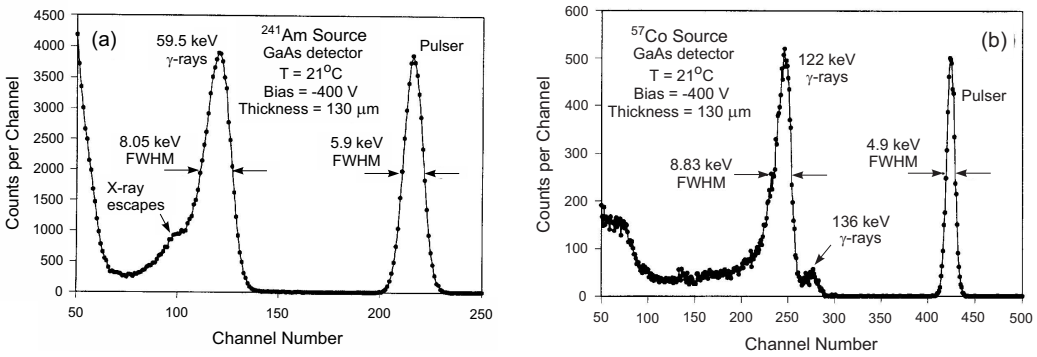

Figure 16.45. Room temperature differential pulse height spectra from a 130 μm thick, 0.5 mm^2 bulk SI GaAs detector. From McGregor and Hermon [1997]; copyright Elsevier (1997), reproduced with permission.

As the bias is increased further, the capture cross section of the EL2 increases [Panousis et al. 1969; Prints and Bobylev 1981; Prinz and Rechkunov 1983], and increases the likelihood that electrons are recaptured, thereby effectively neutralizing a fraction of the deep donors [McGregor et al. 1992, 1994a, 1994b]. McGregor et al. [1994b] propose that the unexpected voltage dependence is a consequence of dynamic trap neutralization of deep centers from electric field enhanced electron capture. Consequently, a quasi-stable constant electric field appears which rapidly decreases to low values at the end of the active region. This balance between trapping and emission at these EL2 sites is a probable reason for low frequency oscillations observed in GaAs biased at high voltages [Holanyak and Bevacqua 1963; Barraud 1963; Sacks and Milnes 1970; Kaminska et al. 1982]. This hypothesis is based on an arbitrary "filling function" applied in the model [McGregor 1994a, 1994b], yet measurements by Berwick et al. [1993] seem to confirm the hypothesis. McGregor et al. [1992, 1994a] and Berwick et al. [1993] found that the electric field active region increased nearly linear with applied voltage, at approximately 1 micron per volt, leaving a considerably wide low-field substrate region with poor charge collection. Unfortunately, with such a peculiar voltage dependence, it takes 1000 volts to produce a 1-mm-thick active region, a voltage that is impractical for most gamma-ray detector applications. Kubicki et al. [1994] attempt to explain the unexpected electric field and depletion characteristic by incorporating leakage currents in their model instead of including the field enhanced capture of electrons. Although the model has merit in explaining the low-field characteristic, it fails to reproduce the dependencies measured by McGregor et al. [1992, 1994b] and Berwick et al. [1993]. Similar results to that of McGregor et al. [1994b] were produced by Cola et al. [1994, 1997], who incorporated the model of McGregor et al. [1994b] and portions of the model of Kubicki et al. [1994]. Overall, Cola et al. [1997] appear to provide additional evidence to field enhanced electron capture by EL2 as the cause of the unusual electric field and depletion characteristic of undoped SI GaAs.

Despite these problems, undoped SI GaAs was found to be useful as a high-speed radiation detector because of the short charge carrier lifetimes [Wagner et al. 1986; Wang et al. 1986, 1989; Friant et al. 1989]. Detectors of this type were used to measure the radiation wave from nuclear weapons tests. Although these detectors were capable of following high-speed radiation pulses, response times were still tens of nanoseconds in duration. The high-speed response was improved by irradiating GaAs materials in a nuclear reactor, which produced a high density of electron and hole traps than appear in bulk-grown GaAs from the damage, thereby reducing the response times to 30 picoseconds [McGregor and Kammeraad 1995].

GaAs pixelated detectors have found use for radiation imaging of low-energy gamma rays and x rays [Manolopoulos et al. 1998; Owens et al. 2001]. The advantages of using GaAs for x-ray imaging over Si

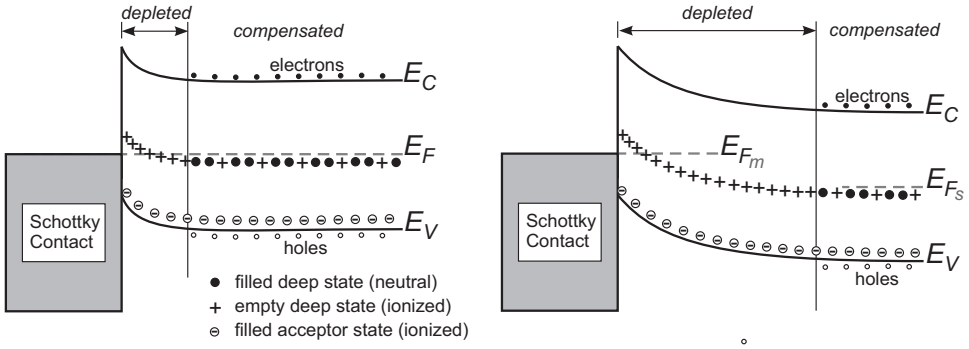

Figure 16.46. Band diagrams of a Schottky contact diode with shallow acceptors and compensating deep donors. (left) With no applied bias, a space charge region appears adjacent to the Schottky contact. (right) With reverse bias applied, the space charge region extends further into the semiconductor as more deep donors become completely ionized. After McGregor et al. [1994a].

include the higher density and Z of GaAs, the higher intrinsic resistivity and lower leakage current, the high Γ valley electron mobility (greater than 8000 $cm^2\ V^{-1}\ s^{-1}$), and pixel isolation is achieved with the semi-insulating substrate rather than a field oxide. There are other semiconductors with higher Z than GaAs, such as CdTe, CdZnTe, and HgI_2, yet the maturity of GaAs and the resultant high quality crystal structure enables common VLSI processing of the pixelated structures.

InP

Indium phosphide (InP) is a compound III-V semiconductor that has received modest attention, sporadically, as a radiation detector. Perhaps one of the more attractive attributes of InP is its relatively high electron charge carrier mobility of 4500 $cm^2\ V^{-1}\ s^{-1}$, with holes having a mobility of 150 $cm^2\ V^{-1}\ s^{-1}$. The saturation velocity is higher than that of GaAs, reaching over 2.5×10^7 cm s^{-1} at an electric field of 1.2×10^4 V cm^{-1}. The average ionization energy is approximately 4.2 eV per e-h pair. The gamma-ray absorption is dominated by the higher Z indium component with atomic number 49 (where phosphorus is only 15), and the density of InP is 4.79 g cm^{-3}. With a direct band gap of approximately 1.35 eV (Fig. 16.47), the intrinsic resistivity is approximately $10^7\ \Omega$ cm, just high enough to operate small devices at room temperature. However, this high resistivity is usually achieved by compensation doping with Fe impurities. Notice from Fig. 16.6 that InP also possesses negative differential resistance for electrons at electric fields above 1.2×10^4 V cm^{-1} and, thus, makes InP attractive for Gunn effect devices.

InP is usually grown by either the liquid encapsulated Czochralski (LEC) method or the vertical gradient freeze (VGF) method. Undoped material is usually n-type, although resistivity control can be attained by purposely doping with the n-type dopants S or Sn. InP can be acquired as p-type material if doped with Zn. High resistivity material is produced by adding a deep accepter compensating dopant to the melt. For detector purposes, Fe-doped semi-insulating (SI) InP has been investigated the most.

SI InP doped with Fe was explored as a high speed radiation photoconductor to measure short bursts of radiation. Fe acts as a deep acceptor site and compensates residual shallow donor impurities to produce a semi-insulating material as described in Sec. 12.5.4. These detectors routinely had response times between 100 ps to 200 ps, determined to be largely dependent upon the bulk recombination of electrons and holes [Hammond et al. 1981, 1983, 1984]. The response times were shown to be dependent upon the Fe concentration and had an obvious reduction in response time as the deep acceptor Fe concentration was increased [Wagner et al. 1986]. Wagner et al. [1986] also found that neutron irradiation damage further improved the high speed response of InP:Fe photoconductors. There is a limit to the neutron damage that can be

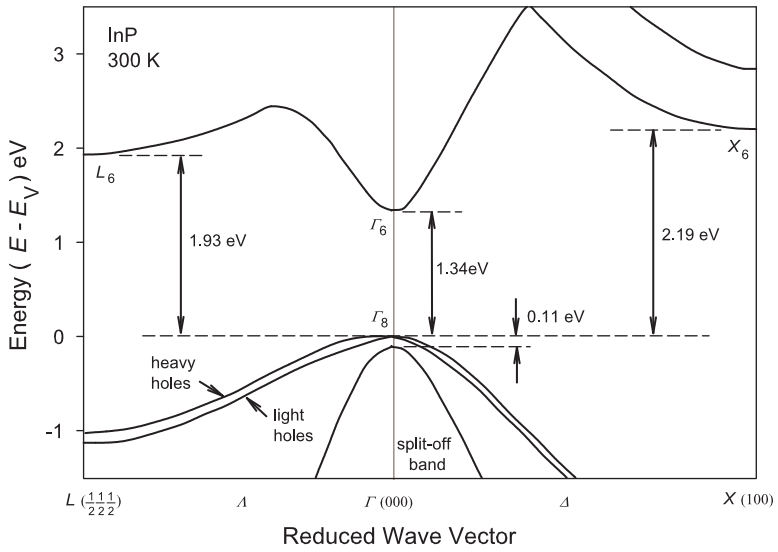

Figure 16.47. The theoretical energy bands of InP at 300 K calculated with a projector-augmented-wave (PAW) method. Data are from Y-S. Kim et al. [2009] and Ioffe [2016].

sustained, mainly because the reaction ^{115}In(n,γ)^{116}In transmutes into ^{116}Sn (14.1 s half-life) through β-particle emission, an n-type dopant for InP and, thus, ultimately reduces the material resistivity over time. Although the transient response of the detectors was shown to closely follow a short radiation impulse, they failed to follow the input power of longer duration pulse trains, in particular, square-pulse inputs from a laser, and instead showed a superlinear response function with elongated tails [Kania et al. 1986; Wagner et al. 1986]. Neutron irradiation damage failed to show improvement for this particular issue. Wagner et al. [1986] surmise that the superlinear behavior and observed failure to follow long pulse excitations was due to an imbalance of electron and hole trapping. Electrons are trapped more efficiently, leading to the slower moving holes carrying the majority of current. Consequently, steady state output is reached only when the electron and hole recombination and generation rates become balanced. This same effect diminishes as the radiation intensity increases. Although these InP:Fe detectors had excellent performance for transient responses, neutron damaged semi-insulating (SI) GaAs demonstrated faster response times without the superlinear problem for longer pulses. Consequently, investigation of high-speed InP radiation detectors diminished in favor of SI GaAs detectors.

InP was also investigated as a possible room temperature semiconductor detector for ionizing radiation and neutrinos [Lund et al. 1988; Olschner et al. 1989; Suzuki et al. 1989]. These initial investigations demonstrated that InP:Fe was sensitive to ionizing radiation, although the spectral performance was poor. The neutrino detection application is generally impractical because of the miniscule solar neutrino cross section [Raghaven 1976] and would require a rather sizeable InP detector as pointed out elsewhere [McGregor and Hermon 1997].[30] Regardless, this concept continues to be of interest [Fukuda et al. 2010]. As for detection of ionizing radiation, trapping and the non-optimal resistivity of SI InP leads to poor performance at room temperature. The charge carrier losses from trapping and the noise from excessive leakage current [El-Abassi et al. 2001] diminish the signal and cause resolution degradation. Owens et al. [2002a, 2002b]

[30] Raghaven [2001] states that a detector with a "modest 4 ton mass of In" would be required, amounting to approximately 1 cubic meter of InP.

reported improved results for small InP:Fe detectors (3 mm × 3 mm × 0.18 mm thick) used as x-ray detectors. By cooling the detectors to 213 K to reduce thermal leakage current, Owens et al. [2002a] achieved 2.5 keV FWHM for 5.9 keV-gamma rays (^{55}Fe) and 9.2 keV FWHM for 59.5-keV gamma rays (^{241}Am). By reducing the detector temperatures even lower to 103 K, Owens et al. [2003b] observed 911 eV FWHM for 5.9-keV gamma rays and 2.5 keV FWHM for 59.5-keV gamma rays.

From the work of Wagner et al. [1986], it was already observed that Fe compensation reduces the electron mean free drift times. From Section 12.5.4, it was shown that the concentration of deep acceptors must be greater than the concentration of shallow donors to produce semi-insulating material. Consequently, there is a lower concentration limit of Fe that must be introduced to maintain high resistivity and reasonably low leakage current. Gorodynskyy et al. [2005] and Yatskiv et al. [2009] proposed that Fe doping could be replaced with alternative co-dopants, such as Ti and Mn or Ti and Zn, and still maintain higher mobilities and improved charge carrier collection. This hypothesis seems to have merit, in that material produced by Gorodynskyy et al. [2005] was measured to have over 90% charge collection efficiency (CCE) for 200-micron-thick devices operated at 250 K with corresponding energy resolution of 3.4% FWHM for 5.48 MeV alpha particles. However, both CCE and energy resolution were compromised at room temperature (300 K), yielding a CCE of 52% and FWHM of 17% for 5.48 MeV alpha particles. Zdansky et al. [2006] report on results for small detectors fabricated from Ta-doped InP irradiated with α-particles, which produced energy resolution of about 6% FWHM at 5.48 MeV. Yatskiv et al. [2009] experimented with InP co-doped with Ti and Zn instead of Fe to achieve high resistivity material with superior CCE. By designing detectors with guard rings and cooling the detectors to 230 K to reduce leakage current noise, CCE up to 99.9% were achieved with a best energy resolution of 0.9% FWHM for 5.48 MeV α particles for 250-micron-thick detectors. The improved α-particle spectral results indicate material improvement, but remain an impractical application for InP, mainly because alpha particle backscattering is significantly less for Si detectors than InP detectors. Because of the relatively poor room temperature performance by comparison to alternative compound semiconductors, InP radiation detectors continue to be mainly experimental.

16.5.3 Detectors Based on Group II-VI Materials

Group II-VI semiconductors are produced from elements in group II and group VI of the periodic table. These materials include binary compounds such as CdTe and CdZnTe, perhaps the two most studied II-VI compounds for radiation detection. The relatively wide band-gap energies of CdTe and CdZnTe allow room temperature operation of these radiation detectors.

CdTe

Cadmium Telluride (CdTe) is a wide band-gap semiconductor of interest as a room-temperature operated gamma-ray spectrometer. CdTe has a cubic zincblende crystal structure. CdTe has a direct band-gap energy of about 1.52 eV, with an indirect L valley of 2.73 eV as shown in Fig. 16.48. A saturation velocity of approximately 1.5×10^7 cm s^{-1} is reached at an electric field of 1.5×10^4 V cm^{-1}, above which CdTe can also exhibit negative differential resistance much like GaAs and InP (see Fig. 16.6). The average ionization energy is 4.43 eV per e-h pair with a 0.11 Fano factor. The dielectric constant for CdTe is 10.36 [Strauss 1977]. The wide band gap produces an intrinsic resistivity of 10^9 Ω cm; however, because of the presence of contaminant impurities, high resistivities greater than 10^9 Ω cm are usually achieved through impurity and defect compensation. CdTe is relatively soft, rating 54 on the Knoop hardness scale (approximately 2.2 on Mohs scale). The elemental constituents have atomic numbers 48 and 52 and the density of CdTe is 5.86 g cm^{-3}. Because of the relatively high Z numbers, photoelectric absorption dominates up to approximately 260 keV. Charge carrier mobilities are 1050 cm^2 V^{-1} s^{-1} for electrons and 100 cm^2 V^{-1} s^{-1} for holes. Electron and hole mean free drift times are material dependent, but often quoted near 3 $\times 10^{-6}$ s and 2×10^{-6} s, respectively.

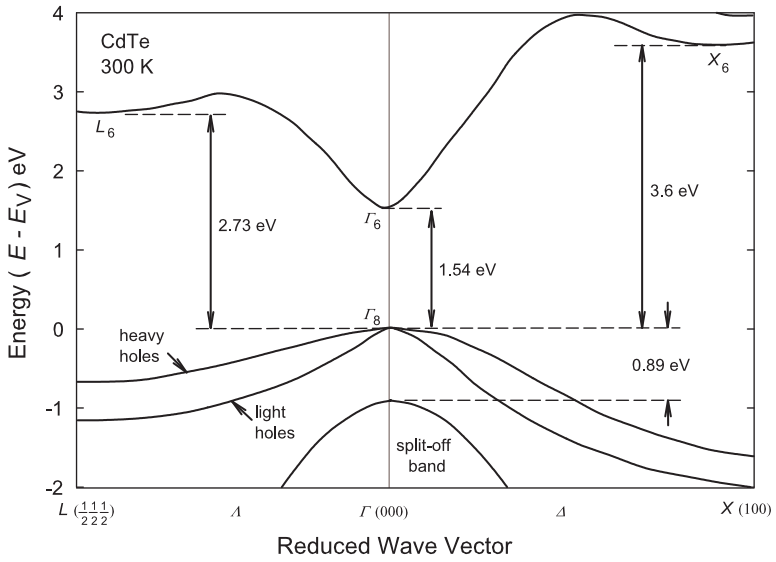

Figure 16.48. The theoretical energy bands of CdTe at 300 K calculated with a pseudopotential method. Data are from Chelikowsky and Cohen [1976].

CdTe has been investigated as a room-temperature gamma-ray detector since the mid-1960s [Autagawa et al. 1967; Mayer 1967; Vavilov et al. 1970; Zanio et al. 1970], and various detailed review articles and books cover CdTe material and detector performance [Whited and Schieber 1979; Kröger and de Nobel 1955; de Nobel 1959; Hage-Ali et al. 1995a, 1995b, 1995c; McGregor and Hermon 1997; Owens and Peacock 2004; Owens 2012]. Because of material imperfections, which include a combination of impurities and native defects, these devices continue to be manufactured as small detectors. Although the band gap is high enough for room temperature operation, background impurity contamination causes the leakage currents to be too high. Dopant compensation, typically with Cl, is used to create high resistivity material. Still the detectors must be manufactured as *pn* junction or Schottky junction diodes to reduce leakage current to manageable levels. As a result, the detector volumes are usually no more than a few millimeters thick. Commercial units are available as small gamma-ray spectrometers. Typically, the best energy resolution is achieved with the assistance of small electronic Peltier coolers.

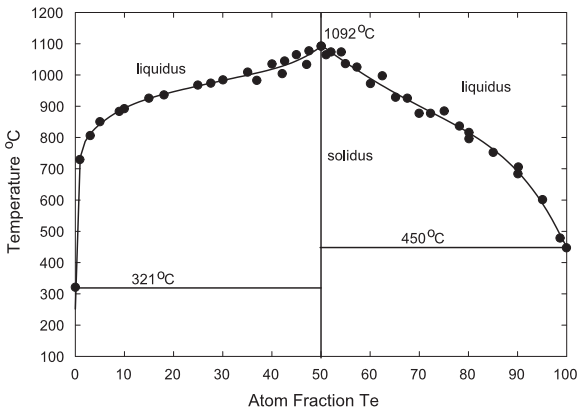

Figure 16.49. Temperature versus composition (T-x) diagram for the Cd-Te system. After Zanio [1978] and references thereof.

The melting point of CdTe is 1092°C and the crystal can be grown through melt-growth processes such as Bridgman and Stockbarger [Zanio 1978; Hage-Ali and Siffert 1995a; Lindstrom et al. 2016]. However, Te precipitates are a chemical consequence of CdTe growth, resultant from the retrograde solubility of tellurium [Zanio 1978]. The CdTe phase diagram shows that the melt temperature decreases dramatically off stochiometry, especially salient for Te-rich solutions (Fig. 16.49). Essentially, a higher concentration of Te can be suspended in a mixture of CdTe liquid and solid, which as the material solidifies into a CdTe crystal, the excess Te forms

precipitates in the solid. To reduce the effects of traditional high-temperature melt growth, the traveling heater method (THM) is commonly used for radiation detector materials. This method has slowly moving heating coils that travel upwards along a vertical sealed ampoule of Te-rich CdTe stock materials. The Te melts at a lower temperature (450°C) and acts as a solvent for the CdTe stock material. Consequently, the CdTe stock dissolves at the hotter leading edge of the melt solution and crystallizes at the cooler trailing edge, much like liquid phase epitaxy. The advantages include a lower process temperature (typically below 900°C), lower Te precipitate concentrations, and lower defect and impurity concentrations. However, THM is a much slower crystal growth method than alternatives, such as high-pressure Bridgman or Stockbarger growth. CdTe grown by THM is usually doped with Cl, by adding $CdCl_2$ to the stock material, which compensates native defects and impurities to produce material with high resistivities of about 10^9 Ω cm.

Ohmic contacts are usually formed with an electroless process, in which noble metal salt solutions of $AuCl_3$, $AgNO_3$ or $PrCl_4$ are applied to a polished and etched surface.[31] The noble metal salt solution etches the CdTe surface and displaces Cd from the surface region while redepositing layers of both the noble metal and Cl [Hage-Ali and Siffert 1995b]. The Cl incorporation can extend beyond 0.5 microns into the surface [McGregor and Hermon 1997]. Calculations show that ohmic contacts are inadequate to reduce leakage currents below the induction current produced by radiation events except for small detectors. Unfortunately, although the resistivity is relatively high, it is still too low to operate CdTe as resistive devices, and instead must either be fabricated with rectifying blocking contacts or small enough such that leakage current is minimal. To reduce leakage current while allowing high operating voltages, detectors have been produced as Schottky junction devices and ion implanted *pn* and *pin* devices [Cornet et al. 1970, 1972], indium diffusion (on p-type material) [Squillante et al. 1989], and LPE growth [Shin et al. 1985].

Although the incorporation of a blocking contact permits higher bias voltages and generally reduced leakage current, the performance of these spectrometers varied. The rectifying junction causes an imbalance in the compensation such that deep level ionization produces space charge that ultimately limits the depletion region depth [Khusainov 1992]. Depletion studies on SI CdTe indicate the presence of non-uniform electric fields within reverse biased diodes [Malm at al. 1974; Siffert et al. 1978a, 1978b; Hage-Ali et al. 1993]. In some cases, the electric field did not extend completely across the device until appreciable voltage was applied, indicating the build-up of a space charge region much like the situation depicted in Fig. 16.46. Polarization is often observed with Cl compensated CdTe, manifested as a gradual change in gamma-ray sensitivity and relative pulse height [Siffert 1978a]. Low resistivity CdTe detectors usually suffer less polarization than high-resistivity detectors, and the problem of polarization can be reduced by using In-doped or low resistivity CdTe [Whited and Schieber 1979]. Illumination with IR light [Bell et al. 1974] and alternative conductive contacts have apparently also helped reduce polarization [Bell and Wald 1972; Puschert et al. 1976]. Takahashi et al. [2002] report on a 2 mm × 2 mm × 1 mm thick CdTe Schottky diode with Pt contacts. In that study, the CdTe detector had minimal polarization and yielded RT energy resolution of approximately 2.3 keV FWHM for 59.5-keV gamma rays, decreasing to 810 eV FWHM at 248 K.

CdTe detectors generally suffer from poor hole collection. Consequently, CdTe detectors are usually small in size, yet the small size also serves to reduce generation current. Regardless, the literature is replete with examples of excellent room-temperature gamma-ray energy resolution for small devices, usually about 1 to 2 mm thick (see references in [McGregor and Hermon 1997]). Methods to compensate the poor hole collection problem include single-carrier geometries and electronic correction methods. Hemispherical detector designs (see Sec. 12.5.2) were explored as room-temperature detectors with good results [Zanio 1977; Siffert 1994; Alt et al. 1994; Hage-Ali et al. 1995c], resulting in energy resolution of 26 keV FWHM for 662-keV gamma rays

[31] Electroless plating is an auto-catalytic chemical reaction process applied to a surface and does not require the application of a voltage. The chemical reaction displaces surface ions and causes the deposition of the metal component onto the surface. De Nobel [1959] provides a description of metal plating processes used on CdTe.

Table 16.9. Typical gamma-ray energy resolutions of a few representative commercial CdTe and CdZnTe semiconductor detectors. Many other sizes are offered by the different vendors.

detector	area (mm^2)	energy (keV)	FWHM (keV)	comments	source*
CdTe	9	122	$\leq$1.2	Peltier cooled	A
Schottky	25	122	$\leq$1.5	Peltier cooled	
CdZnTe	$\approx$ 100	122	$\leq$6.1	room temp	K
hemisphere	$\approx$ 100	662	$\leq$20	room temp	B,K
CdZnTe	100	662	13.2–26.4	room temp	K
coplanar	225	662	16.5–26.4	room temp	

*A = AmpTek, B = Baltic Scientific, K = Kromek.

with a 65 mm^3 active volume. Pulse height discrimination (PHD) methods [Jones and Woollam 1975], in which short pulse heights are eliminated from spectra, help to reduce spectral distortion from hole trapping. These electronic methods have yielded 7.5 keV FWHM at RT for 662-keV gamma rays for a 5 mm $\times$ 5 mm $\times$ 2 mm thick CdTe detector [Richter and Siffert 1992; Richter et al. 1993]. Unfortunately, PHD is a method that electronically eliminates a sizeable volume of the detector, ultimately reducing the detection efficiency. The method of pulse height correction (PHC) (charge loss compensation) improves energy resolution while preserving detection efficiency (see Sec. 15.5.2), where the slope of the pulse rise with respect to time is used to project the expected true pulse height [Richter and Siffert 1993; Richter et al. 1993, 1993; Eisen and Horovitz 1994]. Energy resolution of 6.1 keV FWHM and 6.4 keV FWHM for 122-keV and 356-keV gamma rays, respectively, were achieved by Eisen and Horowitz [1994] with this method. The energy resolution of commercially available detectors are presented in Table 16.9.

With the relatively good energy resolution of CdTe detectors, they have been demonstrated as detectors for slow neutrons [Vradii et al. 1977]. The strong neutron absorption cross section of Cd below 0.5 eV (σ_{th} of ^{113}Cd = 20,000 b) produces prompt gamma-ray emissions, which can be subsequently detected by the CdTe detector. Unfortunately, the gamma-ray capture efficiency is low, and the actual neutron detection efficiency is relatively poor. This type of neutron detector is presented with more detail in Chapter 17.

CdTe detectors are commercially available and have been used for various unique applications for which small room-temperature gamma-ray spectrometers are best applied. These applications include medical instruments, heat shield ablation sensors, nuclear power station activity monitors, nuclear fuel probes, capillary electrophoresis detectors, narcotics and explosive scanners, portable dosimeters, ammunition cartridge control monitors, and various x-ray and gamma-ray imaging devices [see references in McGregor and Hermon 1997]. Small CdTe detectors (5 mm $\times$ 5 mm $\times$ 1 mm thick), coupled to Peltier coolers having excellent energy resolution, of about 850 eV at 122 keV, are commercially available [Amptek 2017]. The operating voltage is nominally 500 volts for these thin devices, thereby requiring cooling below 263 K to reduce the leakage current to manageable levels.

$Cd_{1-x}Zn_xTe$

The introduction of Zn in the growth process of CdTe, nominally between 2% to 15%, has led to the production of CdZnTe detectors.[32] Overall, CdZnTe detectors have the same advantages as CdTe detectors with several added benefits. By adding a small amount of ZnTe to the melt, many important semiconductor

[32] This particular semiconductor is denoted CZT (common), (Cd,Zn)Te (less common), $Cd_{1-x}Zn_xTe$, or CdZnTe. By adhering to traditional elemental symbols, and because of the many different elemental combinations in use for substrates and detectors, the authors choose to use CdZnTe.

properties are drastically improved. The band gap of CdZnTe increases with Zn concentration, with band-gap energy of $Cd_{1-x}Zn_xTe$ at 300 K is well approximated by [Olego et al. 1985]

$$E_g(x) \text{ eV} = (1.51 \pm 0.005) + (0.606 \pm 0.01)x + (0.139 \pm 0.01)x^2 \text{ eV}. \tag{16.87}$$

The band gap ranges from 1.52 to 1.64 eV for Zn contents ranging from $x = 0.02$ to $x = 0.2$; hence the detectors can operate at room temperature without serious leakage current concerns. With an increased band-gap energy, the intrinsic free carrier concentration diminishes, thereby increasing the resistivity while reducing detector leakage current. Butler et al. [1992] report that adding $x = 0.2$ amount of Zn changes the resistivity of CdTe from 3×10^9 Ω cm to 2.5×10^{11} Ω cm for $Cd_{0.8}Zn_{0.2}Te$. The dielectric constant is approximately 10.6 for CdZnTe, although this property is also a function of the Zn concentration. The addition of Zn increases the hardness of CdZnTe over CdTe and decreases the dislocation density [Anand 2013]. The etch pit density (EPD) is a measure of the dislocation defect density. Butler et al. [1993] show a marked reduction in the EPD as the Zn content was increased, with the densities of 1.5×10^5 cm^{-2}, 10^4 cm^{-2}, and 5×10^3 cm^{-2} for Zn contents of 0, 0.04, and 0.2, respectively. Further, CdZnTe detectors do not exhibit the polarization phenomenon at low irradiation levels, which are often observed with CdTe detectors. However, Wang et al. [2013] report the observation of polarization from CdZnTe detectors under high irradiation conditions. An additional benefit of incorporating Zn is that CdZnTe devices, because of the increased band gap and resistivity, can be operated at higher temperatures than CdTe devices, and they can also resolve lower energy photon energies (x rays and gamma rays) traditionally difficult to observe with CdTe detectors. CdZnTe detectors are presently used in handheld gamma-ray spectrometers and for smaller medical imaging apparatuses.

The gamma-ray absorption efficiency of CdZnTe is similar to that of CdTe, with a slight decrease in absorption efficiency with increased concentrations of Zn ($Z = 30$). The ionization energy is approximately 5 eV per e-h pair, although this number changes as a function of band-gap energy. The Fano factor of CdZnTe has been measured to be approximately 0.11 [Bale et al. 1999] at 233 K, with at least one research group [Redus et al. 1997] reporting a lower Fano factor of 0.089 also at 233 K.

Many of the same growth problems with CdTe are also experienced with CdZnTe, including the retrograde Te solubility. Further, the Zn component has a segregation coefficient larger than unity (about 1.3 at 1100°C) and can behave as a migrating impurity during growth, much like a zone-refinement pass [James et al. 1995]. In fact, CdZnTe behaves more like an alloy of CdTe and ZnTe [Owens 2012]. Consequently, there is a Zn concentration gradient through the crystal ingot that causes a change in the band gap over the length of the crystal ingot. This gradient appears to be more salient for relatively short ingots over that of long ingots. Usually, about 2 to 3 cm of material at both ends of the ingot are removed and discarded, and the remainder is used for detector fabrication. The Zn concentration gradient adversely affects the ionization energy by increasing the variance in the number of charge carriers excited per unit energy. Consequently, detectors with a relatively large variance in Zn concentration experience a broadening in spectroscopic energy resolution. Further, detector shot noise increases with the variance in leakage current, also a consequence of non-uniform Zn concentration.

CdZnTe substrates were originally developed as low defect substrates with less lattice mismatch for epitaxial growth of HgCdTe [Bell and Sen 1985; Sen and Stannard 1993], a shallow band-gap semiconductor used for IR detectors. Variations of Bridgman growth were initially used to grow bulk CdZnTe crystals, as outlined in James et al. [1995]. However, it was the high pressure method introduced by Raiskin and Butler [1988] that yielded the material used for the first reported CdZnTe radiation detectors [Butler et al. 1992; Doty et al. 1992a, 1992b]. For many years, high-pressure (HP) Bridgman growth, pressured with Ar to about 100 atm, was used to produce high-resistivity CdZnTe radiation detectors. CdZnTe material was grown on the Te rich side of the phase diagram, and as the crystal cooled and solidified in the growth process, Te precipitates would decorate the grain boundaries in the ingot. Single crystal pieces with low precipitate and

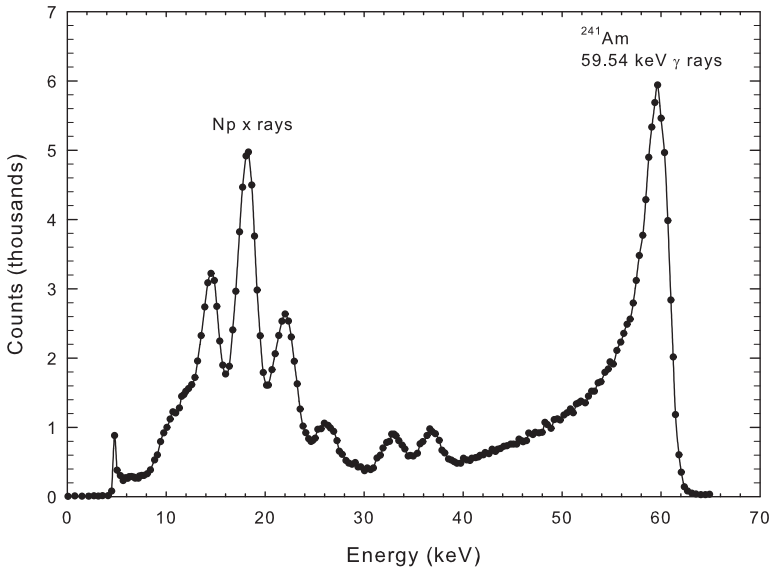

Figure 16.50. Typical spectrum of 59.54-keV gamma rays from ^{241}Am taken with a planar CdZnTe detector. The detector dimensions were 5 mm × 5 mm × 1.2 mm with a bias of 300 volts. Data from Butler et al. [1993].

defect concentrations were "mined" from the CdZnTe ingots, and these pieces were fabricated into detectors. Unfortunately, large defect-free pieces were rare, thereby limiting the useful detector sizes. Due to problems with twinning and the formation of Te precipitates, the useful detector yield with HP Bridgman growth was poor. Much like CdTe, the traveling heater method is now the preferred growth method for CdZnTe. CdZnTe can be grown with the THM at lower temperatures (less than 800°C). This low temperature growth reduces the defect concentration, reduces the precipitate concentration, and also reduces Zn segregation. Although the growth rate is intrinsically limited by the THM method [Peterson et al. 2016], the resultant product is generally of higher quality than that of HB Bridgman grown material [Roy 2013]. Post-growth annealing helps to reduce further the size and concentration of Te precipitates.

Large high-resistivity single crystal CdZnTe ingots are now produced commercially for radiation detectors [Chen et al. 2007, 2008]. Because of the high resistivity, usually greater than 10^{10} Ω cm, CdZnTe detectors are manufactured with ohmic contacts instead of blocking contacts and operated as resistive detectors. Electrical contacts are usually fabricated with electroless $AuCl_3$, although sputtered Pt contacts have shown good results.

Planar detectors fabricated from CdZnTe typically have long pulse height spectrum tails (Fig. 16.50), a consequence of severe hole trapping as described in Section 15.5.1. The severity of the effect increases with the detector width and gamma-ray energy. Because electron transport is superior to hole transport, CdZnTe detectors are invariably designed for cathode irradiation, thereby taking some advantage of the increased gamma-ray absorption nearest the cathode, although the effect diminishes with increasing gamma-ray energy, as shown in Fig. 16.51.

Most planar CdZnTe detectors are less than 3 mm thick so as to increase the values of ϱ_e and ϱ_h. Yet the poor hole transport properties still produce relatively poor energy resolution for penetrating high-energy gamma rays. Owens et al. [2002c] show that energy resolution for low-energy gamma rays can be improved by reducing the detector operating temperature, optimized near 253 K for 59.5 keV gamma rays (see Fig. 16.52).

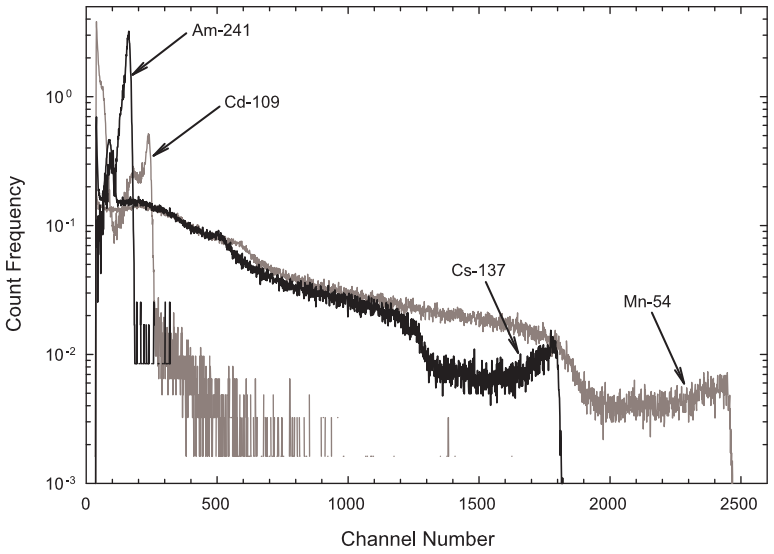

Figure 16.51. Comparison spectra taken with a 1 cm × 1 cm area × 2 mm thick CdZnTe detector irradiated on the cathode side with several monoenergetic gamma-ray sources. Charge carrier trapping effects increase with gamma-ray energy, causing the tailing effect to become more important.

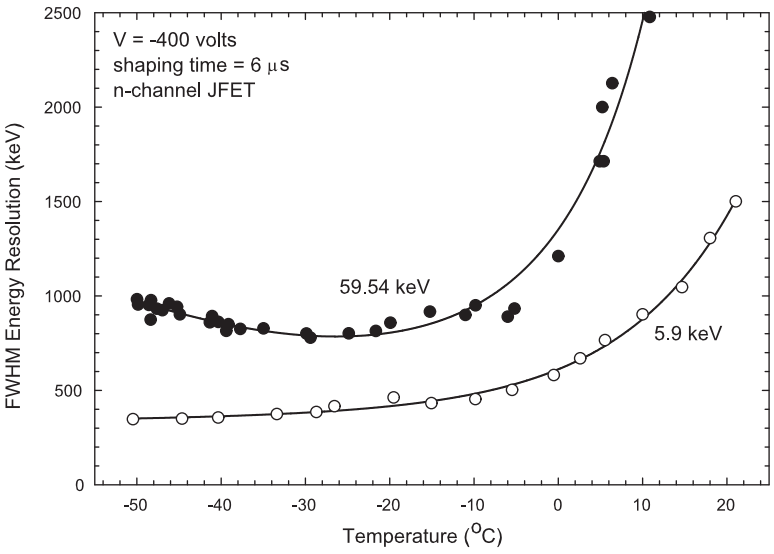

Figure 16.52. The energy resolution temperature dependence of a CdZnTe detector for 5.9-keV and 59.54-keV gamma rays. The detector was 2.5 mm thick by 3.2 mm^2 area. Data are from Owens et al. [2002c].

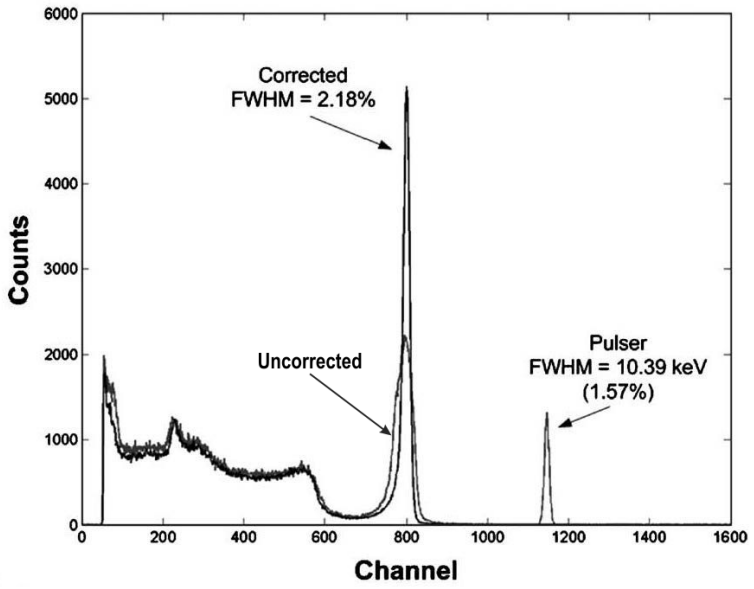

Figure 16.53. Energy resolution of a 1.5 cm × 1.5 cm × 1 cm thick CdZnTe coplanar grid detector, showing the results with and without electronic depth correction. From He and Sturm [2005]; copyright Elsevier (2005), reproduced with permission.

Several methods have been introduced to improve energy resolution and efficiency [see review by Zhang et al. 2013], a few of which are described here. CdZnTe detectors have adequate electron transport properties, but poor hole transport properties due to the combined effects of short hole mean free drift times and low hole mobility. As a result, conventional planar detectors seldom produce useful energy resolution for moderate to high energy gamma rays (greater than 300 keV). Instead, clever geometric detector shapes and electrode contact shapes are used to modify the weighting potential and electronic signal so that electrons dominate signal formation rather than holes. Energy resolution below 7 keV FWHM for 662-keV gamma rays can be achieved at room temperature for these *single carrier* detector designs. Further, electronic correction methods are often applied to improve the spectral performance of CdZnTe.

Luke [1994, 1995] introduced the co-planar grid (CPG) CdZnTe detector, described in Sec. 15.5.2, as a method to remedy poor hole transport. These initial detectors demonstrated superior energy resolution at 662 keV of 24.5 keV FWHM.[33] He et al. [1997] used position sensing to improve the energy resolution with charge compensation methods. He et al. [1998] also demonstrated that an optimized and balanced grid, including a boundary electrode, on a CPG device yielded superior results, and the use of a balanced grid is now routine for CPG CdZnTe detectors. He and Sturm [2005] combined the balanced coplanar design with rise time compensation to achieve room temperature energy resolution of 14.4 keV FWHM at 662 keV for a 15 mm × 15 mm × 10 mm thick device as shown in Fig. 16.53. Owens et al. [2006] also reported similar results, but without electronic correction methods, reporting room temperature energy resolution of about 12 keV FWHM at 662 keV.

[33] Because CdZnTe detector volumes are relatively small by comparison to most HPGe detectors, the 662 keV gamma-ray emission from ^{137}Cs is generally used to report energy resolution rather than the traditional 1332-keV gamma-ray emission from ^{60}Co.

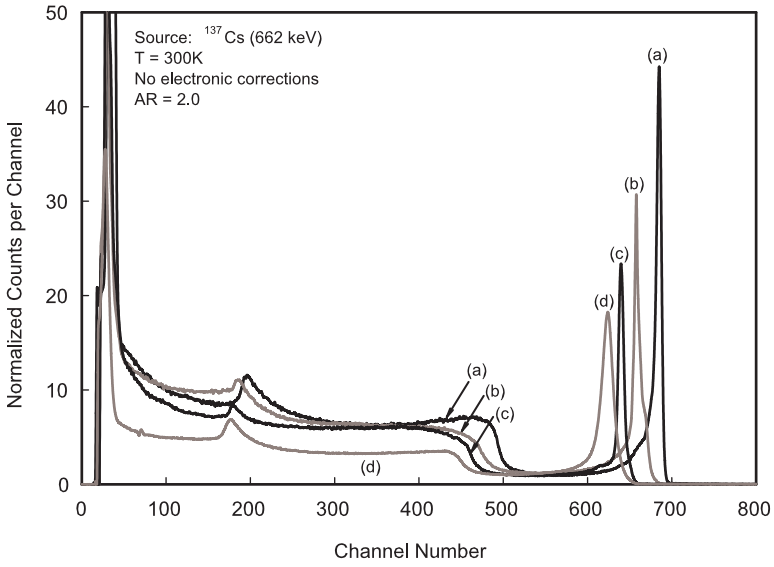

Figure 16.54. Spectroscopic results from ^{137}Cs for several Frisch collar CdZnTe detectors, each having a 2:1 aspect ration. The sizes and FWHM resolutions are (a) 0.9% for a 4.7 mm × 4.7 mm × 9.5 mm device, (b) 1.1% for a 6.5 mm × 6.5 mm × 13 mm device, (c) 1.2% for a 7.8 mm × 7.8 mm × 15.6 mm device, and (d) 2.4% for a 11 mm × 11 mm × 22 mm device. From Dunn and McGregor [2012].

Quasi-hemispherical CdZnTe detectors were introduced by Butler [Apotovsky et al. 1997; Butler 1997], and were commercially available for a short time. These detectors were three terminal devices formed on a parallelepiped CdZnTe block. The detector had a small anode on one surface, and planar cathode on the opposing surface, and a "control" electrode surrounding the anode [Lingren et al. 1998]. These detectors performed well, but were usually small. Energy resolution of 3.68 keV FWHM at 511 keV was reported for a 3 mm × 3 mm × 3 mm device [Butler 1997].[34] Parnham et al. [2000] report the development of a quasi-hemispherical CdZnTe fabricated on a parallelepiped block, on which a top surface has an electrical contact and the bottom half (approximately) of the remaining five sides of the devices were coated with an electrical contact. The design worked to improve the energy resolution above that expected from a planar device, and yielded room temperature (23°C) energy resolution of 10.4 keV at 662 keV for a 10 mm × 10 mm × 5 mm thick device [Bale and Szeles 2006; Szeles et al. 2006].[35] Related to the quasi-hemispherical CdZnTe detector is the ring-drift design [Owens et al. 2007; Alruhalli et al. 2015]. These devices have additional concentric rings around a central anode instead of the single control electrode described by Butler [1997]. These additional electrode rings enable improved steering of electrons to the anode and help to reduce low electric field regions present in the Butler [1997] design. Owens et al. [2007] report 4.85 keV FWHM at 662 keV for a 5 mm × 5 mm × 1 mm thick ring-drift CdZnTe detector.

Various quasi-Frisch grid designs were reported by McGregor, including the parallel strip design [McGregor et al. 1998a; McGregor and Rojeski 1998b], the geometrically weighted design [McGregor et al. 1999a; McGregor et al. 1999b], the Frisch ring design [McGregor and Rojeski 2001; McGregor 2004], and the Frisch collar design [McGregor and Rojeski 2001; Montemont et al. 2001; McGregor 2004; McNeil et al. 2004]. All of these detector designs use an external electrode to alter the weighting potential to enhance the contribu-

[34] These devices were commercially available for a short while from Digirad.
[35] Named CAPture^{TM} Plus detectors, these devices were commercially available for a short time from eV Products.

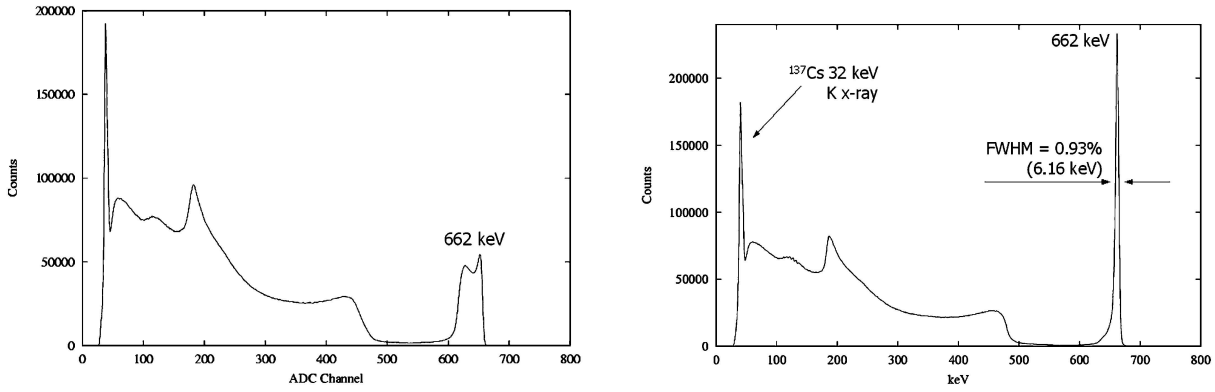

Figure 16.55. Room temperature spectrum of ^{137}Cs acquired with a CdZnTe pixelated detector (left) without depth correction and (right) with depth correction. All pixels are summed for both spectra. Bias conditions were -2200 volts on the cathode and -65 volts on the grid isolating the pixels. ©[2005] IEEE. tion of electron transport to the spectral output. The geometrically weighted Frisch Grid detector combines orientation, geometrical shape (either a trapezoid or pyramid frustum), the small pixel effect, and the charge induction isolation of the Frisch grid to produce enhanced energy resolution. These detectors were capable of delivering room temperature energy resolution of 17.2 keV FWHM at 662 keV for a 1 cm^3 device without electronic corrections [McGregor et al. 1999b]. However, these designs proved difficult to fabricate and led to simpler permutations, denoted either as Frisch ring or Frisch collar detectors [Kargar et al. 2011a, 2011b; Harrison 2009] and the basic distinction between the two is described in Sec. 15.5.2. Without electronic corrections, the Frisch collar design has delivered room temperature energy resolution of 5.9 keV FWHM at 662 keV for a 4.7 mm × 4.7 mm × 9.5 mm device, with comparable energy resolution for larger geometries (see Fig. 16.54).

CdZnTe has been investigated for medical imaging instrumentation, for which a block of CdZnTe is patterned with an array of small electrical contacts called pixels. Doty et al. [1994] report on the first monolithic CdZnTe pixelated device designed for medical imaging purposes. These CdZnTe pixel arrays were fabricated by traditional VLSI methods. This work led to the discovery of the "small pixel effect" [Barrett et al. 1995], described in Sec. 15.5.2, and is commonly used to enhance the energy resolution for gamma-ray spectrometers. CdZnTe pixel devices were successfully used for gamma-ray imaging (examples include Polichar et al. [1994, 1996], and Barber et al. [1997]). This technology has also proved important for gamma-ray spectroscopy [He et al. 1999, 2000; Zhang et al 2005]. He et al. [2000] combined CdZnTe pixel detectors with electronic energy-resolution correction methods to enhance the performance of pixelated detector arrays (see example in Fig. 16.55). Room temperature energy resolution of 6.16 keV FWHM at 662 keV was achieved with large (1.5 cm × 1.5 cm × 1 cm thick) CdZnTe pixelated detectors [Zhang et al. 2005]. With Compton scatter backprojection methods, these devices can be used to determine the gamma-ray energy and the general source direction by producing a near 360° image of radiation source locations and include the perceived intensity [Boucher et al. 2012; Wahl et al. 2015]. After many years of development, these devices are now commercially available.[36]

[36] H3D, Inc.

16.5.4 Detectors Based on Halide Compounds

The halogen semiconductors are produced from materials with at least one constituent atom from group VII of the periodic table. These materials include compounds such as HgI_2, PbI_2, and TlBr. Select materials have wide band-gap energies and can be operated at room and elevated temperatures.

Mercuric Iodide (HgI_2)

Attractive for its large Z components, mercuric iodide (HgI_2) has long been studied as a gamma-ray spectrometer with varying degrees of success [Willig 1971, 1972; Malm 1972; Swierkowsky et al. 1973; Llacer et al. 1974; Ponpon et al. 1975]. HgI_2 has atomic numbers of 80 and 53 with a volume density of 6.4 g cm^{-3}. The α-phase (red) of HgI_2 has measured charge carrier mobilities of 100 $cm^2\ V^{-1}s^{-1}$ for electrons and 4 $cm^2\ V^{-1}s^{-1}$ for holes [Ponpon et al. 1975]. Thus a substantial voltage is required to ensure acceptably high charge carrier collection. HgI_2 has a measured average ionization energy of 4.42 eV per e-h pair with a Fano factor of 0.19 [Ricker et al. 1982]. Because of the large atomic number of mercury (80), the photoelectric effect is predominant for gamma-ray energies below 400 keV (see Fig. 16.1). As a result, HgI_2 detectors can be relatively thinner than other common semiconductors and still have comparable efficiencies. For example, the absorption efficiency for 140-keV gamma rays in a 2-mm-thick HgI_2 detector is similar to 4.2-mm-thick CdTe or CdZnTe detectors and 1.9-cm-thick Ge or GaAs detectors [McGregor and Hermon 1997]. The α-phase of HgI_2 has a band-gap energy of 2.13 eV and has a resistivity of about $10^{13}\ \Omega$ cm.

The melting point of HgI_2 is 259°C, but it also has a relatively low vapor pressure and can be sublimed at lower temperatures if processed in a vacuum. HgI_2 has numerous polymorphs that can form during crystal growth, most of which are metastable tetragonal structures [Hostettler et al. 2001, 2003, 2005]. The two most important polymorphs are the preferred α-phase tetragonal crystals (red) formed and stable at temperatures below 130°C and the β-phase monoclinic crystals (yellow) that form above 130°C. Growing β-phase HgI_2 crystals and subsequently cooling them below 130°C causes a destructive change in the crystals because they can form any number of metastable crystals or polycrystalline α-phase crystals [Newkirk 1956; Hostettler et al. 2003]. Moreover, with a melting point of 259°C, which is higher than the phase change temperature, a suitable method to grow detector-quality HgI_2 that maintains a growth region below 130°C is required.

Solution growth methods were first used to grow large HgI_2 crystals for radiation detectors [Willig 1971], and optically clear crystals have been produced with saturated solutions ranging in temperature between 25°C and 40°C [Mellet and Friant 1989; Nicolau and Joly 1980; Friant et al. 1980]. Unfortunately, detector performance of these solution grown crystals is compromised by impurity contamination introduced from the solvent suspension. Because of the improved crystalline quality and the reduction in impurity contamination, HgI_2 vapor growth methods are preferred [McGregor and Hermon 1997]. There are two main methods of vapor growth, referred to here as the vertical method, initially introduced by Scholz [1974], and the horizontal method, initially introduced by Schieber et al. [1976].

The vertical method has a relatively large ampoule, typically ranging in diameter between 10 cm to 15 cm and 15 cm high. The bottom of the ampoule has a raised pedestal approximately 3 cm in diameter that sits atop a temperature controlled cooler region, usually a cold finger or an air jet. The ampoule is either rotated within a heating coil [Scholz 1974; Schieber et al. 1976] or has a heating framework surrounding a stationary ampoule [Hermon et al. 1992]. There are three main elements to control the thermal profile consisting of a controlled cool region under the pedestal, a base heating element around the pedestal, and an axial heating element. The temperature around and under the ampoule is controlled such that a thermal gradient nucleates a seed crystal on the pedestal. The process takes several weeks to produce a single crystal between 250 g to 1000 g.

Schieber et al. [1976] describe an alternate method to growth HgI_2 in an evacuated horizontal ampoule of 5 to 10 cm diameter and 40 cm long. After loading with purified HgI_2 materials, ampoules are inserted into a two-zone furnace with a crystal formation zone held near 103°C and other source zone varied between

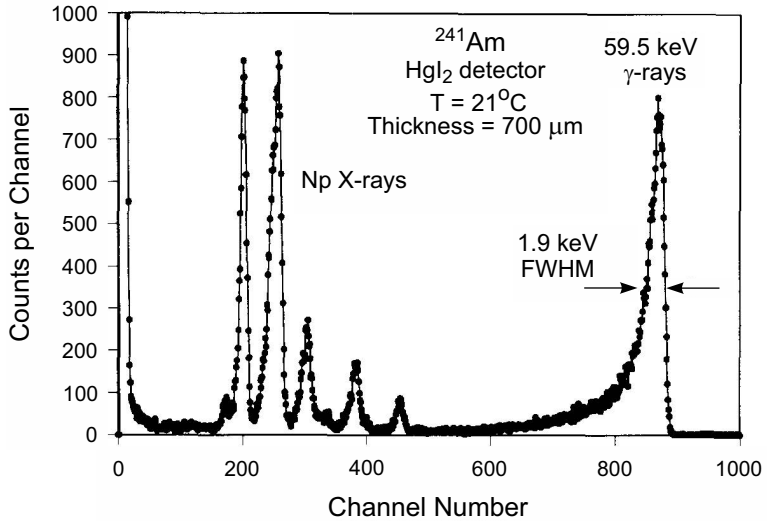

Figure 16.56. Room temperature differential pulse height spectrum from a 700-micron-thick HgI_2 detector. From McGregor and Hermon [1997]; copyright Elsevier (1997), reproduced with permission.

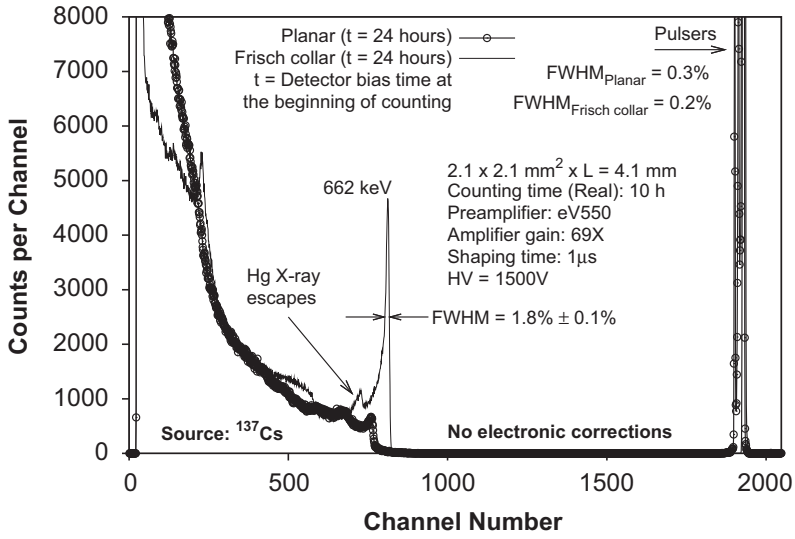

Figure 16.57. Pulse height spectra taken with a 2.1 × 2.1 × 4.1 mm^3 HgI_2 device with and without a Frisch collar. A 1.8% FWHM energy resolution was measured with 662-keV gamma rays from ^{137}Cs when using the Frisch collar. From Ariesanti et al. [2010]; copyright Elsevier (2010), reproduced with permission.

97°C to 110°C. The source zone temperature is raised to nucleate a crystal, or is lowered to etch away poorly formed samples. When one or more good crystals are nucleated, temperature in the source zone is no longer varied and is held at a temperature above 103°C to continue the growth of the HgI_2 singles crystals. The process dynamics prevent the growth of crystals larger than approximately 30 g without twinning. Faile et al. [1980] (also Faile [1981]) simplified the horizontal method by introducing purified HgI_2 into an evacuated growth ampoule approximately 2 to 4 cm diameter and 40 cm long along with low density polyethylene. This ampoule was inserted into a two-zone furnace with the temperature held at 120°C in the source zone and 100°C in the nucleation zone. Several "chance" crystals nucleated and grew near the middle of the ampoule. The size of these crystals ranged from about a few mm^3 to a cm^3 in volume and many appeared as single crystals with better physical and electronic performance than those produced without the addition of polyethylene.

Faile proposed several hypotheses about how polyethylene aided the growth of HgI_2 crystals that included impurity capturing, ampoule surface priming, free radicals or hydrogen reacting with crystal defects, and polymers alloying with HgI_2, to name a few [Faile et al. 1980]. However, none of these hypotheses could explain the observed results. McGregor and Ariesanti [2013] found that the function of low molecular weight polyethylene is to be a source of polar organic ketone molecules, impurities present in low molecular weight HDPE from the manufacturing process.[37] These aromatic ketones attach to the HgI_2 surfaces by weak Van der Waals bonds and inhibit growth on the {110} faces. When tested with purified ketones instead of polyethylene, such as 3-hexadecanone or 14-heptacosanone, improved results were observed and near perfect spectroscopic-grade tetragonal prismatic crystals were produced [Ariesanti and McGregor 2017]. Still the resulting crystals are only a few mm^3 to 1 cm^3 in volume.

HgI_2 detectors have fewer commercial applications than CdTe or CdZnTe detectors, mainly because of process and fabrication issues. Slicing and sectioning of a layered crystal like HgI_2 is difficult, often leading to delamination and mechanical damage. To reduce damage, sectioning is often performed with a chemical string saw, usually soaked with KI solution. A KI solution etch is usually used to remove surface damage after the crystal is reduced to the proper size and shape. HgI_2 is also highly reactive and only a few materials are known to be compatible for electrical contacts, those being carbon (Aquadag®), Pd, and Pt. HgI_2 detectors are usually encapsulated with parylene to prevent decomposition over time. Also, the material is known to *polarize* and is manifested as a gradual change in spectral features over time.

HgI_2 detectors are mostly fabricated as planar detectors, but because of the relatively low hole mobility, significant hole trapping can occur for thick detectors. Such an effect is shown by the lower energy tail in the spectrum of Fig. 16.56. Alternative detector designs with weighting potentials emphasizing electron charge induction have improved energy resolution, with some success realized with pixelated imaging detectors [Patt et al. 1995, 1996, 1997; Zhu et al. 2007]. The Frisch collar design has also been used with good results (see Fig. 16.57), evidently showing no signs of polarization [Ariesanti et al. 2010, 2011]. During the 1980s, HgI_2 was also explored as the photodetector for scintillators having relatively longer wavelengths [Markakis 1988a, 1988b]. Unfortunately, gamma-ray events were also directly detected in the HgI_2 photodetector, which added to the background. This effect was reduced by limiting the thickness of HgI_2 photodetectors to only 2 mm. One such device, when coupled to a 2.54-cm diameter × 2.54-cm-thick block of CsI:Tl, yielded room-temperature energy resolution of 5% FWHM at 662 keV [Markakis 1988b]. A modestly successful application of HgI_2 was as x-ray spectrometers for analysis of lead paint [Wang et al. 1993], and was offered

[37] Crystal improvement is observed only with low molecular weight polyethylene. Addition of high-purity spectroscopic grade polyethylene or HDPE does not produce any observed change in the crystal quality.

commercially for many years.[38] These small detectors proved efficient for low energy gamma rays and x rays and had excellent room temperature energy resolution (see Fig. 16.56, for example). Individual HgI_2 detectors have been offered as commercial units from time to time, but presently are relatively difficult to acquire.

Thallium Bromide (TlBr)

Thallium bromide (TlBr) is a wide band-gap semiconductor that is also of interest as a room-temperature gamma-ray spectrometer. TlBr is a yellowish-green transparent crystal with a 2.68 eV indirect band-gap energy. The crystal forms as a body centered cubic[39] with a density of 7.56 g cm^{-1}. The high Z components ($Z = 81/35$) make it especially attractive for gamma-ray detection. TlBr has an average ionization energy of 6.5 eV per e-h pair, relatively large by comparison to other semiconductors used for radiation detection. With $\epsilon_s/\epsilon_0 = 29.8$, the dielectric constant is also high by comparison to most semiconductors. Consequently, the high dielectric constant increases detector capacitance, and combined with the higher ionization energy reduces the output voltage signal by comparison to traditional semiconductors (such as Si or Ge) of similar dimensions. With such a wide band gap, the expected intrinsic resistivity is about 10^{12} Ω cm, although, in practice, TlBr usually has resistivities between 10^{10} and 10^{11} Ω cm. The electron mobility is only 6 cm^2 V^{-1} s^{-1}. Mean free drift times vary with crystal quality, and electron $\mu\tau$ products as high as 6.5×10^{-3} cm^2 V^{-1} s^{-1} along with the hole $\mu\tau$ products of 4×10^{-4} cm^2 V^{-1} s^{-1} have been reported for highly purified material [Shorohov et al. 2009b; Churilov et al. 2010; Kim et al. 2011; Dönmez et al. 2012] and indicates that high quality TlBr has relatively long charge carrier mean free drift times. Although these $\mu\tau$ values allow relatively efficient charge carrier collection, the low charge carrier mobilities require longer electronic shaping times to reduce the ballistic deficit. TlBr has a melting point of 460°C, making it attractive for traditional melt growth. Several melt growth techniques have been successfully used to produce quality TlBr ingots [for example, Gostilo et al. 2003; Kozlov et al. 2004; Hitomi et al. 2007b; Zhou et al. 2009; Churilov et al. 2010]. Detector fabrication requires careful handling, mainly because TlBr is a soft crystal with a Knoop hardness of 11.9 (approximately 1.38 on the Mohs scale) and is easily damaged.

TlBr was one of the first semiconductors explored as a radiation detector, having been investigated by Hofstadter in 1947 [see also Hofstadter 1949a, 1949b, 1950]. Hofstadter reported that the detectors made during these early investigations were sensitive to radiation, but failed to produce acceptable spectroscopic results. Many years passed after these initial investigations, but TlBr was revisited by Ijaz-Ur-Rahman and Hofstadter starting in 1984 [also Ijaz-Ur-Rahman et al. 1987]. Although these investigations yielded better results than before, they still produced poor energy resolution and also showed polarization when operated at room temperature. From the time of these early studies, much effort has been expended to purify TlBr materials and study the polarization effect.

Several reports indicate that cooling of TlBr detectors seems to improve performance. Ijaz-Ur-Rahman and Hofstadter [1984] note that the polarization effect seemed to become negligible when the detectors were operated at a temperature of 253 K. At even lower temperatures (183 K), alpha particle energy resolution was reported to improve, but still remained relatively poor and comparable to "a crude CsI(Tl) scintillation counter," although gamma-ray contributions to the spectra were non-existent. Shortly thereafter, Shah et al. [1989, 1990] reported improved results from zone-refined material with the appearance of gamma-ray spectra, especially at a reduced temperature (213 K). Elshazly et al. [2010] report that the mean free drift

[38] Offered by TN Technologies KayRay Sensall, Inc., or TN/KSI, for many years, these XRF analyzers used small platelet grown HgI_2 detectors. The TN/KSI name was later changed to Thermo MeasureTech, a subdivision of Thermo Fisher, who no longer produces this device.

[39] By placing Tl-Br pairs at each lattice site, this crystal qualifies as a simple cubic structure. The BCC structure comes from one constituent atom centered between eight of the other constituent atoms, where the eight other constituents populate the corners of a cube. Each unit cell has two atoms, the usual number for BCC. The Pearson notation for the crystal is cP2.

times increase as the temperature is lowered, especially below 160 K, and hypothesize that the notable change may be due to a low temperature phase change.[40]

Purification of the TlBr material can be conducted directly with the compound, and has been shown to make a significant difference in detector performance. Hitomi et al. [2007b] show that zone refinement improves the carrier transport properties and has little effect on the resistivity. Energy resolution was shown to improve for 410-micron-thick planar detectors as the number of zone refinement passes increased. For example, energy resolution improved from 33% FWHM to 11% FWHM for 59.5-keV gamma rays when the refinement passes were increased from 1 to 300. Gostilo et al. [2003] studied the effect of the growth method on performance, mainly as a comparison between Stockbarger and traveling molten zone (TMZ) methods, and concluded that the results were comparable. However, hole transport was observed to improve with the TMZ method while electron transport improved with the Stockbarger method.

TlBr detectors are most commonly constructed as planar detectors. The general process includes slicing wafers from an ingot with a precision wire saw followed by mechanical polishing and surface etching. Examples include Owens et al. [2003a]; Vaitkus et al. [2004]; Hitomi et al. [2009]; and Churilov et al. [2010]. Diamond wire saws and SiC slurry wire saws have both been used for the slicing process. Polishing with Al_2O_3 slurries are the most common, although diamond pastes have also been used. The mechanical polish is often followed by an etch in 5% bromine/methanol solution. The reported final detector thicknesses are usually between 200- to 400-microns thick in most cases. Contact patterns are applied through a shadow mask, and have been fabricated from a variety of metals, including Au, Cr, Tl, Pt, and colloidal carbon, as well as layered structures such as Cr/Au and Tl/Al. Thin Pd wires are often bonded to the conductive contacts with colloidal carbon solutions. Detectors fabricated with a pixel array were processed in the same manner as above, with the exception that the pixel side of the device was patterned with a pixelated shadow mask, while the other was coated as with a common planar detector [Owens et al. 2003c; Hitomi et al. 2007].

Planar detector designs are susceptible to resolution degradation from charge carrier losses, primarily hole trapping, yet have yielded in some cases an energy resolution at room temperature of about 2.2% FWHM at 662 keV for thin devices (nominally 2 mm) [Shorohov et al. 2009a]. Improved performance is achieved with alternative designs using electron-dominated weighting potentials and in some cases electronic corrections. By using the Frisch collar design of McGregor [2004], energy resolution for planar detectors was improved by Kim et al. [2012], and achieved a room temperature energy resolution of 2.4% FWHM at 662 keV for 8.4-mm long TlBr detectors. In that same work, using the depth correction method of He et al. [1996], a 13-mm-thick array, having 25 pixels each 2 mm $\times$ 2 mm, achieved 2% FWHM energy resolution for 662-keV gamma rays at a temperature of 255 K. Room temperature energy resolution of 2% FWHM at 662 keV was achieved with a combination of depth correction and pulse height rejection for a pixel array 1.8-mm thick [Hitomi et al. 2007a]. In recent times (as of this writing), most TlBr detectors are fabricated as pixelated arrays to take advantage of the small pixel effect. Usually one or more pixels outperform the other pixels, an indication of remaining problems with material or contact uniformity. Regardless, energy resolution of about 1.5% FWHM was reported for some pixels on these TlBr detectors [Kim et al. 2009; Churilov et al. 2010].

TlBr has a serious problem with destructive polarization when operated over extended periods of time. As noted originally by Ijaz-Ur-Rahman and Hofstadter [1984], the polarization issue was rendered negligible when detectors were operated at temperatures below 253 K. Studies by Vaitkus et al. [2005] on Au contacted TlBr detectors provide evidence that polarization is caused by the drifting of Tl^+ ions through the TlBr

[40] Notably, TlBr grown as thin films reportedly has a phase change at low temperatures, from the usual body-centered cubic lattice (such as CsCl) at room temperature to either an orthorhombic or NaCl cubic phase [Schulz 1951; Blackman and Khan 1961]. Because these earlier measurements were conducted on thin TlBr films, and that thicker films appear to lack this property, Smith [2013] concludes that a bulk phase change is unlikely. Regardless, there appears to be no additional evidence that a phase change is responsible for the improved performance.

crystal. Datta and Motakef [2015] observed migration and ionic conduction from Tl^+ ions and Br^- ions through TlBr detectors fabricated with thin Au contacts. Using optical transmission, Datta and Motakef [2015] recorded the progression of defect formation across a detector over several hundred hours and found that the defects nucleate at the cathode surface and propagate to the anode. From calculations on the formation of native defects in TlBr, Du [2010] produced three important observations. First, the native defects have low formation energies and do not produce electron traps and, thus, can explain the relatively large $\mu\tau$ products. Second, the resistivity of the material is not caused by traditional deep level compensation, but instead by paired defects that do not induce the formation of deep traps. These defects are nearly stoichiometric TlBr and are mainly Schottky defects that pin the Fermi level near midgap. Third, the material has low diffusion barriers to several native defects, thereby enabling ionic conduction. It is this ionic conduction that can cause the appearance of polarization as these native defects drift through the material, as proposed earlier by Vaitkus et al. [2004, 2005]. Along with these polarization mechanisms generally observed with high-quality TlBr, Du [2010] recommends that temperature reduction can reduce this ionic conduction (already observed by Ijaz-Ur-Rahman and Hofstadter [1984]), and the use of Tl electrodes to neutralize the diffusing (drifting) defects (as observed by Hitomi et al. [2008, 2009]). Kozorezov et al. [2010] report the observation of polarization of TlBr with x rays of energies greater than 50 keV, manifested by a gradual degradation of the detector charge collection efficiency. Consequently, spectroscopic features were also observed to degrade over time. Kozerezov et al. [2010] conclude that the radiation induced polarization is caused by hole trapping and the resultant space charge buildup. Hitomi et al. [2008] studied various metal layered contacts with combinations of Au and Tl. Evidently, long-term operation has been successful with Tl contacts, for which Hitomi et al. [2009] report 600 hours of room-temperature operation without observing the polarization effect. Datta and Motakef [2015] also report improved results with Pt contacts, although measurements still indicated degradation of the Pt contact with time [Motakef and Datta 2015; Datta and Motakef 2015]. TlBr detectors presently remain mainly experimental devices, although some commercial vendors are offering detectors on a custom order basis.

Lead Iodide (PbI_2)

The properties of lead iodide (PbI_2) indicate that it is a promising material for use as a room-temperature radiation detector. It has periodically been investigated as a potential room-temperature operated detector since the initial investigations by Roth and Willig [1971]. PbI_2 has a hexagonal close-pack (HCP) crystal structure and a mass density of 6.16 g cm^{-3}. The dielectric constant reportedly ranges between 4.3 and 5.2 [Glasser et al. 1967]. The band-gap energy is reportedly between 2.3 eV and 2.55 eV. The relatively large band-gap energy leads to low leakage currents even at elevated temperatures. The reported charge carrier mobilities are 8 $cm^2\ V^{-1}\ s^{-1}$ for electrons and 2 $cm^2\ V^{-1}\ s^{-1}$ for holes [Manfredotti et al. 1977]. Unfortunately, these low mobilities, coupled with short mean free drift times, produce small $\mu\tau$ products, the largest measured at $\mu_e\tau_e = 1 \times 10^{-5}$ $cm^2\ V^{-1}$ and $\mu_h\tau_h = 3 \times 10^{-7}$ $cm^2\ V^{-1}$ [Lund et al. 1992]. Deich and Roth [1996] report similar $\mu\tau$ values of $\mu_e\tau_e = 0.8 \times 10^{-6}$ $cm^2\ V^{-1}$ and $\mu_h\tau_h = 6.4 \times 10^{-7}$ $cm^2\ V^{-1}$.

Unlike HgI_2, PbI_2 does not suffer from a destructive phase change at lower temperatures below the melting temperature of 402°C. Hence, PbI_2 can be grown directly from the melt. The high mass density coupled with the high atomic numbers ($Z_I = 53$, $Z_{Pb} = 82$) ensure a relatively high gamma-ray interaction efficiency, similar to that of HgI_2. Initial results from research on PbI_2 detectors indicated that the mean free drift times of the charge carriers are short, and spectra obtained with this material have satellite energy peaks for alpha particles. However, zone refinement purification of the PbI_2 starting material reportedly improved radiation spectrometer performance [Lund et al. 1988, 1992; Oliveira et al. 2002]. Detectors have been fabricated by various methods, and samples are generally cleaved with a fine blade or sliced with a string saw. Detector contacts have been fabricated from Au, Pd, and colloidal graphite (Aquadag®) and all have yielded similar results. The measured mean free drift times are 1.0 μs for electrons and 0.3 μs

for holes. A reported room-temperature energy resolution for a 107-μm-thick device is 712 eV FWHM for 5.9-keV gamma rays and 1.83 keV FWHM for 59.5-keV gamma rays [Deich and Roth 1996]. PbI_2 detectors and materials remain experimental and are not commercially available.

16.6 Additional Semiconductors of Interest

There are a multitude of additional compound semiconductors that have been investigated as radiation detectors, many listed in review articles describing special applications and results [Hofstadter 1949a, 1949b; Chynoweth 1952; Mayer 1966; Swierkowski 1976, Yee et al. 1976, Armantrout et al. 1977, Sakai 1982; Cuzin 1987; McGregor and Hermon 1997; and Owens and Peacock 2004]. Unfortunately, space limitations preclude any lengthy discussion of all these potential alternative semiconductors that could be used for radiation detectors. Here only three are briefly reviewed. The reader is referred to the referenced works for more information about other semiconductor materials.

$Cd_{1-x}Mn_xTe$

Related to CdZnTe is the ternary compound CdMnTe, a magneto-optical material with a large Verdet constant.[41] This material is used for Faraday rotation devices, LEDs, spintronics, electro-magnetic interference free devices, field tunable phase shifters, small coupled solar cells, phased array radar, and harsh environment sensors [International 2017]. The band-gap dependence on elemental composition of $Cd_{1-x}Mn_xTe$ was studied by numerous research groups [Gaj et al. 1978; Bottka et al. 1981; Abreu et al. 1981; Diouri et al. 1982; Lemasson et al. 1983; Lee et al. 1984; El Amrani et al. 1983; Bücker et al. 1985], all of which reported a direct band gap with a linear energy dependence on Mn concentration between $0.0 \leq x \leq 0.7$. The band-gap energy of $Cd_{1-x}Mn_xTe$ at 300 K is generally described by [from data of Lee and Ramdas 1984]

$$E_g(x) \text{ eV} = 1.524 + 1.328x \text{ eV}, \ 0.0 \leq x \leq 0.7. \tag{16.88}$$

The band gap can be expanded to 1.6 eV, the same as $Cd_{0.85}Zn_{0.15}Te$, by using $x = 0.057$, or $Cd_{0.943}Mn_{0.057}Te$, thereby permitting room-temperature operation. The theoretical resistivity of such material should be high enough so that injecting contacts can be used rather than blocking contacts as are needed for CdTe:Cl.

Non-uniformities of Mn concentration causes variances in the band-gap energy and, consequently, also increases the variance in the average ionization energy; hence uniformity is important. The segregation coefficient (k) of Mn in a solution of CdTe is almost 1.0 so that Mn does not segregate during the growth process. For example, Triboulet et al. [1990] report a Mn concentration gradient of only 0.48 to 0.52, when x is 0.5 over a crystal length of 8 cm. The potential uniformity of CdMnTe is a clear benefit over CdZnTe, for which the segregation coefficient (k) of Zn in a CdTe solution is reportedly 1.35 [Tanaka et al. 1989], so that it is difficult to grow homogeneous CdZnTe crystals.

Triboulet et al. [1990] report that $Cd_{1-x}Mn_xTe$ forms as a cubic zincblende crystal for x less than 0.75. However, the crystal structure of MnTe is hexagonal, and consequently there is an increased probability of having mixed crystalline structures between cubic zincblende and hexagonal as the Mn concentration is increased in $Cd_{1-x}Mn_xTe$, especially for x greater than 0.75 for which mixed phases have been shown to appear [Triboulet and Didier 1981]. Further, it is possible to produce hexagonal inclusions within an otherwise cubic lattice system [Mycielski et al. 2005]. Also Triboulet and Didier [1981] report the appearance of cubic $MnTe_2$ precipitates within Bridgman grown crystals, and Triboulet et al. [1990] report the appearance of twinning for Mn concentrations exceeding 15%. However, they also report that both problems can be reduced by subsequently regrowing the ingot by the traveling heater method. From Eq. (16.88) small amounts

[41] The Verdet constant describes the strength of the Faraday effect, a phenomenon in which the plane of light polarization is rotated linearly proportional to the magnetic field in the direction of light propagation.

of Mn greatly affect band-gap changes, reportedly 13 meV [Lee and Ramdas 1984] per atomic percent of Mn,[42] an indication that relatively low concentrations of Mn are required to produce high resistivity material.

Similar to CdZnTe, the formation of Cd vacancies (V_{Cd}) produces intrinsic acceptor centers, usually rendering as-grown material p-type with a resistivity of about 10^3 Ω cm. The resistivity can be increased by annealing the ingot in Cd vapor, thereby reducing the concentration of V_{Cd}. The resistivity can also be increased by including one or more compensating deep donor dopants into the crystal, including V [Burger et al. 1999] and In [Kim et al. 2009]. Owens [2012] notes an additional problem with CdMnTe production is the relatively high reactivity of Mn, which tends to bond with oxides on the growth ampoule surface, as reported by Triboulet and Didier [1981].

The first reported use of CdMnTe for radiation detectors was by Burger et al. [1999], with x equal to either 0.15 or 0.45, and with vanadium added as a compensation dopant. All materials studied reached resistivities exceeding 5×10^{10} Ω cm. Spectroscopic results for detectors fabricated from $Cd_{0.55}Mn_{0.45}Te$ were relatively poor, but the work did show that CdMnTe has promise as a radiation detector material. Since the time of that initial work, there has been some, but limited, pursuit of CdMnTe as a radiation detector [Parkin et al. 2007; Zhang et al. 2007; Babalola et al. 2009; Kim at al. 2009; Rafiei et al. 2012, 2013].

Planar detectors fabricated from $Cd_{1-x}Mn_xTe$ by Kim at al. [2009], with measured values of x between 0.074 and 0.078, had resistivities greater than 1.5×10^{10} Ω cm and $\mu_e\tau_e$ of 10^{-3} cm^2 V^{-1}. However, spectroscopic measurements from low energy gamma rays delivered non-uniform results, with the best being approximately 1.8 keV FWHM (3%) for 59.54-keV gamma rays. By employing the Frisch collar design [see McGregor and Rojeski 2001; McGregor 2004], Kim et al. [2015] produced a 6 mm × 6 mm × 12 mm detector from CdMnTe that yielded a room temperature energy resolution of 13.9 keV FWHM at 662 keV, the best results reported as of this writing. CdMnTe indeed shows promise as an alternative material for room-temperature operated semiconductor gamma-ray spectrometers, but material improvements are still required before commercial detectors are expected to appear.

CdSe

Cadmium selenide (CdSe) has been studied as a possible room-temperature (RT) gamma-ray and x-ray detector periodically over the last several decades [for example Burger et al. 1983; Roth 1989; Chen et al. 1998]. CdSe has atomic numbers of 48/34 with a mass density of 5.8 g cm^{-3}. The crystalline structure of CdSe is wurtzite, a type of hexagonal crystal, and the band-gap energy of CdSe is 1.73 eV. Canali et al. [1972] measured the electron and hole mobilities of CdSe, reporting $\mu_e = 720$ cm^2 V^{-1} s^{-1} and $\mu_h = 75$ cm^2 V^{-1} s^{-1} (the direction was not specified).

CdSe was first identified as a potential RT operated radiation detector by Prince and Polishuk [1967], although it was also recognized that impurity reduction and *pn* junction formation were major obstacles. A theoretical study explored the use of compound semiconductors, including CdSe, as room temperature radiation detectors [Armantrout et al. 1977]. However, Armantrout et al. were not optimistic about CdSe and proposed that AlSb,[43] InP, ZnTe, and CdTe would be better detector candidates.

Burger et al. [1983] were first to report results for CdSe nuclear detectors. These crystals were grown with a vertical unseeded vapor growth technique (VUVG). Typically, this crystal growth method produces *n*-type material with a low resistivity ranging between 1 and 10 Ω cm [Roth 1989] and is a consequence of Se depletion in the crystals. These samples of 250-micron thickness were heat treated at 900°C in a Se environment, resulting in a resistivity increase up to 10^{12} Ω cm, high enough to reduce leakage current for radiation detectors. The samples were polished and etched with bromine based solutions, and subsequently detectors were fabricated by applying Au contacts (non-symmetric) to both sides of the planar samples.

[42] By comparison, the band gap of $Cd_{1-x}Zn_xTe$ increases at 6.7 meV per atomic percent of Zn.

[43] Although studied often, AlSb has not developed into a commercial semiconductor for radiation detection, mainly because of the multiple problems with the material, including the rapid decomposition of AlSb in air.

The energy resolution of the samples when irradiated with 59.54-keV gamma rays from ^{241}Am was poor (or nonexistent). Roth [1989] notes that Se treatment can produce compositional and resistivity inhomogeneities, thereby adversely affecting charge transport properties and probably contributed to the poor resolution performance. Notably, the samples showed temporal stability and no signs of polarization.

Burger and Roth [1984a] and Roth and Burger [1986] improved the performance of CdSe detectors by growing crystals in a Se solution with the temperature gradient solution zoning (TGSZ) method, a technique originally developed by Steininger [1968]. The TGSZ growth method resulted in crystals with resistivities between 10^7 and 10^8 Ω cm. Samples ranging from 200 μm to 1.0 mm thick were prepared by cleaving or slicing the crystals along the $[1\bar{2}11]$ planes and subsequently etching in a bromine-methanol solution, slowly diluted with methanol to prevent the formation of a $CdBr_2$ layer on the surface [Roth and Burger 1986]. Contacts were formed with a carbon Aquadag® colloidal solution. Results reported by Roth et al. [1987] and Roth [1989] gave $\mu_e\tau_e = 1.2 \times 10^{-5}$ cm^2 V^{-1} and $\mu_h\tau_h \approx 7 \times 10^{-7}$ cm^2 V^{-1} for $\mu\tau$ products.[44] With these various changes and improvements (crystal growth, surface preparation, electrical contacts), improved performance was realized, yielding 1.4 keV FWHM at 5.9 keV (^{55}Fe), 4 keV FWHM at 27.4 keV (^{125}I), and 8.5 keV FWHM at 59.54 keV (^{241}Am).

Chen et al. [1998] reported on CdSe detectors fabricated from commercially produced CdSe crystals with resistivity of 10^{10} Ω cm. The detectors were nominally 4 mm $\times$ 4 mm area. The process used to fabricate the devices seemed to return to the earliest detector fabrication methods and employed mechanical polishing with alumina abrasive followed by a 2-minute etch in a 5% bromine-methanol solution. Final sample thicknesses ranged from 150 μm to 1.2 mm, and Au contacts were applied to opposite detector sides by physical vapor deposition. The detectors were exposed to 59.54-keV gamma rays, and produced an energy resolution of 18 keV FWHM for 150 μm thick detectors, 25 keV FWHM for 300 μm thick detectors, and no discernible resolution for the 1.2-mm-thick detectors.

Ternary compounds such as CdZnSe [Burger and Roth 1984b; Burger et al. 1985] and CdTeSe [Fiederle et al. 1994; Kim et al. 2008] have been explored as alternative semiconductors for radiation detection. Recall that CdSe is a hexagonal crystal, it is interesting to note that the crystal structures of both ZnSe and CdTe are cubic (zincblende). Hence, the varied concentrations of Se and Zn, or Se and Te, can cause not only band-gap changes, but also crystal structural changes. Burger et al. [1985] report that the leakage current from a $Cd_{0.7}Zn_{0.3}Se$ sample, a wurtzite structure, was approximately an order of magnitude lower than that of a CdSe detector of comparable size. However, the spectroscopic results were similar to CdSe reported by Roth [1989], having 1.8 keV FWHM at 5.9 keV (^{55}Fe) and 4 keV FWHM at 27.4 keV (^{125}I). Fiederle et al. [1994] reported on detectors fabricated from $CdTe_{0.9}Se_{0.1}$, a cubic zincblende crystal. Devices 1.34 mm thick yielded 6 keV FWHM for 59.54-keV gamma rays. Kim et al. [2008] also describe the performance of p-type Cl compensated CdTeSe, which had reported resistivity of 4.5×10^9 Ω cm. The measured charge carrier mobilities were $\mu_e = 59$ cm^2 V^{-1} s^{-1} and $\mu_h = 33$ cm^2 V^{-1} s^{-1}, yet the reported $\mu\tau$ products were high, reported to be $\mu_e\tau_e = 6.55 \times 10^{-2}$ cm^2 V^{-1} and $\mu_h\tau_h = 8.12 \times 10^{-2}$ cm^2 V^{-1}. However, despite these seemingly beneficial properties, the detectors had high leakage current and performed marginally with an energy resolution of 18 keV FWHM for 59.54-keV gamma rays.

There has been limited investigation of this wide band-gap semiconductor in recent years, perhaps due in part to the success of other compound semiconductors such as CdZnTe. Regardless, CdSe has enjoyed renewed success as a nanomaterial for quantum dot fabrication. Apparently accurate control over the quantum dot size is achievable, thereby allowing the band gap to be tailored with great precision. Potential alternative uses include highly efficient lasers and light emitting diodes, quantum computing, and photovoltaic

[44] Chen et al. [1998] report much different values from various sources, listing $\mu_e\tau_e = 6.3 \times 10^{-5}$ cm^2 V^{-1} and $\mu_h\tau_h = 7.5 \times 10^{-5}$ cm^2 V^{-1}.

applications through multiple exciton generation, an improvement over conventional Si solar panels [Colvin et al. 1994; Robel et al. 2006; Somers et al. 2007].

GaSe

Gallium selenide (GaSe) was investigated as a possible room temperature radiation detector several decades ago [for example, Manfredotti et al. 1974a; Mancini et al. 1976; Sakai et al. 1988; Nakatani et al. 1989], although in recent years interest appears to have subsided. GaSe has atomic numbers of 31/34 with a mass density of 4.55 g cm^{-3}. The crystal is hexagonal with covalently bonded Se-Ga-Ga-Se layers held together by van der Waals bonds. GaSe has a direct band gap of 2.03 eV, wide enough for room-temperature operation. The motivation of pursuing GaSe as a radiation detector included the search for materials capable of operating at elevated temperatures, low cost fabrication, and minimal leakage current, all of which GaSe seemed to possess [Manfredotti et al. 1974a; Castellano 1986].

Manfredotti et al. [1974a] communicate two methods used to produce the GaSe crystals, namely Bridgman growth [Cardetta et al. 1972a] and a chemical transport method [Cardetta et al. 1972b]. The Bridgman growth produced sizeable crystals of about 1 cm$^2\times$ 4 cm length with resistivities ranging between 10^3 to 10^6 Ω cm [Manfredotti et al. 1974a, 1974b]. The reported charge carrier mobilities were $\mu_e = 60$ cm^2 V^{-1} s^{-1} and $\mu_h = 215$ cm^2 V^{-1} s^{-1} measured along the c axis. The $\mu\tau$ products were about $\mu_e\tau_e = 1.4\times10^{-6}$ cm^2 V^{-1} and $\mu_h\tau_h = 3.65\times10^{-6}$ cm^2 V^{-1}, thereby indicating mean free drift times of $\tau_e = 2\times10^{-6}$ s and $\tau_h = 5\times10^{-6}$ s. Current-voltage tests produced space charge limited characteristics as described by Lampert and Mark [1970]. Samples grown by chemical transport were smaller in size, the largest being about 50 mm^2 area and 150 μm thick and had substantially higher resistivities between 10^8 to 10^9 Ω cm. However, the reported transport properties were inferior to the Bridgman samples, with $\overline{\mu_e\tau_e} = 1.3\times10^{-7}$ cm^2 V^{-1} yielding $\tau_e \approx 2\times10^{-9}$ (results for holes were not reported). Detectors were fabricated by evaporating 7 mm^2 area Au contacts onto opposite sides of planar samples ranging between 50 to 120 μm thick. Measurements with these detectors yielded a poor energy resolution of 1.13 MeV FWHM for 5.486 MeV alpha particles, along with the observation of satellite peaks, an indication of inhomogeneous electrical properties [Manfredotti et al. 1974a]. By collimating the alpha particles to a 0.8 mm^2 area on the detector the energy resolution was improved to 370 keV FWHM.

Sakai et al. [1988] and Nakatani et al. [1989] report on Bridgman grown GaSe material with measured charge carrier mobilities of $\mu_e = 70$ cm^2 V^{-1} s^{-1} and $\mu_h = 45$ cm^2 V^{-1} s^{-1}. The average ionization energy was found to be between 4.0 and 4.5 eV per e-h pair, and falls on the alternate dependence of the Klein model (see Fig. 16.2), like many other layered semiconductors (HgI_2, PbI_2). The best RT energy resolution reported by Sakai et al. [1988] and Nakatani et al. [1989] was approximately 250 keV FWHM for 5.486 MeV alpha particles. Yamazaki et al. [1993] experimented with GaSe doping of various elements, primarily Si, Ge, and Sn, a doping which decreased the leakage currents. Spectroscopic measurements with these doped samples yielded varied energy resolution, ranging from 220 keV (4%) FWHM to 850 keV FWHM for 5.486 MeV alpha particles. Yamakazi et al. [1993] also report that the best of the undoped GaSe detectors they fabricated yielded an energy resolution of 252 keV (4.6%) FWHM for 5.846 MeV alpha particles. Most of the undoped GaSe samples generally produced leakage current too high to yield spectroscopic results.

GaSe has also been explored for x-ray and low energy gamma-ray detection [Castellano 1986; Arutyunyan et al. 1989; Mandal et al. 2007], and also as muon beam monitors [Manfredotti et al. 1975; Mancini et al. 1976]. Castellano [1986] and Arutyunyan et al. [1989] studied GaSe as an x-ray beam dose monitors, and reported primarily on the photocurrent produced by x-ray beams. Castellano [1986] promoted the concept of using GaSe for x-ray dosimetry because of its apparent thermal stability, low dark current, and simplistic detector construction. Mandal et al. [2007] report on the spectroscopic performance of In-doped Bridgman grown GaSe exposed to 59.54-keV gamma-rays, yielding 2.4 keV (4%) FWHM.

Problems that exacerbate the progress of GaSe as a radiation detector include the fragility of the crystals, relatively low charge carrier mobilities, and the resultant relatively low $\mu\tau$ products. The crystals are soft (Mohs hardness of 2) and usually separate or cleave along the van der Waals bonds, thereby making slicing and detector fabrication challenging. The addition of In as a dopant appears to have a positive effect on strengthening the crystal structure [Voevodin et al. 2004]. Improvements with purification and crystal growth may increase charge carrier mean free drift times and result in higher $\mu\tau$ products; however, the direct band gap indicates relatively short charge carrier lifetimes still persist. The charge carrier mobilities are intrinsic properties, thereby meaningful improvements are not expected.

The layered structure of GaSe produces highly anisotropic electrical properties that are beneficial for non-linear optics [Brebner 1964]. Non-linear GaSe optical materials are used in the frequency conversion of laser light, which involves shifting the wavelength of monochromatic laser light to alternate wavelengths [Kübler et al. 2005], and has been exploited recently for THz generation with an extremely large bandwidth of up to 41 THz [Huber et al. 2000; Liu et al. 2004]. GaSe is one of the most widely employed crystals for non-linear optical generation and detection of THz radiation. Consequently small GaSe crystals are commercially available, but primarily with common sizes about 1 $\text{cm}^2 \times$ 200 μm to 1 mm thick.

16.7 Summary

Semiconductor materials are attractive as radiation detectors for two principle reasons. First, because of their low average ionization energy w, semiconductors produce a large number of signal charge carriers per unit energy, thereby decreasing statistical fluctuations beyond that of gas-filled and scintillation detectors and, as a consequence, produce a much better energy resolution. Second, semiconductor materials have energy band structures that allow their electrical properties to be altered through the addition of impurities. These materials can be manipulated to have a majority of negative (n-type) electrical charge carriers, or electrons, or positive (p-type) charge carriers, denoted as "holes". Adjacent n-type and p-type materials can be manipulated to form detectors with rectifying contacts, in which both leakage current and electrical noise are reduced.

Moreover, semiconductor detectors can be fashioned into various types of detectors especially designed for x-ray detection, γ-ray detection, or charged-particle detection. Detector performance is optimized by semiconductor choice and device design. Charged-particle detectors are generally designed with low Z material, such as Si, to reduce backscattering. Higher Z materials, because of their improved absorption efficiencies, are generally used for γ-ray detectors. Low energy x-ray and γ-ray detectors are often fabricated from Li-drifted Si (Si(Li) detectors), although the most commonly used semiconductor for photon detection is high-purity Ge (HPGe detectors). Both Si(Li) and HPGe detectors must be cooled to low temperature for best operation. Wide band-gap semiconductors, such as CdZnTe, can be used as room-temperature operated γ-ray spectrometers.

Finally, semiconductor materials can be fashioned into arrays to yield spatial interaction information. These arrays can be arranged from the tiling of numerous individual detectors, or they can be fabricated as pixels upon a single semiconductor substrate. Commercial vendors offer numerous varieties of semiconductor detectors, which include particle, x-ray, and γ-ray detectors, in the form of individual devices or as arrays.

PROBLEMS

1. A 7-mm slab of π-type Si with $N_A = 10^{14}$ cm^{-3} has a layer of Li evaporated upon it. The temperature is raised to 400°C for 3 hours. Afterwards, the temperature is lowered to 120°C, and 500 volts are applied for a period of 100 hours. What is the resulting compensated width?

2. A surface-channel CCD device is to be used to measure alpha particles from ^{148}Gd. The background concentration is $N_A = 10^{12}$ cm^{-3}, the effective operating bias is 10 volts, and the oxide thickness is 0.15

microns. If the pixel sizes are 5 micron × 5 micron area, what is Q_{max}? Will this device operate for the intended use?

3. A Si(Li) detector has a linearly varying residual positive space charge. Derive a general expression for the electric field distribution in a planar detector under such a condition.

4. Determine the electron and hole velocities for a 5 mm × 5 mm × 1 cm thick CdZnTe detector operated at 1000 volts.

5. How would a change in the Fano factor in a germanium detector affect the energy resolution of the detector?

6. Plot your estimate of the energy resolution of a HPGe detector as a function of the incident photon energy between 100 keV and 10 MeV. Assume that there is complete charge collection and that there is negligible noise.

7. How thick must the depletion region in a Si(Li) be to record the full energy of a 4-MeV alpha particle?

8. You have a Si surface barrier detector with the following characteristics: n-type Si, $n = 2 \times 10^{14}$ n-type dopant impurities cm^{-3}, and $V_{bi} = 0.3$ volts. You also have an ^{241}Am alpha particle source. The detector is operated in vacuum. (a) What does the differential pulse height spectrum appear as with no voltage on the detector? (b)What does the differential pulse height spectrum appear as with 25 volts applied? (c) How much voltage is required to extend the detector depletion region just beyond the alpha particle range?

9. Given a Si(Li) detector with a 3.5-mm-thick drifted region, determine the energy that the detector can measure from an energetic electron of 20 MeV if the electron passes through the detector.

10. You measure spectra from a detector fabricated from CdTe that suffers much charge carrier trapping. A few measurements reveal the following: electron mean free drift times are 0.5 microseconds, electron mobility = 1000 cm^2 V^{-1} s^{-1}, hole mean free drift times are 0.2 microseconds, electron mobility = 80 cm^2 V^{-1} s^{-1}, and saturation velocity for both carriers is 10^7 cm s^{-1}.

The operating voltage is kept at 100 volts. (a) With highly penetrating gamma rays (high energy), what is the maximum detector thickness that the detector can be to keep the measured pulses below 20% deviation? (b) 10% deviation? (c) 1% deviation?

11. What is the best theoretical energy resolution that you can achieve with Ge for 122-keV gamma rays in Ge? Give answers in energy and percent. Repeat for 1.17 MeV gamma rays.

12. You are given pure Ge material with the properties: $N_C = 10^{19}$ cm^{-3} and $N_V = 6 \times 10^{18}$ cm^{-3}. (a) What is the value of n_i at T = 77K? (b) What is the value of n_i at T = 300K? (c) Explain why germanium detectors are operated at cryogenic temperatures.

13. Why are escape peaks generally more prominent in spectra from HPGe detectors to those observed with NaI:Tl detectors of equal volume?

14. What properties of a semiconductor material are of most concern to you when considering using the material as a radiation detector? Consider both technical and practical aspects of using the material.

Chapter 17

Slow Neutron Detectors

When a neutron enters a nucleus, the effects are about as catastrophic as if the moon struck the earth. The nucleus is violently shaken up by the blow, especially if the collision results in the capture of the neutron. A large increase in energy occurs and must be dissipated, and this may happen in a variety of ways, all of them interesting.

I.I. Rabi

Neutron detection is challenging primarily because neutrons, like photons, do not have an electrical charge, i.e., they are classified as indirectly ionizing radiation. Unlike α and β radiations, neutrons must first interact in a medium to produce directly ionizing reaction products, or at least some other observable effect. Neutron detectors usually rely upon an interaction with the atomic nuclei within the detector medium and most often it is an absorption or scattering interaction. Slow neutron detectors usually incorporate neutron reactive materials with relatively large neutron absorption cross sections in the low energy region below about 1 keV, whereas fast neutron detectors quite often have relatively large scattering cross sections for neutron energies above 500 keV. Because the differences between the detection methods are considerable, this chapter is devoted to *slow* neutron[1] detectors while the next chapter discusses *fast* neutron detectors.

Slow neutron detectors usually rely upon reactive neutron absorptions for the detection mechanism. Neutrons are absorbed in the target material and the resulting compound nucleus emits ionizing radiations. Most of the neutron absorbing materials used for the neutron detection emit heavy charged particles, although some of the less frequently used materials emit conversion electrons, beta particles, or gamma rays. The three most popular reactive materials for slow neutron detection are ^{3}He, ^{10}B, and ^{6}Li while alternative reactive materials include Gd, U, Hg, and Cd.

17.1 Cross Sections in the $1/v$ Region

An important characteristic of the ^{3}He, ^{10}B, and ^{6}Li isotopes is that they are all so-called $1/v$ absorbers. Radiative capture of low-energy neutrons can be modeled with the Breit-Wigner one-level formula [Lamarsh 1966]

$$\sigma_\gamma(E_c) = \pi\gamma_1^2 g\sqrt{\frac{E_1}{E_c}}\frac{\Gamma_n\Gamma\gamma}{(E_c - E_1)^2 + \Gamma^2/4}, \tag{17.1}$$

[1] In most instances the totality of slow neutrons are called thermal neutrons, i.e., neutrons with speeds that are in thermal equilibrium with the thermal motion of the ambient medium through which they diffuse (see Problem 17-1). An exception would be a beam of monoenergetic slow neutrons produced by a neutron diffractometer.

where E_1 is the energy of the lowest absorption resonance peak, E_c is the center-of-mass energy between the neutron and target nucleus, γ_1 is the reduced de Broglie wavelength for a neutron at energy E_1, g is a statistical factor that is a function of the spin of the target nucleus and the resulting compound nucleus, and Γ_n, Γ_γ, and $\Gamma = \Gamma_n + \Gamma_\gamma$ are, respectively, the width for neutron emission, the width for the (γ, n) reaction, and the total width of the resonance.[2]

The statistical factor g gives the probability that a particular compound state is formed and is given by

$$g = \frac{1}{2}\left(\frac{2J+1}{2I+1}\right), \quad I \neq 0 \tag{17.2}$$

or $g = 1$ if $I = 0$, where I and J are, respectively, the spins of the target nucleus and the compound nucleus. The Breit-Wigner formula is derived for the center-of-mass system so that for an incident neutron of speed v the value of γ_1 is given by

$$\gamma_1 = \frac{\hbar}{\mu v}, \tag{17.3}$$

in which μ is the reduced mass of the nucleus-neutron system, i.e.,

$$\mu = \frac{Am_n}{A+1}, \tag{17.4}$$

where m_n is the neutron mass and Am_n is the mass of the target nucleus. For heavy nuclei $A \gg m_n$ and $\mu \simeq m_n$ so these center-of-mass nuances are not important; but they are for light target nuclei.

Because E_1, γ_1, Γ_γ, Γ_n, and Γ are constants in Eq. (17.1), the radiative capture cross section produces the observed $1/v_c$ behavior at low neutron energies ($E_c \ll E_1$), namely

$$\sigma_\gamma \approx K_1\sqrt{\frac{E_1}{E_c}} = \frac{K_2}{v_c}, \tag{17.5}$$

where K_1 and K_2 are proportionality constants.

Similarly, the cross section for neutron capture resulting in the release of charged particle reaction products can be expressed as [Lamarsh, 1966]

$$\sigma_{(a,b)} = \sqrt{\frac{E_b}{E_a}}H(E_a) \approx \frac{K_3}{v_a}, \tag{17.6}$$

for the reaction $X(a,b)Y$, where E_a and E_b are the kinetic energies of the particles in the center-of-mass system and $H(E_a)$ is a correction factor for non-$1/v$ behavior for moderately large $E_a \ll E_1$, and K_3 is a proportionality constant. Neutrons at low energy ($E_a \ll E_1$) have little effect on the reaction Q value, so the Q value of the reaction is nearly equal to E_b. In such cases, $H(E_a) \approx 1$.

Consider the laboratory system in which neutrons approach target nuclei with relative velocities

$$\mathbf{v_r} = \mathbf{v} - \mathbf{V}, \tag{17.7}$$

where $\mathbf{v}$ is the neutron velocity vector and $\mathbf{V}$ is the target nuclei velocity vector in the laboratory system. As observed from the target nuclei, the incident neutrons are a differential beam of intensity

$$dI = n(\mathbf{v})v_r \; d\mathbf{v}, \tag{17.8}$$

[2]The "width" is a measure of the probability the compound nucleus decays in a specific manner; it is equal to $\hbar$ times the decay constant for the particular process.

where n($\mathbf{v}$) is the neutron density distribution and $v_r = |\mathbf{v}_r|$. The neutrons interact with the nuclei at a reaction density rate

$$dF = n(\mathbf{v})N(\mathbf{V})\sigma(v_r)v_r \; d\mathbf{v} \; d\mathbf{V} \; (\text{cm}^{-3} \; \text{s}^{-1}), \tag{17.9}$$

where $N(\mathbf{V})$ is the target nuclei velocity density distribution and $\sigma(v_r)$ is the neutron cross section at the relative speed v_r. The total interaction rate density is then

$$F = \iint n(\mathbf{v})N(\mathbf{V})\sigma(v_r)v_r \; d\mathbf{v} \; d\mathbf{V}. \tag{17.10}$$

If the target nuclei exhibit a $1/v$ absorption behavior, then from Eq. (17.5) and Eq. (17.6), any arbitrary absorption cross section $\sigma_a(v_{ro})$ for relative speed v_{ro} is related to the cross section at v_r by

$$\sigma_a(v_r) = \frac{\sigma_a(v_{ro})v_{ro}}{v_r}. \tag{17.11}$$

Substitution of Eq. (17.11) into Eq. (17.10) yields

$$\begin{aligned} F_a &= \iint n(\mathbf{v})N(\mathbf{V})\sigma_a(v_r)v_r \; d\mathbf{v} \; d\mathbf{V} \\ &= \iint n(\mathbf{v})N(\mathbf{V})\frac{\sigma_a(v_{ro})v_{ro}}{v_r}v_r \; d\mathbf{v} \; d\mathbf{V} \\ &= N\sigma_a(v_{ro})nv_{ro} = \Sigma_a(E_o)nv_o, \end{aligned} \tag{17.12}$$

where $\Sigma_a(E_o)$ is the macroscopic reaction cross section at an arbitrary reference speed v_o (most often chosen as 2200 m/s), n is the total neutron density, and N is the total target nuclei density. The result of Eq. (17.12) is very important and shows that the reaction rate of neutrons with a $1/v$ material is *independent of the neutron or target nuclei velocity distributions*. Hence, a measurement using a reaction rate to determine detection efficiency is independent of the neutron energy distribution for $1/v$ absorbers. Note that the result of Eq. (17.12) is restricted to the $1/v$ region of the neutron cross section, generally applicable to only slow neutrons. In the case that the absorber nuclei are non-$1/v$, a temperature dependent Westcott correction factor $g_a(T)$ is required to correct for non-$1/v$ interaction behavior [Lamarsh 1966]

$$F = g_a(T)\Sigma_a(E_0)nv_0, \tag{17.13}$$

where T is the neutron temperature of the assumed Maxwellian spectrum of interacting thermal neutrons.

17.2 Slow Neutron Reactions Used for Neutron Detection

As previously noted, the three most popular isotopes for slow neutron detection are ^{3}He, ^{10}B, and ^{6}Li, all having $1/v$ dependence in the slow neutron region (see Fig. 17.1). In all three cases, reactions with slow neutrons cause the reaction products to be ejected in opposite directions (180°). While ^{3}He is used for gas-filled detectors, both ^{10}B and ^{6}Li are used in a variety of detector configurations, including gas-filled, scintillator, and semiconductor devices.

There are also numerous large Z absorbers used for neutron detection that do not exhibit $1/v_c$ behavior because of resonances appearing in the epithermal and thermal-neutron range. Unfortunately, the interaction rate for such absorbers is dependent on the neutron and target nuclei velocities. Consequently, more information must be known about the neutron flux and energy distribution to accurately calibrate instruments utilizing these absorbers than expressed by the simple expression of Eq. (17.12). Nevertheless, many are useful for neutron detection, with some of the more important ones that have very large thermal-neutron absorption cross sections being ^{113}Cd, ^{157}Gd, ^{199}Hg, and ^{235}U.

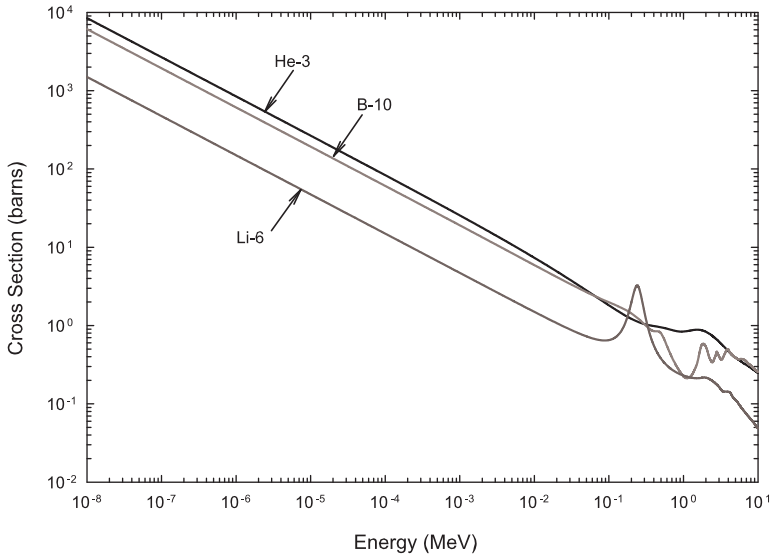

Figure 17.1. Neutron absorption cross sections in barns for common $1/v$ neutron detector materials. The energy is the incident neutron energy in the center-of-mass coordinate system. Data are from [ENDFPLOT, 2015].

17.2.1 The ^{3}He Reaction

There are two natural isotopes of helium, namely ^{3}He and ^{4}He with natural abundances of 0.000137% and 99.999863%, respectively. The isotope ^{3}He has a relatively large total thermal-neutron cross section of 5320 barns at 2200 m/s,[3] of which the ^{3}He(n,p)^{3}H reaction constitutes 5316 barns. By contrast the thermal-neutron absorption cross section for ^{4}He is essentially zero. The microscopic thermal-neutron absorption cross-section for ^{3}He decreases with increasing neutron energy, with a dependence proportional to the inverse of the neutron speed ($1/v$) up to about 0.1 MeV, as shown in Fig. 17.1.

For an incident neutron with negligible kinetic energy, the ^{3}He(n,p)^{3}H reaction has the following energetics:

$$^3\mathrm{He} + {}^1_0\mathrm{n} \rightarrow {}^3\mathrm{H}\ (0.191\ \mathrm{MeV}) + {}^1\mathrm{H}\ (0.573\ \mathrm{MeV}) \quad \text{with} \quad Q = 0.764\ \mathrm{MeV}. \tag{17.14}$$

The reaction products, while emitted isotropically, are emitted opposite to each other in order to preserve the almost zero incident momentum of the neutron.

The density of natural He gas is 0.1786 g L^{-1} at standard temperature and pressure (STP),[4] with an atom density of 2.686×10^{19} cm^{-3}. Hence, the macroscopic absorption cross section (Σ_a) for pure ^{3}He at STP is 0.1492 cm^{-1}. Most neutron detectors based on ^{3}He are pressurized to increase the value of Σ_a. A common pressure for ^{3}He gas-filled neutron detectors is 2.8 atm; however, detectors with pressures ranging from 1 atm up to 20 atm are commercially available. Because of the pressurization, various national aircraft regulations may limit the transport of these detectors.

[3] Thermal neutrons generally have a wide range of energies that are often well-described by a Maxwellian flux distribution, which has a most probable energy of 0.0253 eV (corresponding to a speed of 2200 m/s) for a neutron temperature of 293.5 K. In this chapter, the thermal-neutron cross section refers to the 2200 m/s cross section whose values are taken from the 2017 ENDF/B-VIII library.

[4] STP is 273.15 K (0 °C) and 100 kPa (0.9869 atm).

For low energy neutrons, the neutron contributes very little to the overall reaction product energies; hence the final energy shared by the reaction products is essentially the reaction Q value. As the neutron kinetic energy increases, the reaction products absorb and share this additional energy, yet for energies in the slow to epithermal region, this additional energy is usually masked by the Q value energy; hence, spectroscopic energy information is lost. The same is true for the neutron momentum, which contributes little, thereby causing almost all momentum to be shared between the two reaction products. Hence, for slow neutrons, reaction product net momentum is essentially zero. If one neglects the energy and momentum of the neutron, conservation of energy and momentum yields,

$$E(^3\mathrm{H}) + E(^1\mathrm{H}) = Q = 0.764 \text{ MeV}, \tag{17.15}$$

and

$$M(^3\mathrm{H})v(^3\mathrm{H}) = M(^1\mathrm{H})v(^1\mathrm{H}), \tag{17.16}$$

or

$$\sqrt{2E(^3\mathrm{H})M(^3\mathrm{H})} = \sqrt{2E(^1\mathrm{H})M(^1\mathrm{H})}. \tag{17.17}$$

From Eq. (17.15) and Eq. (17.17), the reaction product energies shown in Eq. (17.14) are readily obtained.

Neutron detectors based on ^{3}He are generally considered a standard for neutron measurements and are widely used in various nuclear industries. However, the natural abundance of ^{3}He is low. The problem is further exacerbated by the dwindling supply of ^{3}H gas,[5] which decays by β-particle emission into ^{3}He. Liquid ^{3}He also has unique superfluid properties for ultra-low-temperature physics, thereby creating another demand for this scarce resource. Consequently, ^{3}He gas and detectors are relatively expensive, costing thousands of US dollars per liter at STP.

17.2.2 The ^{10}B Neutron Reaction

There are two natural isotopes of boron, namely ^{10}B and ^{11}B with natural abundances of 19.9% and 80.1%, respectively. The isotope ^{10}B has a relatively large thermal-neutron (2200 m/s) cross section of 3847 barns, of which the ^{10}B(n,α)^{7}Li cross section constitutes 3844 barns. The microscopic thermal-neutron absorption cross section for ^{10}B decreases with increasing neutron energy, with a dependence proportional to the inverse of the neutron speed ($1/v$) over much of the slow energy range, as shown in Fig. 17.1. The density of natural B is 2.35 g cm^{-3}, and the density of enriched ^{10}B is 2.16 g cm^{-3}. The resulting macroscopic thermal-neutron cross section (Σ_a) for natural B material is 100 cm^{-1} and 497 cm^{-1} for fully enriched ^{10}B material.

The ^{10}B(n,α)^{7}Li reaction leads to the following reaction energetics when the incident neutron has negligible energy:

$$^{10}\mathrm{B} + {}^1_0\mathrm{n} \rightarrow \begin{cases} ^7\mathrm{Li}^* \text{ (0.840 MeV)} + \alpha \text{ (1.470 MeV)} & Q = 2.310 \text{ MeV} \quad 94\% \\ ^7\mathrm{Li} \text{ (1.015 MeV)} + \alpha \text{ (1.777 MeV)} & Q = 2.792 \text{ MeV} \quad 6\% \end{cases} . \tag{17.18}$$

The reaction products are emitted isotropically but in opposite directions when thermal neutrons (with negligible momentum) are absorbed by ^{10}B. After absorption, 94% of the reactions leave the ^{7}Li ion in its first excited state, which rapidly deexcites to the ground state in about 10^{-13} s by releasing a 480-keV gamma ray. For a variety of neutron detectors, especially gas-filled neutron detectors, the 480-keV gamma ray usually escapes and does not contribute to the detection output. The remaining 6% of the reactions

[5] Much of the world's ^{3}H came from the tritium generated for nuclear weapons production, which today has been significantly reduced by international treaties.

produce a ^{7}Li ion in its ground state. Conservation of energy and momentum then requires

$$E(^7\text{Li}^*) + E(^4\text{He}) = Q = 2.310 \text{ MeV}, \tag{17.19}$$

$$E(^7\text{Li}) + E(^4\text{He}) = Q = 2.792 \text{ MeV}, \tag{17.20}$$

and

$$\sqrt{2E(^7\text{Li}^*)M(^7\text{Li}^*)} = \sqrt{2E(^4\text{He})M(^4\text{He})}, \tag{17.21}$$

$$\sqrt{2E(^7\text{Li})M(^7\text{Li})} = \sqrt{2E(^4\text{He})M(^4\text{He})}. \tag{17.22}$$

Simultaneous analysis of Eq. (17.19) with Eq. (17.21), and Eq. (17.20) with Eq. (17.22) yields the reaction product energies shown in Eq. (17.18).

17.2.3 The ^{6}Li Neutron Reaction

There are two natural isotopes of lithium, namely ^{6}Li and ^{7}Li, with natural abundances of 7.59% and 92.41%, respectively. The isotope ^{6}Li has a relatively large thermal-neutron cross section of 938.8 barns with the ^{6}Li(n,t)^{4}He reaction contributing 938.0 barns. The nuclide ^{7}Li has a relatively small thermal-neutron absorption cross section of approximately 45.5 mb. The microscopic thermal-neutron absorption cross-section of ^{6}Li decreases with increasing neutron energy, with a dependence proportional to the inverse of the neutron speed ($1/v$) over much of the energy range, with a notable resonance near 240 keV as shown in Fig. 17.1. The density of natural Li is 0.534 g cm^{-3}, and the density of enriched ^{6}Li is 0.463 g cm^{-3}. With an atomic density of 4.65×10^{22} atoms cm^{-3}, the resulting macroscopic thermal neutron cross section (Σ_a) for natural Li material is 3.300 cm^{-1} and 43.48 cm^{-1} for enriched ^{6}Li material. The ^{6}Li(n,t)^{4}He reaction leads to the following products:

$$^6\text{Li} + {}^1_0\text{n} \rightarrow {}^4\text{He (2.05 MeV)} + {}^3\text{H (2.73 MeV)} \qquad Q = 4.78 \text{ MeV}. \tag{17.23}$$

Again they are emitted isotropically but in opposite directions if the incident neutron energy is sufficiently small. Conservation of energy and momentum, for negligible incident neutron momentum, yields

$$E(^4\text{He}) + E(^3\text{H}) = Q = 4.78 \text{ MeV}, \tag{17.24}$$

and

$$\sqrt{2E(^4\text{He})M(^4\text{He})} = \sqrt{2E(^3\text{H})M(^3\text{H})}. \tag{17.25}$$

Simultaneous solutions of Eq. (17.24) with Eq. (17.25) yields the reaction product energies shown in Eq. (17.23).

Because of its higher absorption cross section, the ^{10}B(n,α)^{7}Li reaction leads to a generally higher reaction probability than the ^{6}Li(n,t)^{4}He reaction for neutron energies below 100 keV. However, the higher energy reaction products emitted from the ^{6}Li(n,t)^{4}He reaction lead to greater ease of detection than do the particles emitted from the ^{10}B(n,α)^{7}Li reaction.

Although there are neutron detectors based on enriched ^{6}Li metal, careful handling is required because Li metal is highly reactive in the presence of water moisture or other oxidizers. A popular and relatively non-reactive Li compound used for neutron detection is ^{6}LiF. The molecular density of ^{6}LiF is 6.12×10^{22} molecules cm^{-3} which also equals the atomic density of the ^{6}Li atoms.[6] The mass density of ^{6}LiF is 2.54 g cm^{-3}, which produces a macroscopic thermal-neutron (n,α) cross section of 57.41 cm^{-1}.

[6] It is interesting to observe that the atomic density of Li atoms in LiF is actually higher than in pure Li metal.

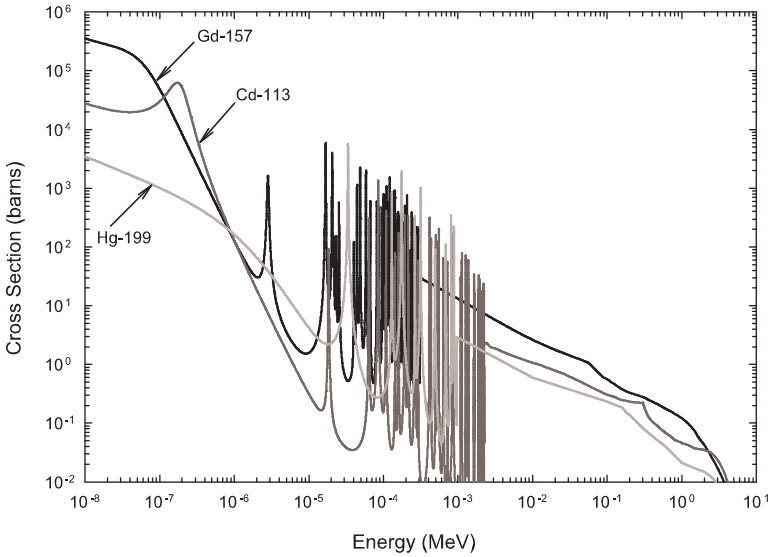

Figure 17.2. Neutron absorption cross sections in barns for common non-$1/v$ neutron detector materials, showing the radiative capture cross sections for ^{113}Cd, ^{157}Gd, and ^{199}Hg. For such heavy nuclide targets the center-of-mass neutron energy almost equals the neutron energy in the laboratory system. Data are from [ENDFPLOT, 2015].

17.2.4 The ^{155}Gd and ^{157}Gd Neutron Reactions

The ^{157}Gd(n,γ)^{158}Gd reaction leads to the emission of low energy internal conversion electrons, most of which are emitted at energies below 220 keV, along with an assortment of gamma rays. The attractiveness of using ^{157}Gd is because of its large (n,γ), thermal-neutron cross-section of 252.9 kb. ^{157}Gd has low-energy absorption resonance at 2.82 eV and, consequently, its microscopic neutron absorption cross section does not have a $(1/v)$ dependence in the sub eV range as is evident from Fig. 17.2. Another neutron absorbing Gd isotope that cannot be ignored is ^{155}Gd, which has a thermal-neutron (n,γ) cross section of 60.74 kb. Together these two isotopes of Gd are perhaps the largest of the solid-state thermal-neutron absorbers.[7] The density of natural Gd is 7.901 g cm^{-3}, and the natural abundances of ^{155}Gd and ^{157}Gd are 14.80% and 15.65%, respectively.

Table 17.1. Conversion electron energies and emission fractions for neutron interactions in natural Gd. The conversion electrons are produced from both ^{155}Gd(n,γ)^{156}Gd and ^{157}Gd(n,γ)^{158}Gd reactions. Data are from [Schulte et al., 1994].

Energy (keV)	Electrons/ neutron (%)	Energy (keV)	Electrons/ neutron (%)
29	9.82	149	0.84
39	4.19	173	1.46
71	26.80	180	0.31
78	6.17	191	0.30
81	4.97	198	0.06
88	1.16	228	0.40
131	3.41	246	0.02

Although some of the other existing Gd isotopes have significant thermal-neutron (n,γ) cross sections, they do not contribute to the neutron detection capability of this element. For example, ^{152}Gd has a 735.1 b 2200-m/s (n,γ) cross section and an abundance of 0.020% while ^{154}Gd has a 85.2 b cross section and a

[7] The radioactive gas fission product ^{135}Xe has a thermal-neutron (n,γ) cross section of 2.6 Mb, the largest of any isotope.

2.18% abundance. The three other stable isotopes ^{156}Gd, ^{158}Gd and ^{160}Gd have negligible cross sections of 1.80 b, 2.03 b, and 1.41 b, respectively.

Given the natural abundances of the isotopes in natural Gd, the natural Gd macroscopic thermal-neutron absorption cross is 1467 cm^{-1}. This macroscopic absorption cross section could be increased by using enriched ^{157}Gd; however, in practice it is impractical due to the high cost of isotope separation.

Neutron absorptions in Gd produce an abundance of spontaneous internal conversion electrons and gamma-rays from the excited ^{156}Gd and ^{158}Gd nuclei. Although the gamma-ray emissions can be used to indicate neutron interactions, it is usually the conversion electrons that are used in the detection process. Shown in Table 17.1 is a list of conversion electron energies and relative emissions (%) per captured neutron, totaling only 59.91% of the product yield [Aoyama et al. 1992]. The most salient emission of conversion electrons is that from the excited state of ^{158}Gd nucleus and produces an electron with an energy of 71 keV. There are also two conversion electron emissions near 80 keV totaling 11.14% of the product yield. The total fraction of conversion electrons above 85 keV amounts to only 7.96% of the total emissions. Hence, the lower level discriminator must be set below 71 keV equivalent in order to detect most of the conversion electrons. These relatively low energy conversion electrons (and accompanying gamma-ray emissions) can be difficult to distinguish from background gamma rays in a high radiation field.

17.2.5 The ^{113}Cd Neutron Reaction

Natural cadmium has eight existing isotopes, of which radioactive ^{113}Cd ($T_{1/2} = 8.04 \times 10^{15}$ y) strongly absorbs thermal neutrons, and has a thermal-neutron (n,γ) cross section of 19.96 kb. The density of natural Cd is 8.65 g cm^{-3}, and the isotope ^{113}Cd has a natural isotopic abundance of 12.23%. The natural Cd macroscopic thermal-neutron absorption cross section is 113.1 cm^{-1}. The cross section as a function of neutron energy is shown in Fig. 17.2. This macroscopic absorption cross section could be greatly increased by using Cd enriched in ^{113}Cd, but high isotopic separation costs preclude this approach.

The ^{113}Cd(n,γ)^{113}Cd reaction produces numerous gamma-ray emissions, ranging from relatively low energies up to and beyond 9 MeV. However, there are two salient prompt gamma-ray emissions of interest at 558.6 keV and 651.3 keV [Lone et al. 1981; Tuli 1997], with branching ratios of 72.73% and 13.9%, respectively. These gamma rays can be discerned with a relatively high-resolution gamma-ray spectrometer. Unfortunately, a gamma-ray spectrometer capable of detecting the ^{113}Cd(n,γ)^{113}Cd emissions also detects other background gamma rays, a signal which can potentially confound interpretation of a measurement. Also, unlike neutron reactive detector materials that emit charged-particle reaction products, neutron detectors that rely on the absorption of prompt gamma-ray emissions suffer a higher signal loss because of reaction products escaping the detector and, thus, the detection efficiency is reduced. Further, at the prompt emission energies of 558.6 keV and 651.3 keV, the most probable gamma-ray interaction in detectors is Compton scattering, which produces a continuum of energies that can be difficult to distinguish from background gamma rays that undergo Compton scattering in the detector and surroundings.

17.2.6 The ^{199}Hg Neutron Reaction

The element Hg is also an interesting material for neutron detection. It has one strongly neutron reactive isotope, ^{199}Hg, with a thermal-neutron (n,γ) cross section of 2150 b (see Fig. 17.2).[8] The density of natural Hg is 13.534 g cm^{-3}, with a ^{199}Hg natural abundance of 16.94%, and has a natural Hg macroscopic thermal-neutron (n,γ) cross section of 14.80 cm^{-1}. As with ^{157}Gd and ^{113}Cd, enriched ^{199}Hg is rare and not an economically practicable option. Hg is a toxic liquid at room temperature, which causes additional handling

[8] The naturally occurring isotope ^{196}Hg has an even larger thermal-neutron (n,γ) cross section of 3079 b, but its small natural abundance of 0.15% has negligible effect on the ability of Hg to absorb thermal neutrons. The five other naturally occurring isotopes of Hg have thermal cross sections of, at most, a few barns.

problems.[9] Detectors that use ^{199}Hg as the neutron reactive material are usually a room temperature solid compound or alloy of Hg.

Similar to the ^{113}Cd(n,γ)^{113}Cd reaction, there are numerous gamma-ray emissions from the ^{199}Hg(n,γ)^{200}Hg reaction; however, there is one prominent gamma-ray emission of interest at 368.1 keV [Lone et al. 1981; Tuli 1997] with a branching ratio of 81.35%. When Hg is coupled with a high resolution gamma-ray spectrometer, the 368.1-keV energy peak can be used as a measure of neutron interactions. Note that this prompt gamma-ray emission energy is low enough to have a reasonably high probability of being fully absorbed in the detector, which works to improve the visibility of a full energy peak. However, this spectral feature can still overlap with background gamma-ray spectra, thereby making measurements difficult to analyze.

17.2.7 Fission Reactions

Fissile materials are also used as neutron detection materials, primarily in gas-filled proportional counters named "fission chambers". Fissile materials, such as ^{235}U and (rarely) ^{239}Pu, are also used for slow neutron detectors (see Fig. 17.3). The fission reaction releases approximately 200 MeV of energy, approximately 150 MeV of which is transferred to the heavy charged particle reaction products. Unlike other reactions described in this chapter, these reaction products vary, with over 100 possible reaction products emitted after a fission reaction. However, the reaction products generally fall into a low energy branch and a high energy branch, centered near 60 MeV and 90 MeV, respectively.

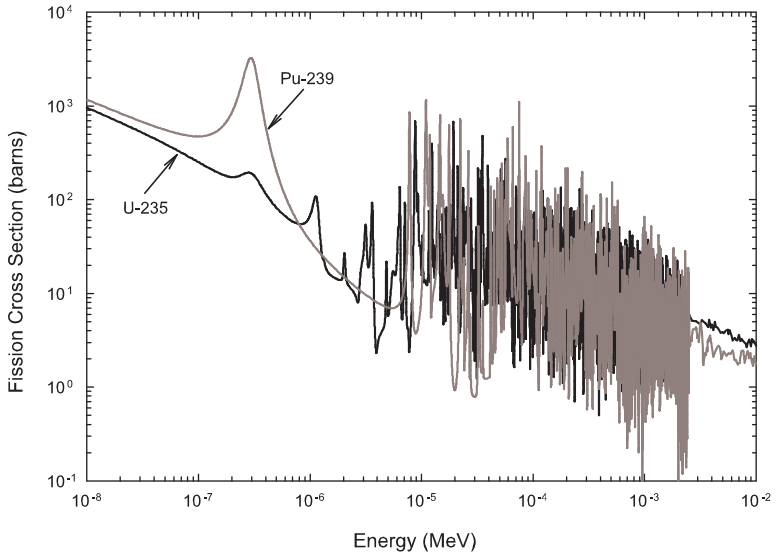

Figure 17.3. Neutron fission cross sections in barns for materials used in slow neutron fission chambers, ^{235}U and ^{239}Pu [data are from ENDFPLOT, 2015].

The 2200 m/s thermal-neutron fission cross section for ^{235}U is 585.0 barns, although the fission plus capture thermal-neutron absorption cross section is higher at 683.7 barns. The nuclide ^{235}U is also radioactive with a halflife of 7.038×10^8 years, and decays by alpha-particle and gamma-ray emission. The gamma-ray emissions have energies of 143.76 keV, 185.72 keV, and 204 keV with branching ratios of 11%, 55%, and 5%,

[9] Many organic compounds of Hg are extremely toxic.

respectively. Principal alpha particles are emitted with energies of 4.366 MeV, 4.398 MeV, and 4.58 MeV with branching ratios of 18%, 57%, and 8%, respectively. Consequently, detectors fashioned with ^{235}U as the neutron reactive converter always have an intrinsic radiation background. However, the signal produced by the fission reaction is enormous by comparison to signals produced by the background radiations; hence these background signals can usually be rejected by a discriminator circuit when operated in pulse mode, and they add very little to the output current if the detector is operated in current mode. The main advantage of using fissile materials for neutron detection is the large output signal per event that can stand out in the midst of a high radiation background.

Slow neutron detectors based on fission reactions are usually not fabricated with highly enriched ^{235}U, but instead with natural U or low enriched ^{235}U. Hence, a large constituent of the material is ^{238}U, which is fissionable but not fissile. ^{238}U has a long half life of 4.468×10^9 years, and decays mainly by alpha-particle emission with energies of 4.15 MeV (25%) and 4.20 MeV (75%). Slow neutron capture in ^{238}U, with a thermal-neutron capture cross section of 2.684 barns, can transmute into ^{239}U ($T_{1/2} = 23.47$ minutes) which upon beta particle decay creates ^{239}Np ($T_{1/2} = 2.345$ days) and upon another beta particle decay, eventually into fissile ^{239}Pu. Hence, a detector with a proper mixture of ^{235}U and ^{238}U can be used to prolong the useful detector life through neutron transmutation of ^{238}U into ^{239}Pu.

The thermal-neutron fission cross section for ^{239}Pu is 747.4 barns, although the total thermal-neutron absorption cross section is slightly higher at 1017.5 barns due to a thermal-neutron capture cross section of 270.1 barns. A cross resonance at 0.295 eV yields a fission cross section of 3258 b (see Fig. 17.3). ^{239}Pu is radioactive with a halflife of 2.411×10^4 years, and decays mainly by alpha-particle decay (5.105 MeV at 11% and 5.156 MeV at 88%), although there are also several gamma-ray and conversion electron emissions with low branching ratios. Hence, an intrinsic radiation background component gradually increases with detector use. As with ^{235}U, the fission products produce much larger signals than the background alpha particle radiations, and can be easily discerned with a discriminator circuit.

17.3 Gas-Filled Slow Neutron Detectors

Gas-filled slow neutron detectors can be generally classified as one of two types: those that use neutron reactive gases and those that use conventional proportional gases with a solid neutron reactive material inside the detector. Grosshoeg [1979] provides a review describing the origins of these detectors. There are two main types of neutron detectors that are backfilled with either of two neutron reactive gases, namely ^{3}He gas or $^{10}BF_3$ gas. There are several variants for gas-filled detectors having internal components composed of solid neutron reactive materials, including detectors based on ^{10}B, ^{6}Li, or ^{235}U materials. In all of these detectors, slow neutrons react with the neutron absorbing material and induce currents from the charged-particle reaction products with energies much greater than the kinetic energy of the slow neutrons. These large reaction Q-values mask the small kinetic energies of slow neutrons and, hence, do not preserve the original information of the neutron energy. Consequently, they cannot be used directly as neutron spectrometers, but rather they serve as neutron counters. However, spectral features of the reaction products do play an important role in neutron detection, mainly, the pulse height spectra allow the user to set the discriminator at an acceptable level to remove background signals while optimizing the neutron response.

17.3.1 Detectors with Neutron Absorbing Fill Gases

The class of detectors containing neutron reactive gases all have similar energy deposition features, a consequence of *wall* and *end* effects. Gas pressure and detector volume strongly affect the limiting neutron detection efficiency in these detectors. Increased pressure generally increases the probability of absorption, although it may also affect signal proportionality and response speed. Further, these detectors are also

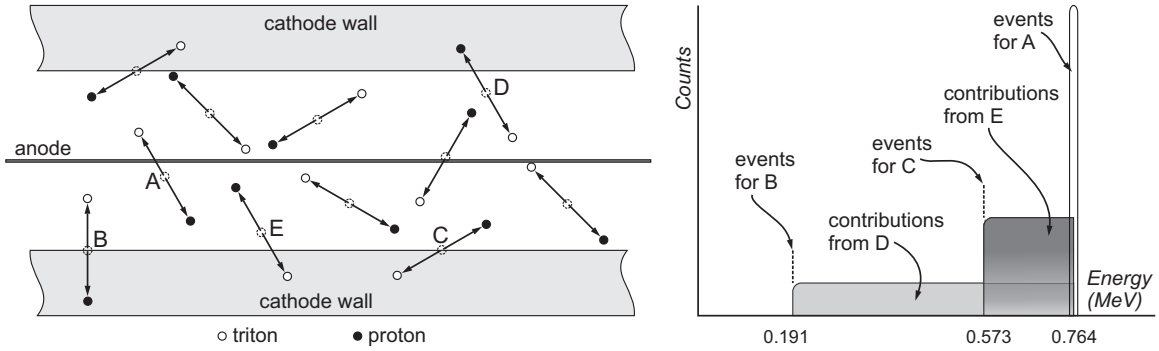

Figure 17.4. (left) Trajectories of reaction products that cause the appearance of the wall effect. (right) Contributions to the pulse height spectrum for the various trajectories. See the text for an explanation of the consequences.

relatively radiation hard and temperature resistant so they are able to operate at elevated temperatures and higher neutron fluxes than other neutron detectors.

^{3}He Gas-Filled Detectors

^{3}He detectors were originally introduced in 1952 [Batchelor 1952; see also Batchelor et al. 1956] and are presently the most popular commercially available neutron detectors. These detectors are operated in the proportional region of the gas pulse-height curve (see Fig. 10.1). Because ^{3}He is a rare and expensive gas, these detectors are not available as gas-flow proportional counters. Instead, they are generally designed as hermetically sealed coaxial detectors. The detection method is straightforward. Neutrons enter the gas volume and are absorbed by the ^{3}He to produce a compound nucleus, which spontaneously decays by emitting two energetic charged-particle reaction products. The two reaction products pass through the gas and produce electron-ion pairs. The electrons rapidly drift towards the anode and create a Townsend avalanche. The drifting motion towards the cathode of the positive ion cloud from the avalanche induces current to flow which is transformed into a voltage pulse by the attached amplification circuitry.

Wall Effect Neutron interactions can occur randomly within the ^{3}He detector, and in some of these cases, the interaction occurs near the chamber cathode wall. If a reaction product strikes the wall, its residual kinetic energy is deposited in the wall rather than the gas and does not contribute to gas ionization. Hence, the resulting amplitude of the output pulse is reduced below that of that for a full energy deposition event. Consequently, there are certain spectral features that are intrinsically observed from a ^{3}He gas-filled detector, primarily a consequence of this *wall effect*.

Shown in Fig. 17.4 are various possible reaction product trajectories in a ^{3}He detector that form the main wall effect features. Trajectory A represents cases in which a neutron is absorbed in the gas and both reaction products deposit all of their initial kinetic energy in the gas volume. Reactions like type A form a full energy peak in the pulse height spectrum. Trajectories B and C represent cases in which the neutron is absorbed next to the cathode wall and only one of the reaction products enters the gas, while the other reaction product deposits all of its energy in the wall. Cases B and C form the limiting *minimum* energy cases for each reaction product type and produce a stairstep feature in the pulse height spectrum. Because each reaction product has a different energy, there are two such stairstep features that appear at the triton energy (0.573 MeV) and at the proton energy (0.191 MeV). Trajectories D and E represent those cases in which the neutron is absorbed near the cathode wall and all of one reaction product energy is absorbed in the gas, while only part of the other reaction product energy is absorbed in the gas before striking the wall. Cases D and E fill in the wide range of possibilities between the limiting cases of partial energy deposition B and C and that of full energy deposition A. Hence, cases for D and E produce a continuum of energies in the

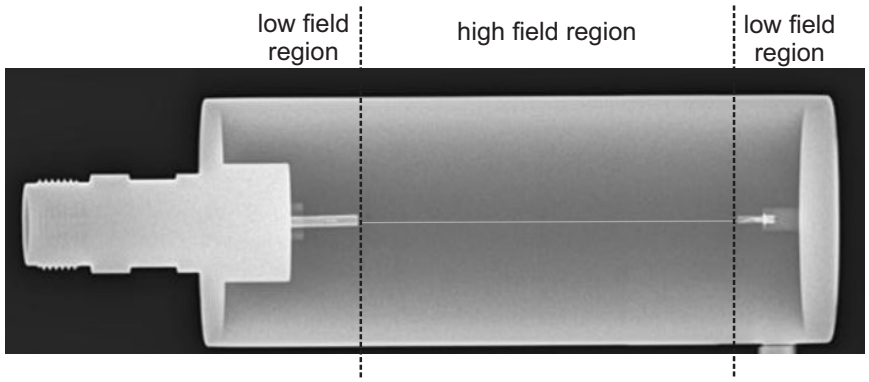

Figure 17.5. X-ray image of a sealed ^{3}He gas-filled neutron detector. The detector gas chamber is 13 cm long; however, only 8 cm of that length are in the high field region.

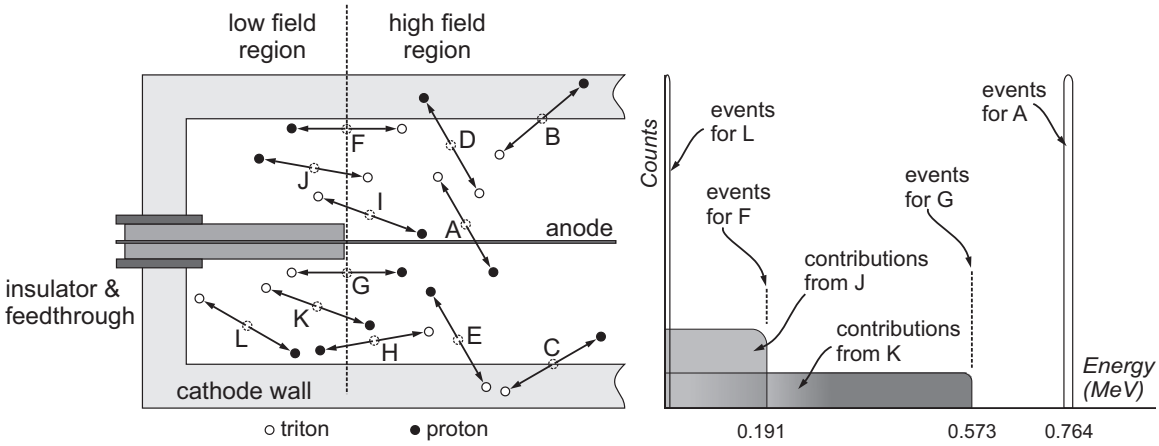

Figure 17.6. (left) Reactions produce trajectories that cause the appearance of both the end effect and the wall effect. (right) Additional features that appear in the pulse height spectrum from the end effect. See the text for an explanation of the consequences.

pulse height spectrum between the limiting minimum energy and the full energy peak. The wall effect forms a "valley" between the radiation background (and electronic noise) and the neutron reaction pulse height spectrum and is a natural location to set the lower level discriminator (LLD).

End Effect The wall effect appears in a spectrum regardless of the geometry for a ^{3}He detector if any portion of it is placed in a neutron field. However, if the detector is entirely immersed in a neutron field, another effect, which is often called the *end effect*, can also be observed. Many gas-filled proportional counters have long insulating stand-offs or field tubes at the ends designed to reduce leakage current, arcing, and spurious counts (see Fig. 17.5). These structures reduce the electric field below the critical field strength necessary for impact avalanche ionization. Hence, these low field regions operate more like an ion chamber instead of a proportional counter. Ionization produced in the low field region appears in the lower energy spectral channels and usually does not contribute to the output signal.

Included in Fig. 17.6 are additional reaction product trajectories that produce the end effect. Trajectories H and I are cases in which a neutron reaction occurs in the high field region near the low field region, in

which one particle deposits some energy in the low field region and the other particle deposits all energy in the high field region. Hence, the low field region forms a virtual wall effect, essentially having the same effect as cases D and E. Similarly, the trajectories of F and G have the same effect as cases B and C. Additional effects, however, are from trajectories J and K, along which a neutron is absorbed in the low field region and only one particle emerges into the high field region. The case is analogous to the self-attenuation effect observed with neutron reactive coatings. Variations of cases J and K produce a continuum of energies in the pulse height spectrum ranging from zero up to each of the reaction product energies (either 0.191 MeV or 0.573 MeV), thereby forming a reverse stair step spectrum from that of the wall effect (see Fig. 17.6). Finally events described by trajectory L are essentially lost. The added counts appear in the pulse height spectrum in the low energy valley (or gap) region between the background counts and the wall effect spectrum. Further, the end effect adds pulses to the lower portion of the wall effect spectrum, consequently enhancing that part of the spectrum. The main spectral features expected from a combination of the wall and end effects are depicted in Fig. 17.7.

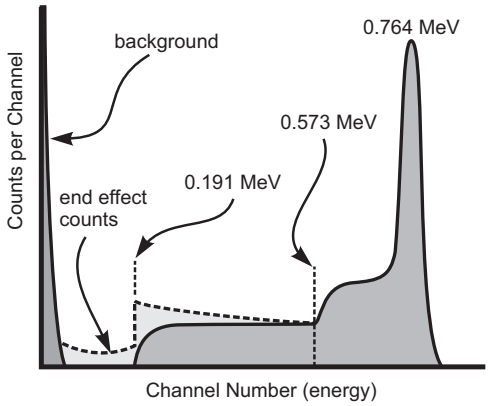

Figure 17.7. Depiction of the main features expected in a pulse height energy spectrum from a ^{3}He gas-filled neutron detector. End effect counts are depicted in light gray.

The end effect is less likely to appear in detector configurations in which a beam of neutrons is incident perpendicularly to the cylindrical side of the detector. However, for detectors operated in a radiation field in which neutrons interact more or less uniformly over the detector volume, the end effect is likely be observed. Shown in Fig. 17.8 are two spectra for different irradiation conditions. The gray spectrum is the result of a collimated thermal-neutron beam intersecting perpendicular to the central region of the detector of Fig. 17.5. In this spectrum, features of the main wall effect are discernible, but end effect features are absent. The white spectrum of Fig. 17.8 is a summed composite in which the collimated thermal-neutron beam was stepped along the detector length at 5 mm intervals from the end to end, which shows the combined spectral features from both the end and wall effects.

Both the wall effect and end effect features increase with surface to volume ratio of a detector. Hence, both of these effects become less prominent for large volume ^{3}He detectors. However, the spectral energy resolution of larger detectors is usually lower than smaller counterparts.

$^{10}BF_3$ Gas-Filled Detectors

Another gas of interest for neutron detection is BF_3, introduced in 1939 [Korff 1939; Korff and Danforth 1939; see review by Wilpert 2012]. Neutrons interact with the ^{10}B and cause the spontaneous ejection of the reaction products of Eq. (17.18). These reaction products ionize the host gas, $^{10}BF_3$, in the same manner as reaction products emitted in a ^{3}He detector. To increase interaction efficiency, modern BF_3 detectors usually have an enrichment of about 96% in $^{10}BF_3$.

Much like ^{3}He gas-filled detectors, $^{10}BF_3$ gas-filled proportional counters also show wall and end effects in the pulse height spectra. Because there are two reaction product branches, there is the possibility of observing four wall effects features, as shown in Fig. 17.9. However, the energy resolution of a $^{10}BF_3$ usually is not adequate to clearly define the 6% branching ratio wall effect features at 1.05 MeV and 1.78 MeV (see Fig. 17.10). The resulting pulse height spectrum is formed from the reaction products and is not defined by the energy of the absorbed neutrons. However, good spectral energy resolution assists with defining an appropriate location for the LLD, thereby allowing pulse height discrimination between neutron and

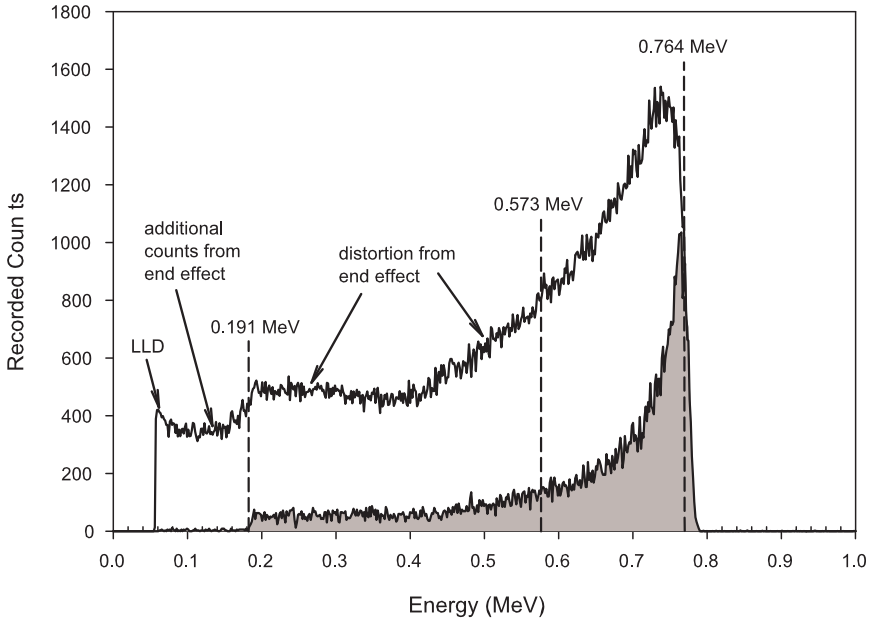

Figure 17.8. Comparison of pulse height spectra from a ^{3}He gas-filled neutron detector irradiated with a thermal-neutron beam directed perpendicular through the center (gray) and a composite spectrum from neutron irradiations at incremental positions along the length (white). The detector was a 2 inch diameter, 6 inch long ^{3}He detector pressurized to 4 atm, which had insulating standoffs >2 cm long at each end. Both wall and end effects are apparent in the composite spectrum.

gamma-ray events. For most applications, the LLD is set in the valley between the wall effect features and the background counts (see Fig. 17.9).

The pressure of the BF_3 gas affects the observed energy resolution of the detector, and ultimately works to limit the maximum neutron detection efficiency. A study by Fowler [1963] clearly showed spectral deterioration as BF_3 gas pressure was increased from 0.131 atm (or 13.33 kPa) up to 0.789 atm (80 kPa), in which the 94% full energy peak FWHM broadened from 8% up to 56%. Although the detector continued to register counts at the higher pressures, the energy resolution was poor, which under some circumstances remains important for neutron detection. Described by Fowler [1963], the best performance was observed for backfill pressures near 0.26 atm (26 kPA). Unfortunately, at these low pressures, the advantage of using the high absorption of $^{10}BF_3$ gas is compromised, yielding typically lower efficiencies than observed with common ^{3}He gas-filled detectors.

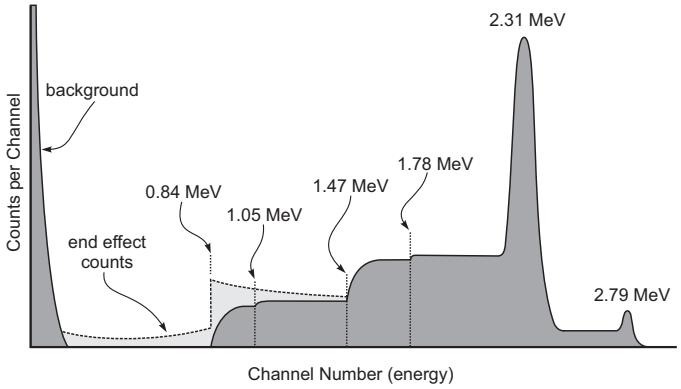

Figure 17.9. Depiction of the main features expected in a pulse height spectrum from a $^{10}BF_3$ gas-filled neutron detector. End effect counts are depicted in light gray.

The efficiency of a BF_3 gas-filled detector can be estimated by calculating the total neutron absorption in the ^{10}B gas region within the active volume of the detector [Sampson and Vincent 1971],

$$\epsilon(E) = \prod_{i=1}^{M} e^{-x_i \Sigma_t^i(E)} \left[\frac{\Sigma_a^{^{10}\mathrm{B}}(E)}{\Sigma_t(E)} \right] (1 - e^{-L\Sigma_t(E)}), \tag{17.26}$$

where $\Sigma_t^i(E)$ and x_i denote the macroscopic total cross sections and thicknesses of the ith ($i = 1 \ldots M$) non-sensitive regions, L is the length of the sensitive BF_3 gas volume, and where

$$\Sigma_t = \Sigma_a^{^{10}\mathrm{B}} + \Sigma_s^{^{10}\mathrm{B}} + \Sigma_t^{^{11}\mathrm{B}} + \Sigma_t^{\mathrm{F}} + \Sigma_t^{\mathrm{Ar}} \tag{17.27}$$

with t, s, and a denoting the total, scattering, and absorption cross sections of the homogeneous gas components. Note in the approximation of Eq. (17.26), all scattered neutrons are neglected and are assumed not to produce any subsequent counts.

BF_3 detectors can be acquired with relatively thin entrance windows at one end, which allows the long axis of the detector to be pointed towards the neutron source. Such devices have increased absorption in the sensitive volume and improved detection efficiency. However, many BF_3 detectors are designed with thick end caps, along with relatively large insulating standoffs for the central wire, thereby producing significant dead regions at the ends. Consequently, pointing such a device towards the neutron source may reduce the count rate and observed detection efficiency. Hence, when modeling a detector for a particular neutron detection application, one must be aware of the orientation of the detector with respect to the neutron source. Most commercial manufacturers do not quote efficiency for BF_3 gas-filled detectors in percent efficiency, but rather as cps/nv (counts per second per unit thermal-neutron flux), and are evaluated with the entire detector irradiated with neutrons incident from all directions, a condition in which Eq. (17.26) is inaccurate and not applicable.

Example 17.1: Consider a 2200-m/s neutron beam of 10-mm diameter intersecting a $^{10}BF_3$ gas-filled detector with the following specifications: 25-mm inner diameter, 2 mm thick Al cylindrical casing, 0.8 atm pressure, 250 mm total length with anode wire insulating standoffs each 20 mm long at the ends. Assume an enrichment of 96% ^{10}B with a fill pressure of 0.8 atm. The density of BF_3 is 2.76 mg cm^{-3} at 1 atm and the molar mass is 67.82 g mol^{-1}. What is the thermal-neutron intrinsic efficiency if the neutron beam intersects perpendicular to the BF_3 detector midsection? Afterwards, if the detector is pointed endwise directly at the neutron beam, what is the thermal-neutron intrinsic detection efficiency?

Solution:
First, determine the macroscopic absorption cross section for the ^{10}B atoms,

$$\Sigma_a^{^{10}\mathrm{B}} = \frac{0.96 P \sigma \rho N_a}{A} = \frac{0.96(0.8 \text{ atm})(3844 \text{ b})(0.00276 \text{ g cm}^{-3})(6.022 \times 10^{23} \text{ mol}^{-1})}{67.82 \text{ g mol}^{-1}}$$
$$= (1.88 \times 10^{19} \ ^{10}\text{B cm}^{-3})(3844 \times 10^{-24} \text{ cm}^2) = 0.0723 \text{ cm}^{-1}$$

The total 2200-m/s cross section of Al is 1.68 b so the macroscopic absorption cross section of Al is,

$$\Sigma_t^{\mathrm{Al}} = \frac{\sigma \rho N_a}{A} = \frac{(1.68 \times 10^{-24} \text{ cm}^2)(2.7 \text{ g cm}^{-3})(6.022 \times 10^{23} \text{ mol}^{-1})}{26.98 \text{ g mol}^{-1}} = 0.101 \text{ cm}^{-1}.$$

Here it is assumed that attenuation from F and ^{11}B in the gas is negligible, i.e., $\Sigma_t \approx \Sigma_a^{^{10}\mathrm{B}}$, and all neutrons absorbed by the ^{10}B in the gas produce a detectable count. Because the beam diameter is small, the incident

neutrons all pass through 0.2 cm of Al to enter the tube. Then from Eq. (17.26)

$$\epsilon = [e^{-x\Sigma_t^{\mathrm{Al}}}][1 - e^{-D\Sigma_a^{^{10}\mathrm{B}}}] = [e^{-(0.2\ \mathrm{cm})(0.101\ \mathrm{cm}^{-1})}][1 - e^{-(2.5\ \mathrm{cm})(0.0723\ \mathrm{cm}^{-1})}] = 0.162.$$

Hence, the maximum intrinsic detection efficiency is 16.2% for a crosswise thermal-neutron beam. Absorption or scattering with the detector tube and F in the gas, along with unfavorable reaction product trajectories, causes the efficiency to be lower than this ideal case.

Turning the detector lengthwise into the beam, the neutron sensitive region is only 210 mm long with 20 mm dead regions at each end,

$$\epsilon = [e^{-x_{\mathrm{Al}}\Sigma_t^{\mathrm{Al}}}][e^{-x_{^{10}\mathrm{B}}\Sigma_a^{^{10}\mathrm{B}}}][1 - e^{-L\Sigma_a^{^{10}\mathrm{B}}}]$$

$$= [e^{-(0.2\ \mathrm{cm})(0.101\ \mathrm{cm}^{-1})}][e^{-(2\ \mathrm{cm})\ (0.0723\ \mathrm{cm}^{-1})}][1 - e^{-(21\ \mathrm{cm})(0.0723\ \mathrm{cm}^{-1})}] = 0.662.$$

yielding 66.2% intrinsic thermal-neutron detection efficiency.

Although ^{10}B is a $1/v$ neutron absorber with a relatively high thermal neutron absorption cross, the absorption efficiency for epithermal neutrons is quite low. The efficiency for these higher energy neutrons can be increased by increasing the gas pressure, but pressurizing the gas above about 1 atm unfortunately compromises detector performance and energy resolution; hence, it is usually avoided. Consequently, most BF_3 detectors are limited mainly to slow neutron detection.

Argon gas is sometimes added to BF_3 gas-filled detectors, mainly because the Ar (a common proportional gas) helps preserve the spectral energy resolution [Fowler, 1963; Padalakshmi and Shaikh 2008]. Most commercial detectors have significantly more Ar gas in the detector tube than actual $^{10}BF_3$ gas and have pressure ratios greater than about 40:1 Ar:BF_3. The addition of Ar reduces the avalanche voltage, decreases the gas multiplication and shifts the counting plateau to lower voltages. For instance, as detailed by Padalakshmi and Shaikh [2008], the addition of 100 torr Ar to a vessel filled with 10 torr BF_3 effectively reduced the average ionization energy from 35.5 eV for pure BF_3 gas down to 26.8 eV for the mixtures of BF_3 and Ar mixture. Hence, equivalent avalanche gains appear at much lower operating voltages for the BF_3 and Ar mixture at 110 torr than for the pure BF_3 gas at 10 torr, despite the total gas pressure being increased by more than a factor of 10. Further, the onset of the high voltage counting plateau was observed to decrease for the BF_3 and Ar mixtures below that observed for the pure BF_3 gas samples. Padalakshmi and Shaikh [2008] note that excellent resolution and stable operating performance was observed for mixtures between 600–800 torr Ar and 100 torr BF_3. Fowler [1963] notes that the increased pressure of a BF_3 and Ar mixture suppresses the wall effect while retaining good energy resolution.

An increase in the pressure of the BF_3 within the gas chambers increases the probability of neutron absorption (and detection efficiency), but also causes the maximum gain of the detector to decrease as a function of voltage. For instance, Fowler [1963] reports an avalanche gain of 100 achieved with 1000 volts bias for 10 torr BF_3, but to achieve the same gain at 600 torr BF_3 required a bias of 6000 volts. Further, electron attachment and columnar recombination become problematic at higher pressures and ultimately cause the formation of smaller electronic signals. Although BF_3 and Ar mixtures can be adjusted to achieve optimal results at a given total pressure, the general trend indicates that at a set applied voltage the avalanche gain decreases with BF_3 partial pressures above 10 torr, and increasing the BF_3 pressure also causes degradation in spectral energy resolution. Typical pressures average about 600 torr for commercial BF_3 detectors, but detectors can be acquired with pressures ranging from 100 torr up through 1300 torr.

As with most proportional counters, BF_3 detectors have dead times on the order of tens of microseconds, which ultimately limits the practical pulse mode count rate to less than about 2×10^4

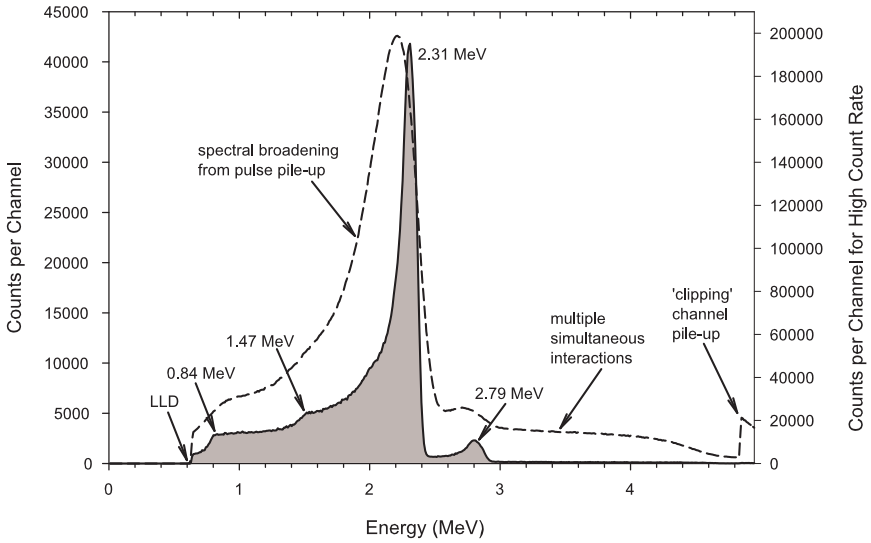

Figure 17.10. Pulse height spectrum from a $^{10}BF_3$ gas-filled neutron detector at low (shaded region) and high (dotted line) neutron interaction rates. The detector was irradiated with a collimated thermal-neutron beam intersecting the mid-section; hence, end effects are not apparent. The wall effect features at 1.05 MeV and 1.78 MeV are not easily discernible.

cps before dead time issues become troublesome. At low count rates with low probability of pulse pile-up, the spectral features remain recognizable. However, as the count rate increases, the spectral features become smeared because of multiple coincident events distorting the pulse height spectrum, as shown in Fig. 17.10. Another feature of BF_3 detectors is that the gas becomes exhausted over an extended operation time. Qian et al. [1998] report performance degradation due to gas depletion appearing for total neutron interactions in the detector gas between 10^{10} and 10^{11}. Depending on the size of a BF_3 detector, typical operating voltages may range from 500 volts for small diameter detectors (about 12 mm) up to 3000 volts for some large diameter detectors (about 50 mm). Also, usually quoted operating temperatures range from -50 °C to 100 °C. Operating the detectors at much higher temperatures than room temperature degrades energy resolution, and in some cases, at elevated temperatures, appears to cause irreversible damage.

BF_3 gas is designated as a level 3 health hazard by the National Fire Protection Association (NFPA 704). This classification means that short exposure to the gas can cause serious temporary or residual injury. Many organizations have abandoned the use of $^{10}BF_3$ primarily because of the health risks. Because of the toxic nature of BF_3 gas, the government has imposed special restrictions on the transport of these devices; however, because $^{10}BF_3$ detectors are an important type of neutron detector, there is not a complete ban on the shipping of certain types of these detectors. The International Air Transport Association (IATA) Special Provision A190 permits the aircraft shipment of BF_3 detectors containing more than 1 gram up to 12.8 grams of BF_3 and filled to pressures no more than 105 kPa absolute at 20°C. It also applies to radiation detection systems containing up to 51.2 grams of BF_3. The U.S. Department of Transportation (DOT) special provision 238 basically reiterates the same provisions. Overall, these detectors must be packed in a sealed plastic bag or plastic liner along with an absorbent capable of absorbing all of the gas contained in the detectors should the gas detector leak during transportation. Detector manufacturers can obtain special transport permits for detectors with higher BF_3 mass and gas pressures than allowed by IATA SP A190 or DOT SP 238.[10]

17.3.2 Detectors with Neutron Reactive Coatings and Layers

The class of neutron detectors that incorporate reactive materials as coatings on the walls, or reactive inserts inside the gas container, are often called coated neutron detectors. This term actually applies to variations

[10]IATA SP A190 and DOT SP 238 were still effective at the time of writing this book.

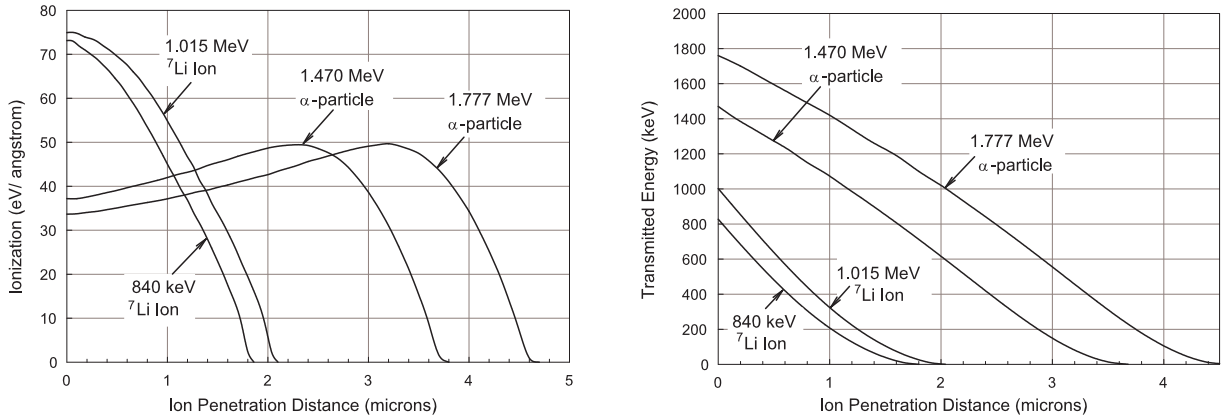

Figure 17.11. (left) The Bragg ionization curve for pure ^{10}B material, showing the specific ionization of ^{10}B(n,α)^{7}Li reaction products as they pass through the material. (right) The residual energy retained by ^{10}B(n,α)^{7}Li reaction products as they pass through pure ^{10}B material [from McGregor et al. 2003].

of coated gas-filled, scintillator, and semiconductor neutron detectors, and the basic analysis applies to all, with minor differences.

It is important to note that the charged particles have discrete ranges within a material, and they lose energy as a function of the specific stopping power of the material through which they pass. Charged particle energy loss is not linear with distance, and the energy loss for high-energy heavy charged particles can generally be described by Eq. (4.147). For non-relativistic particles this equation reduces to

$$-\frac{1}{N}\frac{dE}{dx} = \frac{4\pi z^2 e^4}{4\pi\epsilon_o^2 m_e v^2} Z \ln\left(\frac{m_e v^2}{\overline{I}}\right), \tag{17.28}$$

in which ze is the charge of the heavy ion, $v(x)$ the speed of the charged particle after traveling a distance x, N is the atomic density, m_e is the rest mass of an electron, Z is the material atomic density, and $\overline{I}$ is an experimentally determined mean excitation energy describing the average excitation potential of a representative atom in the material.

Although the average range is treated as constant, the actual range fluctuates from particle to particle because of deviations in the number of Coulombic scatters per unit distance and deviations in energy loss per collision. The fluctuation may exceed 5% of the total range, and this fluctuation is referred to as the straggle in the particle range. Recall from Fig. 4.26, R_p is the mean or average range and $R_e > R_p$ is the extrapolated range. The slope of the fraction reaching R_p is $1/(\alpha\sqrt{\pi})$ so that the two ranges are related by

$$R_p = R_e - \frac{\sqrt{\pi}}{2}\alpha. \tag{17.29}$$

A Bragg curve is a plot of the ionization versus penetration distance, averaged over a large number of individual identical source ions. Let $I(x)$ be the Bragg curve ordinate, i.e., the average ionization per unit differential path length at a distance x from the source. Then $I(x)$, accounting for straggling, is [Evans 1955]

$$I(x) = \int_x^\infty \frac{i(r-x)}{\alpha\sqrt{\pi}} \exp[(R_p - r)/\alpha]^2 \, dr, \tag{17.30}$$

where $i(r-x)$ is the specific ionization (LET) along the path of an individual particle at a distance $(r-x)$ from the *end* of its path, and x is the distance an individual particle is from the source. An interesting

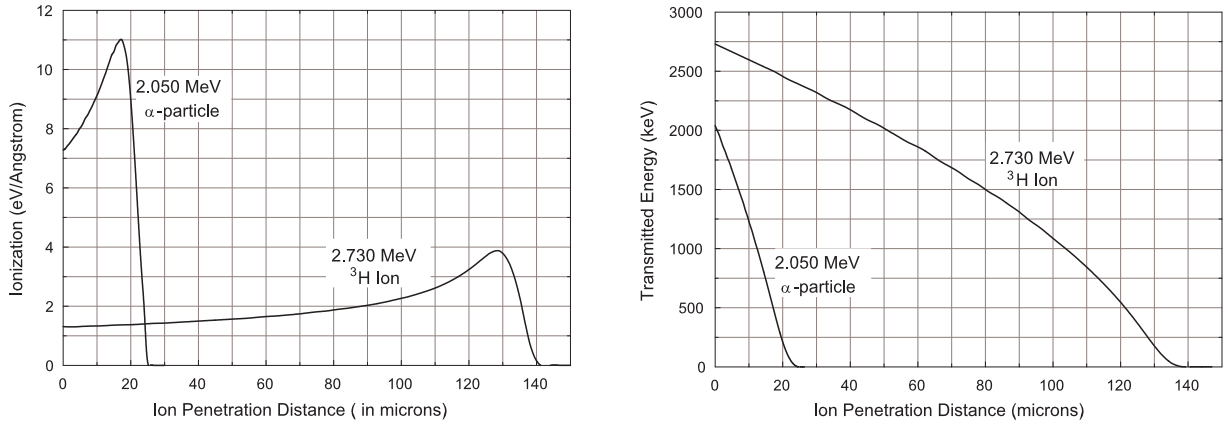

Figure 17.12. (left) The Bragg ionization curve for pure ^{6}Li metal, showing the specific ionization of ^{6}Li(n,t)^{4}He reaction products as they pass through the metal. (right) The residual energy retained by ^{6}Li(n,t)^{4}He reaction products as they pass through pure ^{6}Li metal [from McGregor et al. 2003].

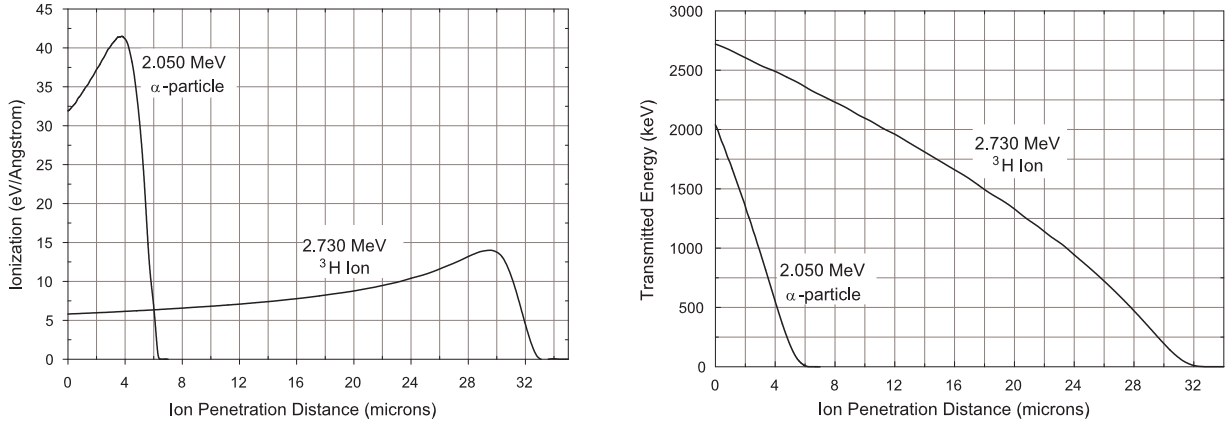

Figure 17.13. (left) The Bragg ionization curve for pure ^{6}LiF material, showing the specific ionization of ^{6}Li(n,t)^{4}He reaction products as they pass through the material. (right) The residual energy retained by ^{6}Li(n,t)^{4}He reaction products as they pass through pure ^{6}LiF material [from McGregor et al. 2003].

characteristic of the Bragg ionization curve for alpha (α) particles is the increase in columnar ionization per unit volume as the ion energy decreases. Hence, the highest density of electron-hole pairs is excited near the end of the range for α-particles.

In the present treatment the average effective range, denoted by $\overline{L}$, is the distance through which an ion may travel within the neutron reactive film before its energy decreases below the set minimum detectable threshold, typically defined by the electronic lower-level-discriminator (LLD) setting. The effective range $\overline{L}$ does not take into account additional energy losses from contact "dead regions". $\overline{L}_{SR}$ and $\overline{L}_{LR}$ denote the average effective ranges for the short-range and long-range reaction products, respectively. The graphs of Fig. 17.11, Fig. 17.12, and Fig. 17.13 can be used to determine the reaction product effective ranges as a function of LLD for pure enriched ^{10}B, ^{6}Li, and ^{6}LiF, respectively.

Neutrons may interact anywhere within the reactive film. From Fig. 17.11, Fig. 17.12, and Fig. 17.13, it is apparent that the reaction products also lose energy as they move through the reactive film, thus limiting the energy that can be transferred to the detector gas (or semiconductor material). The finite specific energy loss in the reactive film limits the usable film thickness that can be deposited on the walls of the gas chamber or over the semiconductor device. The voltage signal measured is directly proportional to the number of ion pairs created within the detector gas or semiconductor. Reaction products that deposit most or all of their energy in the active volume (the gas or semiconductor where ionization is recorded) produce much larger voltage signals than those reaction products that lose most of their energy in the surface films and contacts.

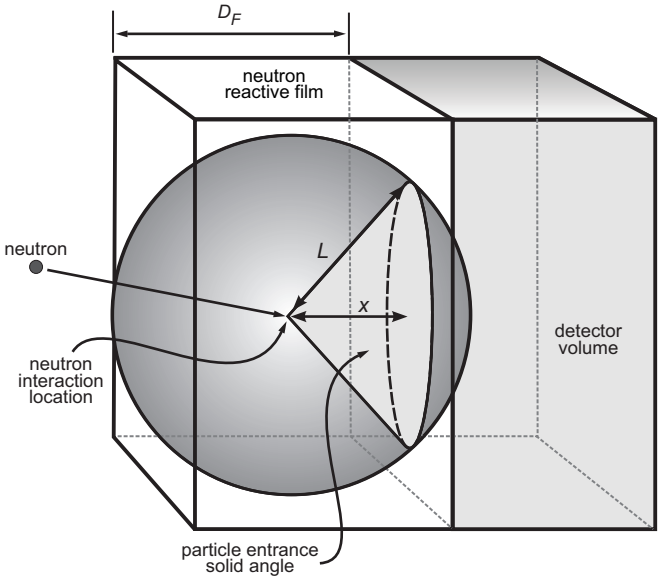

Figure 17.14. The solid angle formed by a reaction product range that subtends the detector at the interface determines the neutron detection probability.

The neutron flux transported through the film a distance x, ignoring neutron scattering, is

$$I(x) = I_o \exp[-x\sigma_a N_a] = I_0 \exp[-x\Sigma_a]. \quad (17.31)$$

where I_0 is the initial neutron flux, N_a is the atomic density of the neutron reactive isotope in the film, σ_a is the microscopic thermal-neutron absorption cross-section of the film, and Σ_a is the film macroscopic thermal-neutron absorption cross section. The fraction of neutrons absorbed in the film while traveling a distance dx about x is,

$$p(x)dx = \Sigma_a \exp[-x\Sigma_a]dx. \quad (17.32)$$

Besides the attenuation of neutrons as they travel in the reactive film, the reaction products are also attenuated as they traverse the reactive film. This ion self-attenuation depends on the ion emission angle with respect to the normal of the film. Once a neutron is absorbed and the reaction products are emitted, the probability that a reaction product enters the detector is determined by the solid angle subtending the surface within the average effective range $\overline{L}$ of the reaction particle. From Fig. 17.14, a neutron interaction taking place at distance x from the semiconductor surface has a probability of entering the active volume equal to the fractional solid angle that subtends the detector, i.e.,

$$p_{\rm p}(x) = \frac{\Omega(x)}{4\pi} = \frac{2\pi}{4\pi}\left(1 - \frac{x}{\overline{L}}\right) = 0.5\left(1 - \frac{x}{\overline{L}}\right), \quad x \le \overline{L}, \quad (17.33)$$

where the subscript "p" refers to the reaction ion of interest. Because the reactions of interest in the present work release two different reaction products per event, the total probability of detecting a neutron reaction consists of adding the detection probabilities of both reaction products. Note that at some interaction locations only one reaction product may be able to reach the active volume of the detector.

Efficiency Analysis for Detectors with ^{10}B, ^{6}Li, or ^{6}LiF Coatings

First consider a simple case. Suppose a layer of neutron reactive material is placed within gas-filled detector upon an inside surface, as depicted in Fig. 17.15. The thermal-neutron reactive materials ^{10}B and ^{6}Li emit these reaction products in opposite directions; hence, only one of the particles can enter the detector gas. The neutrons may be absorbed in the neutron reactive coating on the entry side of the detector (cases A, C,

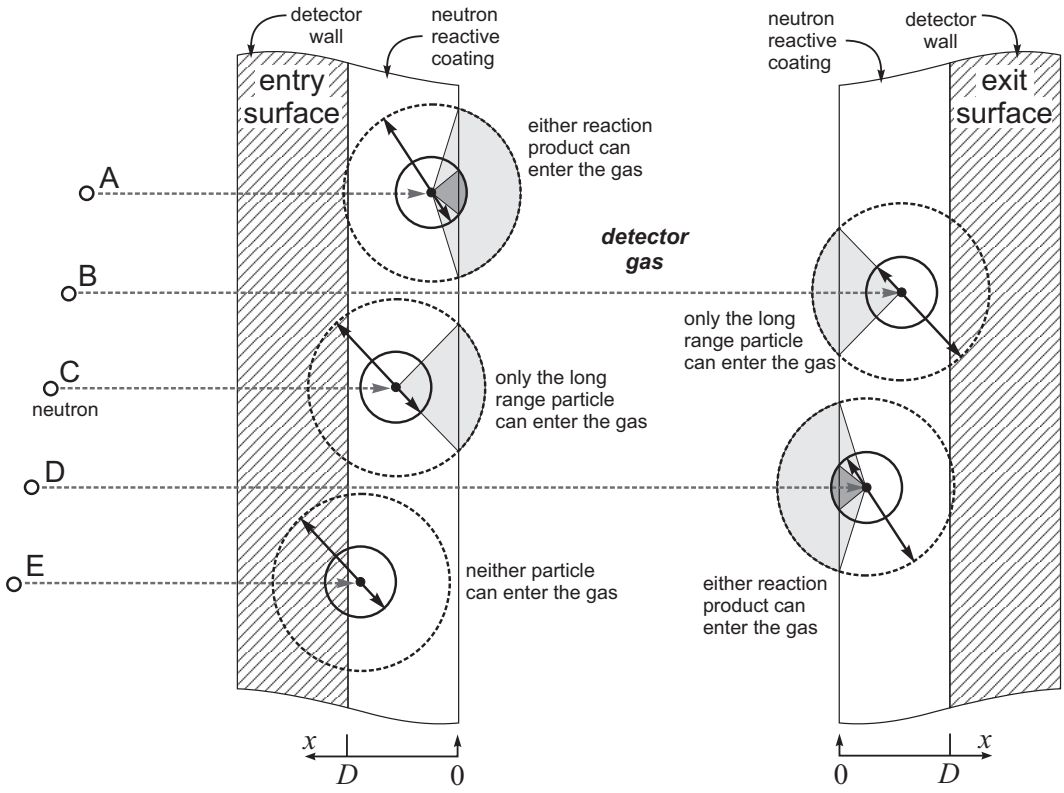

Figure 17.15. Escape of reaction products from a neutron reactive film coating inside the gas-filled region of a detector.

and E in Fig. 17.15), or may pass through and become absorbed in the neutron reactive coating on the exit side of the detector (cases B and D in Fig. 17.15), or may pass through the detector without being absorbed.

Consider cases in which neutrons interact with the coating on the entrance side in the gas-filled detector. Because the reaction products are emitted in opposite directions for thermal neutron absorptions, only one reaction product per event can enter the detector active region. Each reaction product can be analyzed separately and the results are subsequently summed to determine the total detection efficiency. Situation A in Fig. 17.15 depicts the case in which either reaction product can enter the gas region of the detector, and situation C depicts the case in which only the long range reaction product can reach the detector gas. Situation E depicts that case in which neither reaction product can reach the active volume of the detector. Note that the calculation must account for any neutron interactions in the detector wall, because those neutrons are lost before entering the detector and, consequently, reduce the overall detection efficiency.[11]

For the coordinate orientation for the entry surface shown in Fig. 17.15, Eq. (17.32) and Eq. (17.33) are multiplied and integrated over the coating thickness D to find the efficiency for each reaction product. Here the neutrons are assumed to be normally incident on the wall. Also the wall/coating interface is placed at

[11] Actually, some wall scattered neutrons do reach the detector gas and may produce a count. Thus, the analysis in this section, which treats a scatter as an absorption, represents a lower bound on the detector efficiency.

$x = 0$ so that $y = D - x$. If the overall coating thickness D is less than the reaction product effective range $\overline{L}$, the sensitivity contribution (or probability of entering the detector gas or semiconductor) of that reaction product is,

$$S_P(D) = \frac{F_p}{4\pi} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \int_0^D 2\pi\Sigma_a e^{-\Sigma_a(D-x)} \left(1 - \frac{x}{\overline{L}}\right) dx,$$

$$= 0.5F_p \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \left[\left(1 + \frac{1}{\Sigma_a \overline{L}}\right)(1 - e^{-\Sigma_a D}) - \frac{D}{\overline{L}}\right], \quad D \le \overline{L}, \tag{17.34}$$

where F_p is the branching ratio of the reaction product, Σ_t^i and T_i denote the different material total thermal macroscopic cross sections and thicknesses of those materials through which neutrons must pass before encountering the reactive coating, M is the number of these materials encountered, D is the thickness of the reactive coating, Σ_a is the macroscopic thermal-neutron absorption cross section of the reactive coating, and $\overline{L}$ is the effective range of the reaction product.

If the overall coating thickness D is greater than the reaction product effective range $\overline{L}$, the self-absorption neutron losses within the entry coating layer must be included. The sensitivity contribution of that reaction product is, for $D > \overline{L}$,

$$S_P(D) = \frac{F_p e^{-\Sigma_a(D-\overline{L})}}{4\pi} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \int_0^{\overline{L}} 2\pi\Sigma_a e^{-\Sigma_a(D-x)} \left(1 - \frac{x}{\overline{L}}\right) dx$$

$$= 0.5F_p e^{-\Sigma_a(D-\overline{L})} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \left[\left(1 + \frac{1}{\Sigma_a \overline{L}}\right)(1 - e^{-\Sigma_a \overline{L}}) - 1\right]. \tag{17.35}$$

For a cylindrical tube detector, neutrons that do not interact in the coating as they enter the detector may transit the detector gas and interact in the coating on the opposite surface, as shown by cases B and D in Fig. 17.15. These interactions with neutrons interacting with the exit surface of the detector can produce additional detectable events that must be added to the events recorded for interactions with the coating on the entry surface. The analysis is simplified if the axis is reversed, as shown in Fig. 17.15 for the exit surface. Eq. (17.32) and Eq. (17.33) are multiplied and integrated over the coating thickness D to find the efficiency for each reaction product. If the coating thickness D is less than the reaction product effective range $\overline{L}$, the sensitivity contribution of that reaction product is, for $D \le \overline{L}$,

$$S_P(D) = \frac{F_p e^{-\Sigma_a D}}{4\pi} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \int_0^D 2\pi\Sigma_a e^{-x\Sigma_a} \left(1 - \frac{x}{\overline{L}}\right) dx,$$

$$= 0.5F_p e^{-\Sigma_a D} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \left[\left(1 - \frac{1}{\Sigma_a \overline{L}}\right)(1 - e^{-\Sigma_a D}) + \frac{D}{\overline{L}} e^{-\Sigma_a D}\right], \tag{17.36}$$

where losses in the entrance coating are included. If the coating thickness D is greater than the reaction product effective range $\overline{L}$, the sensitivity contribution of that reaction product (also accounting for reaction product losses in the entrance surface coating) is

$$S_P(D) = \frac{F_p e^{-\Sigma_a D}}{4\pi} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \int_0^{\overline{L}} 2\pi\Sigma_a e^{-x\Sigma_a} \left(1 - \frac{x}{\overline{L}}\right) dx,$$

$$= 0.5F_p e^{-\Sigma_a D} \prod_{i=1}^{M} e^{-\Sigma_t^i T_i} \left[\left(1 - \frac{1}{\Sigma_a \overline{L}}\right)(1 - e^{-\Sigma_a \overline{L}}) + e^{-\Sigma_a \overline{L}}\right]. \tag{17.37}$$

Usually a coated gas-filled detector is backfilled with a gas that is relatively unreactive with neutrons; hence it is usually neglected in sensitivity calculations. However, if the gas is an absorber of neutrons, then those losses imposed by the gas must also be taken in account. After the sensitivity components are calculated for all reaction products and branching ratios, they are summed to determine the intrinsic neutron detection efficiency, i.e.,

$$\epsilon_{int} = \sum_{p=1}^{M} S_p(D)\Big|_{entry} + \sum_{p=1}^{M} S_p(D)\Big|_{exit}. \tag{17.38}$$

Example 17.2: Consider a two-inch inner diameter gas-filled detector backfilled at 1 atm with P-10 counting gas. The detector is fabricated from 2-mm-thick Al tube. The walls are coated with $D = 10$ microns of $\gamma = 94\%$ enriched ^{6}LiF. The detector is best operated with the LLD set to an equivalent of 250 keV. For a 1-cm diameter beam of 2200 m s^{-1} neutrons intersecting perpendicularly through a cross section of the detector, what is the expected neutron detection efficiency ϵ_{int}?

Solution:
The mass density of common LiF is 2.635 g cm^{-3} and the atomic weight is $A = 25.939$. From these data the macroscopic cross section of the ^{6}LiF material is found as

$$\begin{aligned}\Sigma_a &= \sigma_a N = \frac{\sigma_a \gamma \rho N_a}{A} \\ &= \frac{(938 \times 10^{-24}\ \text{cm}^2)(0.94)(2.635\ \text{g cm}^{-3})(6.022 \times 10^{23}\ \text{mol}^{-1})}{25.939\ \text{g mol}^{-1}} = 53.9\ \text{cm}^{-1}.\end{aligned}$$

The residual energy graph (at an LLD of 250 keV) for pure enriched ^{6}Li, shown in Fig. 17.13, is used here to estimate the values of $\overline{L}$, with $\overline{L}_\alpha \approx 4.8$ microns and $\overline{L}_t \approx 29.5$ microns even though the density used in the figure is slightly different than in this problem. Because $\overline{L}_t > D$, Eqs. (17.34) and (17.36) are used to determine the triton contribution to the efficiency. The 2200-m/s total microscopic cross sections for Al and Ar are 1.68 b and 1.32 b, respectively; hence, it is assumed that 2 mm of Al and 5 cm of Ar at 1 atm have little effect on neutron losses and can be neglected. Further, the branching ratio for the reaction products is 100%; hence, $F_p = 1$. Equations (17.34) and (17.36) reduce to

$$\begin{aligned}S_P(D)\Big|_{entry} &= 0.5\left[\left(1 + \frac{1}{\Sigma_a \overline{L}_t}\right)(1 - e^{-\Sigma_a D}) - \frac{D}{\overline{L}_t}\right], \\ &= 0.5\left[\left(1 + \frac{1}{(53.9\ \text{cm}^{-1})(29.5 \times 10^{-4}\ \text{cm})}\right)\left(1 - e^{-(53.9\ \text{cm}^{-1})(10^{-3}\ \text{cm})}\right)\right. \\ &\qquad \left. - \frac{10^{-3}\ \text{cm}}{29.5 \times 10^{-4}\ \text{cm}}\right] = 0.0218.\end{aligned}$$

and

$$S_P(D)\Big|_{exit} = 0.5e^{-\Sigma_a D}\left[\left(1 - \frac{1}{\Sigma_a \overline{L}_t}\right)(1 - e^{-\Sigma_a D}) + \frac{D}{\overline{L}_t}e^{-\Sigma_a D}\right] = 0.0207.$$

Because $\overline{L}_\alpha < D$, Eqs. (17.35) and (17.37) are used to determine the alpha particle contribution to efficiency, which along with the previous assumptions, yield

$$S_P(D)\Big|_{entry} = 0.5e^{-\Sigma_a (D - \overline{L}_\alpha)}\left[\left(1 + \frac{1}{\Sigma_a \overline{L}_\alpha}\right)(1 - e^{-\Sigma_a \overline{L}_\alpha}) - 1\right] = 0.0062,$$

and

$$S_P(D)\Big|_{exit} = 0.5e^{-\Sigma_a D}\left[\left(1 - \frac{1}{\Sigma_a \overline{L}_\alpha}\right)(1 - e^{-\Sigma_a \overline{L}_\alpha}) + e^{-\Sigma_a \overline{L}_\alpha}\right] = 0.0061.$$

These results are summed to determine the intrinsic efficiency,

$$\epsilon_{int} = \sum_{p=1}^{M} S_p(D)\Big|_{entry} + \sum_{p=1}^{M} S_p(D)\Big|_{exit} = 0.0218 + 0.0062 + 0.0207 + 0.0061$$
$$= 0.0548 \text{ or } 5.5\%.$$

Self-Attenuation Effect

Because the reaction products are released in opposite directions, only one of these particles can enter the gas region, as explained previously. Consequently, the pulse height spectrum extends from zero up to the highest energy of any single reaction product. The fact that energy can be lost by a reaction ion before depositing the remainder of its energy in the gas is known as the "self-attenuation effect".

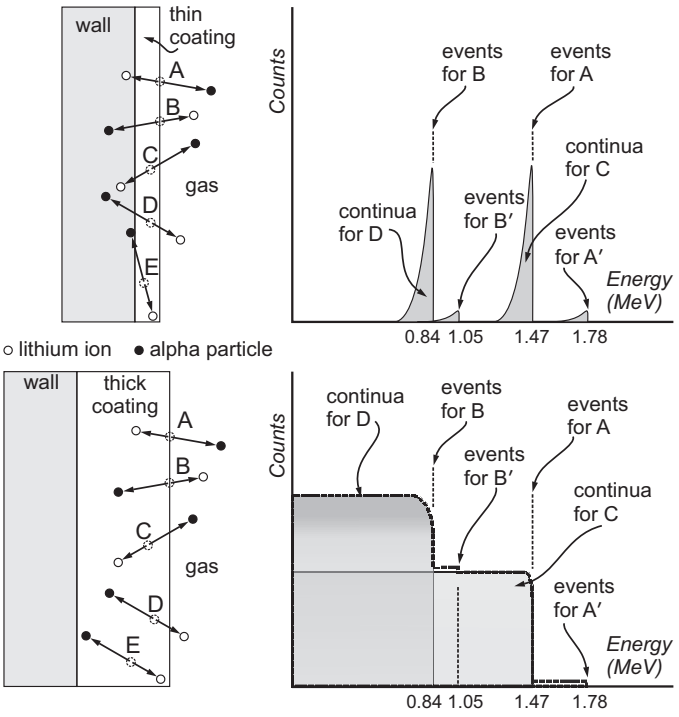

Figure 17.16. Escape of reaction products and spectral features for a gas-filled detectors with thin (upper) and thick (lower) ^{10}B coatings. The 94% branching ratio energies are represented by A and B, and the 6% branching ratio energies are represented by A′ and B′.

Consider the case of a gas-filled detector with a ^{10}B coating on the inner cathode surface, as depicted in Fig. 17.16. Neutron absorptions that occur at the gas/coating interface, depicted as cases A and B, allow either the alpha particle or ^{7}Li ion to deposit all their energy in the gas. Note that in either case none of the energy from the other reaction product is absorbed in the gas, but instead is completely lost in the coating and detector wall. Under no circumstance is the full Q-value of the reaction recorded for this detector configuration. For all interactions that occur deeper in the ^{10}B coating, depicted by cases C and D, energy self-attenuation lowers the amount of energy registered for those particles that emerge into the detector gas. Consequently, these events appear at lower energies in the pulse height spectrum and range from zero up to the full energy of the four possible reaction product energies. Case E depicts those events in which neither particle emerges into the detector gas; hence the events are not recorded.

For thin ^{10}B coatings, the probability of case E occurring is relatively low, and energy self-attenuation is minimized, thereby allowing spectral features of the energies of the different reaction products to appear in the pulse height spectrum, as depicted in Fig. 17.16. For thick ^{10}B coatings, these spectral features are lost, and instead a "stair-step" spectrum is produced. The stair-step feature is a consequence of the combined effects of solid angle, interaction depth, and energy self-attenuation. The resulting probability of depositing energy between zero and the maximum is approximately constant for each reaction product, thereby producing a rectangular shaped pulse height spectrum for each reaction product, that when added together forms the familiar stair-step spectrum. The calculated results for different converter thicknesses of a ^{10}B-lined detector are shown in Fig. 17.17.

^{10}B-Lined Tubes

Detectors coated with ^{10}B, generally called boron-lined detectors, and (along with lithium-lined detectors) are perhaps the first type of gas-filled slow neutron detectors introduced to the scientific community [Dunning et al. 1935a; Mitchell 1936].[12] They are commercially available with casings usually constructed from either aluminum or stainless steel. The coatings, in units of mass thickness, range from 0.025 mg cm^{-2} up to 1 mg cm^{-2} or in thicknesses of 0.1 micron up to 4.33 microns. Coatings thicker than 4.6 microns are greater than the range of the most penetrating reaction product (see Fig. 17.11) and do not increase the detection efficiency but serve only to reduce the neutron flux. The thicker coatings, often quoted with mass thicknesses between 0.5 and 1.0 mg cm^{-2}, produce pulse height spectra with the self-attenuation stair-step feature shown in Figs. 17.16 and 17.17. Efficiency is usually quoted in units of total count rate from the detector per unit flux (cps/nv), with the detector completely immersed in a neutron field. If used in a neutron beam, the orientations described in Example 17.1 and method of Example 17.2 should be used to estimate the expected efficiency.

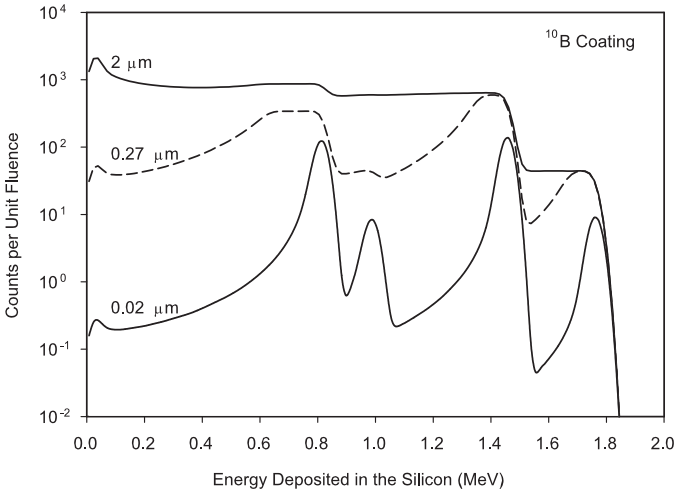

Figure 17.17. Pulse height spectra for a boron-lined detector for three boron layer thicknesses. Although the total number of registered counts increases with boron thickness, the self-attenuation effect is also enhanced and degrades the reaction product spectrum.

Boron-lined tubes are available in various sizes, with diameters usually ranging from 13 mm up to 77 mm. Because neutrons interact in the coating attached to the walls, detectors are designed for irradiation through the side wall; hence, there is dead space near the tube ends from the insulating standoffs and/or field tubes.

Boron-lined gas-filled detectors can use practically any counting gas, an advantage over detectors based on ^{3}He or $^{10}BF_3$ gases. Boron-lined tubes designed as ion chambers can be commercially acquired with hydrogen as the backfill gas, while boron-lined proportional counters are usually backfilled with traditional proportional gases such as argon. Boron-lined gas-filled detectors compensated for gamma-ray background can be acquired with a variety of fill gases, including hydrogen, nitrogen, and xenon. Boron-lined tubes can be used under relatively higher temperature conditions (up to about 200°C) than is possible with $^{10}BF_3$ gas-filled detectors.

Unfortunately, the self-attenuation effect limits boron-lined gas-filled neutron detectors to approximately 9% maximum intrinsic thermal-neutron detection efficiency, much lower than that measured for ^{3}He or $^{10}BF_3$ gas-filled detectors. Neutron measurements often require the LLD be set to reduce gamma-ray background counts. Unfortunately, any non-zero setting of the LLD also eliminates neutron counts, effectively reducing the detection efficiency below the maximum possible. This problem is a consequence of the reaction product self-attenuation, which produces no "valley" feature in the pulse height spectrum in the low energy region (unlike ^{3}He or $^{10}BF_3$ gas-filled detectors). Detectors with axially aligned ^{10}B-coated fins, inserts, or honeycomb structures inside a boron-lined tube have been investigated as a method to increase the efficiency [McGregor et al. 2013a; Nelson et al. 2012, 2014; Edwards et al. 2018]. The total neutron detector efficiency increases with the added boron-coated surface area in the gas chamber.

[12] Curie and Joilet [1933] and Bonner [1933] had already shown that ionization by neutron recoil collisions can be detected.

Compensated Ion Chambers

A form of ion chamber widely used for nuclear reactor controls is the *compensated ion chamber*. Ion chambers, when operated in *current mode*, can be used in high radiation environments. If a gas-filled neutron detector is placed near a nuclear reactor, it responds to both neutrons and gamma rays. Yet, current mode operation does not permit pulse height discrimination between neutron and gamma-ray interactions as does pulse mode operation. The compensated ion chamber design is used to distinguish between the two types of radiations.

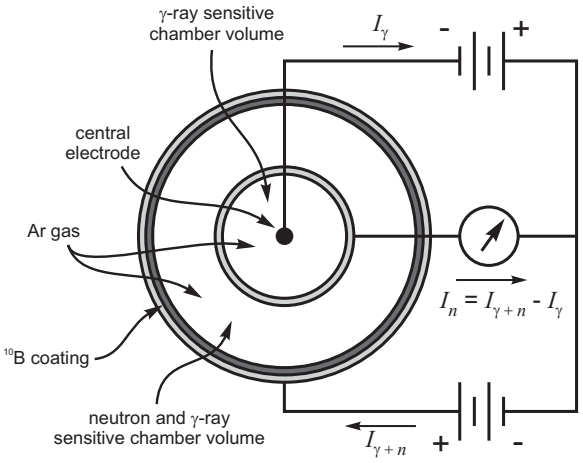

Figure 17.18. Cross section diagram of concentric compensated ion chamber. The configuration allows both chambers to experience the same radiation field. Differences between the two chambers can be properly calibrated by adjusting the operating voltages.

Typically the chamber has three concentric electrodes, one coated with a neutron sensitive material such as ^{235}U or a compound containing ^{10}B. As seen from Fig. 17.18, the ^{10}B (or ^{235}U) coated chamber is generally referred to as the "working" chamber and the uncoated chamber is referred to as the "compensating" chamber. When exposed to a combined gamma-ray and neutron source, the voltage potential for the working chamber causes current to flow that deflects the meter in one direction. The voltage potential in the compensating chamber, sensitive only to gamma rays, causes current to flow in the opposite direction. The voltage potentials on the chambers can be adjusted so that the two gamma-ray induced currents are equal. As a result, in the compensating chamber the two gamma-ray currents cancel each other so the net signal is solely from the neutron induced current. Compensated ion chambers are widely used in nuclear reactors because of their ability to respond to neutron fields that vary up to ten orders of magnitude, i.e., these detectors have a very large "dynamic range".

$^{10}B_4C$-Coated Straw Tubes

Miniaturized version of the boron-lined neutron detector, dubbed "boron straw tubes", have been introduced in recent years [Lacy et al. 2009, 2013]. These detectors have similar properties to those of the straw tubes described in Sec. 10.6.7. Boron straw tubes are fabricated from either Al or Cu metal foil that has been coated with BC_4, enriched to approximately 96% ^{10}B [Lacy et al. 2013]. The BC_4 material is applied with physical vapor deposition (PVD) to produce a durable layer that can withstand shock and relatively high temperatures. Afterwards, the metal foil is rolled and welded to form the envelope. Each straw tube is designed as a coaxial detector, with a central anode wire and the metal foil envelope acting as the cathode. These detectors range in diameter from 2 mm to 15 mm, and can be over 1 meter long, depending on the design.

A single detector has the same efficiency limitations as any other boron-coated gas-filled neutron detector. However, because of their relatively low production cost, compact size, and durability, large groups of boron straw tubes are usually bundled together in a larger vessel, thereby increasing the overall neutron detection efficiency. Recent designs deviate from the conventional cylindrical tube, adapting instead a "star-shaped" straw tube. The star shape design increases the overall neutron reactive surface while allowing the straws to pack together in an interlocking manner [Lacy et al. 2013]. Such a configuration increases the amount of ^{10}B-coated surfaces encountered by an intersecting neutron beam. Approximately 31 straw tubes, each nominally 4.43 mm diameter, can be packaging inside a 1.15 in (29.2 mm) diameter Al tube and operated

as a single detector. Lacy et al. [2016] have also adopted the axial fin design [McGregor et al. 2013a] inside straw tubes to improve thermal neutron detection efficiency.

A disadvantage of such small geometries is that the reaction product ranges are typically much greater than the straw-tube cross dimensions. Consequently, much of a reaction product energy is lost when it encounters an opposing surface; hence only a portion of the reaction energy is actually deposited in the straw tube, thereby producing a smaller output signal. Energy deposition can be increased by increasing the pressure inside the straw tube. One advantage of the small size is the reduced ionization in the detectors from background gamma rays so that the background radiation interference is reduced. Charged particles are naturally shielded from entering the vessel, and electrons excited through gamma-ray and x-ray interactions inside a straw tube can not physically deposit much energy (low $-dE/dx$) before encountering a surface. Hence, the discriminator can be set lower than that of a conventional boron-coated detector and, thereby allows more neutron-induced counts to be tallied.

The overall efficiency is a function of the BC_4 thickness, enrichment, gas pressure, LLD setting, and the number of surfaces encountered. Shown in Fig. 17.19 are calculated efficiencies, using a combination of Eqs. (17.34), (17.35), (17.36), and (17.37) for each ^{10}B surface encountered in a stack, illustrating the efficiencies that are achievable by stacking multiple boron-coated straw tubes. For optimal conditions at an LLD setting of 73 keV equivalent with a neutron beam intersecting perpendicular to the vessel, a 29.2 mm diameter vessel with 31 round straw tubes can achieve an efficiency exceeding 35%, while 31 star shaped close packed straw tubes can achieve efficiencies exceeding 50% [Lacy et al. 2013]. These numbers vary with LLD setting. Presently, boron coated straw tubes are being incorporated into field instruments, including portal monitors, backpack monitors, and vessels having traditional form factors as those of conventional ^{3}He detectors [Lacy et al. 2013].

Gas-Filled Detectors with ^{6}Li Metal

A relatively new technology that shows great promise is a neutron proportional counter loaded with ^{6}Li metal foil sheets, made possible by film advancements by the Li battery industry. These ^{6}Li foil sheets can either be attached to the container walls or, more effectively, several ^{6}Li foil inserts can be suspended inside the detector chamber. A system of analytical equations can be used to determine the theoretical efficiencies of stacked detector variations [McGregor et al. 2003] or, instead, Monte-Carlo methods can be used to determine the expected efficiencies [Nelson et al. 2012].

Relatively large neutron detectors can be constructed by laminating the walls of a chamber with thin ^{6}Li foils, between each foil a multiwire proportional counter is constructed (see Fig. 17.20). A single detector box typically has two foils, one on each side, and each additional detector increment adds two more foils. This type of Li foil detector has similar properties to the boron lined gas-filled detector or any of the coated detector variants, in which only one of the reaction products from the ^{6}Li(n,t)^{4}He reaction can escape into the detection gas. The efficiency can be calculated using the method introduced by Eqs. (17.34) to (17.37), while accounting for neutron absorption losses through each detector box. The resulting calculated efficiencies are shown in Fig. 17.21. Although foils less than 20 micron in thickness can reach thermal-neutron detection efficiencies exceeding 50%, this value is presently impractical due to limitations with manufacturing the thin Li foils. Presently, the quoted lower limit is 55 microns,[13] and yields a saturated maximum intrinsic thermal neutron detection efficiency of 47%. Because there are additional neutron losses from the box materials, it is expected that the actual efficiency is somewhat lower.

Large neutron detectors can also be constructed by suspending framed sheets of ^{6}Li foils inside a gas-filled chamber interspersed between multiwire anodes as shown on the right-hand side of Fig. 17.22 [McGregor et al. 2013a, 2017]. Unlike coated detectors, the thin ^{6}Li foil may allow both reaction products to reach

[13] Source: Rockwood Lithium.

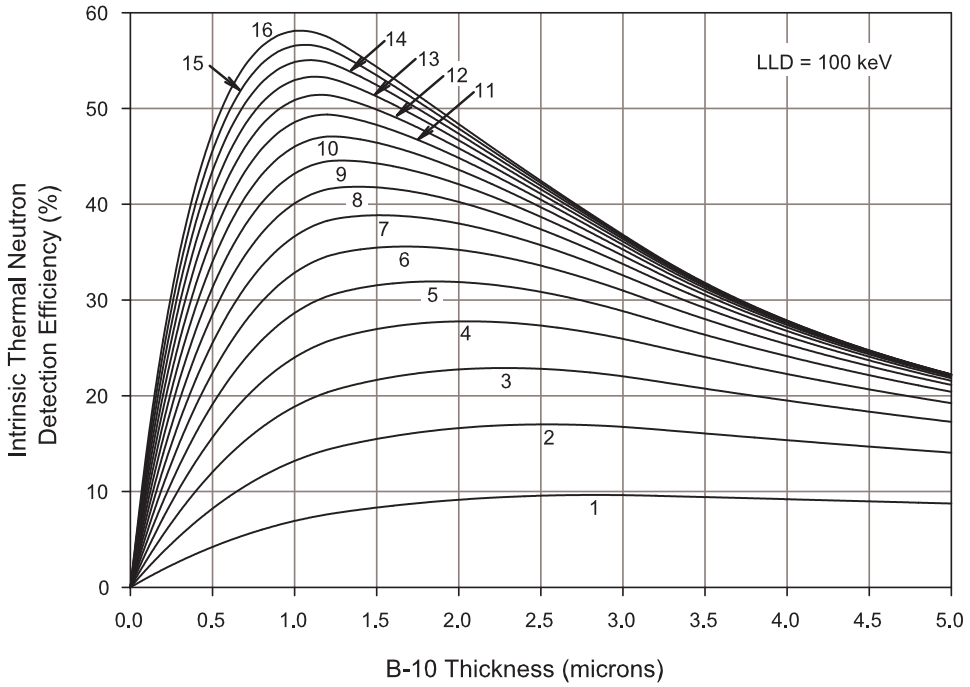

Figure 17.19. Calculated efficiencies for a stack of ^{10}B-lined tubes irradiated with a thermal-neutron beam normal to the axis. The efficiency is shown as a function of the ^{10}B film thickness and the number of tubes intersected by the thermal-neutron beam.

the detection gas, as depicted in Fig. 17.22. Situation A in Fig. 17.22 depicts the case in which either reaction ion can enter the gas region of the detector with a small possibility of both ions entering the gas on opposite sides. Situation B depicts the case in which only the long range reaction product can reach the detector gas from either side of the foil. Situation C depicts that case in which either one of the reaction ions can reach the detector gas but not both. The thermal-neutron detection efficiency for this type of detector can be calculated with the system of equations listed in the literature [McGregor et al. 2003], an analytical method that can be somewhat tedious. Alternatively, widely used Monte-Carlo codes, such as MCNP-6 or GEANT-4, can also be used to calculate the thermal-neutron detection efficiency [Nelson et al. 2012]. The resulting calculated efficiencies are shown in Fig. 17.23. For the minimum ^{6}Li foil thickness of 55 microns, a detector with 10 foils can deliver 72% thermal-neutron detection efficiency. The efficiency reported for ^{6}Li 5-foil detectors exceeds 56%. It is interesting to note that a ^{6}Li-foil detector with a single suspended foil (maximum 24% efficiency) outperforms a two foil detector of the laminated design (maximum 20% efficiency).

The main advantage of the laminated ^{6}Li design is that each detector box in a stack requires only one bank of multiwire anodes. However, the laminated design cannot achieve the high efficiency of the suspended foil design. The main advantage of the suspended foil design is that it can achieve efficiencies similar to those of ^{3}He gas-filled detectors. In either case, the detector is backfilled with a proportional counter gas rather than a rare or caustic reactive gas (which may also not exhibit ideal signal proportionality). A variety of detector shapes and sizes are described in the literature [Nelson et al. 2012, 2014, 2015].

Although Li foils react and decompose in the presence of water moisture, fabrication problems can be mitigated by constructing the detectors within a “dry room”, in which water moisture can be kept below

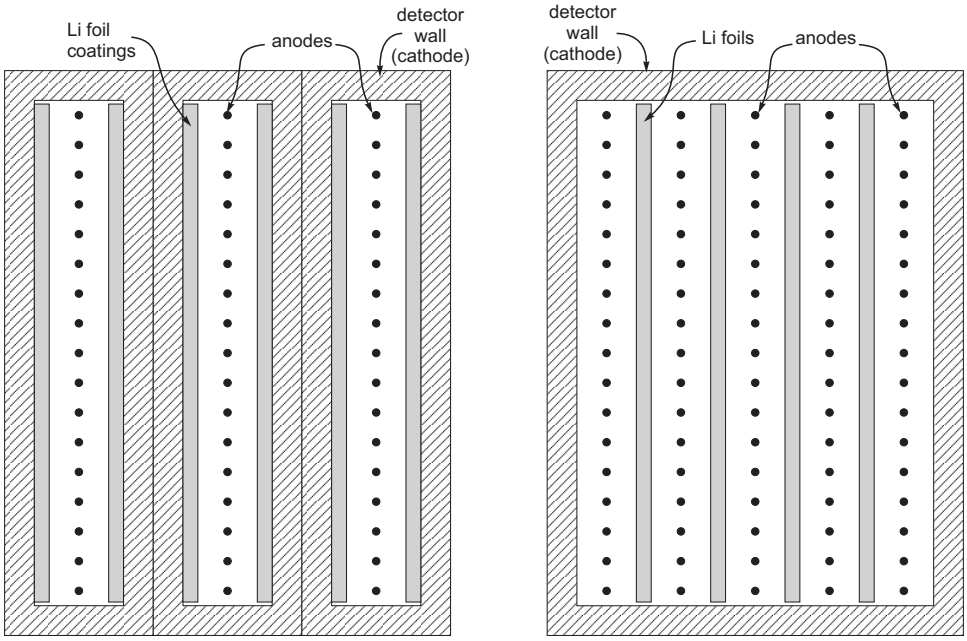

Figure 17.20. For large area Li-foil detectors, there are two basic design constructions. Depicted are (left) a laminated construction with six ^{6}Li foils and (right) a suspended construction with four ^{6}Li foil inserts in the gas container.

10 ppb. The detectors operate with proportional gases, such as argon. However, it is inadvisable to use quenching gases that contain oxygen, such as CO_2, because these gases cause the Li foils to decompose over time. Instead, saturated hydrocarbons such as the linear alkanes methane, ethane, and propane can be used as quenching gases. To prevent foil decomposition, all gases introduced into the chamber should have ultra-high purity, generally with less than 1 ppm of either O_2 or water moisture contamination.

Fission Chambers

A special type of coated gas-filled radiation detector is a fission chamber. This type of detector has fissile materials (such as ^{233}U, ^{235}U, ^{239}Pu) or fissionable materials (such as ^{237}Np, ^{232}Th, ^{238}U) as coatings in which a fission reaction emits two highly energetic fission products. The energy eventually released per ^{235}U fissioned is approximately 207 MeV, with about 168 MeV of that energy as the kinetic energy of the two fission fragments. The remaining 39 MeV is released in the form of gamma rays, fast neutrons, beta particles, and neutrinos, most of which escape detection. Usually two fission fragments share 168 MeV as kinetic energy, although there is a slight chance of triplet fission, that produces two relatively large fission products and a much smaller fission product (such as a triton, alpha particle, Li ion, or B ion). The two fission fragments are released with different kinetic energies and masses, with average energies of 68.1 MeV for the heavy fragment and 99.2 MeV for the light fragment. The variety of possible fission fragments numbers in the hundreds with atomic masses ranging from 70 to 170. The fission product mass and energy distributions for fissile materials (^{233}U, ^{235}U, ^{239}Pu) have similar distributions, although there are slight differences. Threshold detectors can be used for fast fission reactions, which include ^{237}Np, ^{238}U, and ^{232}Th to measure only the fast flux while discriminating epithermal and slow neutrons (see Fig. 17.24).

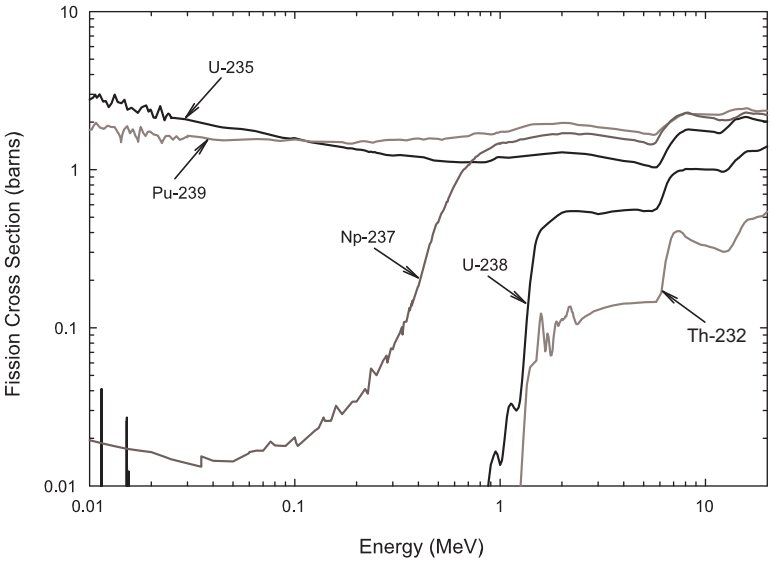

Figure 17.24. Fast neutron fission cross sections for several materials used for fission chambers. The isotopes ^{238}U, ^{237}Np, and ^{232}Th are used as threshold converters, in which neutrons below an energy threshold are unlikely to interact in the detector. Data are from [ENDFPLOT 2015]. (The slow neutron cross sections for ^{235}U and ^{239}Pu are shown in Fig. 17.3).

The large kinetic energy of the fission provides an attractive converter for neutron detectors, mainly because the energy from either fission product (fragment) can be measured without the need for avalanche multiplication. As a result, most fission chambers are designed as ion chambers. The ranges of fission products in 1 atm of Ar are between 1.5 cm and 2.9 cm, depending on their mass and energy; hence many fission chambers are designed with dimensions of a few centimeters. In a fission event, the fission fragments are ejected in approximately opposite directions, although the other energetic fission emissions, such as prompt fission neutrons, cause a slight change in the opposite fission product trajectories. Consequently, much like other coated neutron detectors, only one of the fission products is likely to cause ionization of the chamber gas and be measured.

Although the number of electron-ion pairs created in the gas depends on the amount of energy deposited by the fission fragments, it is also a function of the effective Z of the fission products. The average number of ion pairs created, per unit energy deposited, is higher for an alpha particle than for fission fragments,

assuming full energy deposition and identical operation conditions [Rao et al. 1990]. This outcome is a consequence of heavy ions losing energy to competing processes, such as direct nuclear collisions, that do not produce electron-ion pairs (discussed in Sec. 16.2.7). Hence, the actual pulse height produced by a fission fragment does not scale linearly with its initial energy, unlike the more linear relation for alpha particles. Also, the average charge on a fission fragment reduces rapidly as it passes through a medium as the fission fragment captures ambient electrons. Consequently, the specific ionization of a fission fragment is *highest* upon entering a medium and decreases as the fission fragment loses energy. This changing charge of the ion is quite different than that experienced by alpha particles and protons. Overall, for full energy deposition, the total amount of energy converted to electron-ion pairs for fission fragments is considerably higher than observed by alpha particles, beta particles, or gamma rays.

Theoretical models, developed by Kahn et al. [1965], predict the pulse height spectra produced by fission fragments emitted within a 2π solid angle from a thin film coating of UO_2 on a surface within a gas detector. Selected predictions are compared to measured pulse height spectra in Fig. 17.25. For relatively thin films, the two fission fragment branches are clearly discernible. For thicker films, the energy distribution becomes skewed towards the lower energies, a consequence of energy self-absorption for fission products that lose energy as they transit the UO_2 film before emerging into the detector gas. Because the lightest and most energetic fission products cannot reach the detector gas if born at a distance greater than about 8.0 microns from the coating surface, there is no practical reason to apply films any thicker. Hence, the thermal-neutron detection efficiency for a $^{235}UO_2$-coated detector is limited to less than about 0.5%. Fission chambers with U metal instead of UO_2 are also manufactured, and have a higher density of U per unit volume. However, the fission product ranges in U are also shorter (less than about 6 μm) than in UO_2; consequently, the resultant thermal-neutron detection efficiencies are also less than about 0.5%.

One method to increase the thermal-neutron detection efficiency of fission chambers is to include in the chamber multiple plates each of which is coated with fissile material [Lamphere 1960]. These plates are separated by small gaps usually of about 2 to 5 mm [Bogdzel et al. 1982; Wender et al. 1993]. The chambers are usually backfilled with Ar, often at elevated pressures to improve energy absorption of the fission products in the small gaps. The plates are biased with opposing voltages to collect electron-ion pairs liberated in the gas by the fission fragments.

Fission chambers deployed in a nuclear reactor suffer from burnup just as does the nuclear fuel. Over time the amount of fissile material becomes depleted and the detector response decreases. The initial sensitivity of a fission chamber can be increased by using enriched ^{235}U, but the signal rapidly diminishes with neutron fluence and decreases to approximately half the initial response after an exposure of 10^{21} thermal neutrons cm^{-2} [Jackson 1967]. Consequently, without periodic recalibration, the signal output no longer accurately measures the reactor power. This problem of decreasing sensitivity can be mitigated by including fissile and fertile materials in the fission chamber, thereby producing a type of breeder detector known as a *regenerative* fission chamber. Some regenerative chambers include ^{235}U and ^{234}U [Jackson 1967], ^{239}Pu and ^{238}U [Böck and Balcar 1975], ^{235}U and ^{238}U and natural U with ^{232}Th [Reichenberger et al. 2014]. With appropriate mixing ratios of these isotopes, the signal variation can be constrained to less than 5% for neutron fluences extending, in some cases, beyond 10^{22} cm^{-2}, which correspond to fluences accumulated over several years in the core of a power reactor.

The build-up of fission products inside the chamber increasingly makes the chamber radioactive. Consequently, a background signal from the radioactive emissions of the fission products increases with time, and remains even after the reactor is shut down. This effect is often called the *memory effect* [Roux 1966]. The amount of fission product build-up and memory current is a function of the fissile material mass, neutron flux, and irradiation time. Consequently, the residual memory effect, as described by normalized currents, differs among fission chamber designs. To understand the general effect of fission product build-up, Roux [1966] describes the memory effect as a normalized current which varies with the irradiation time in a nuclear

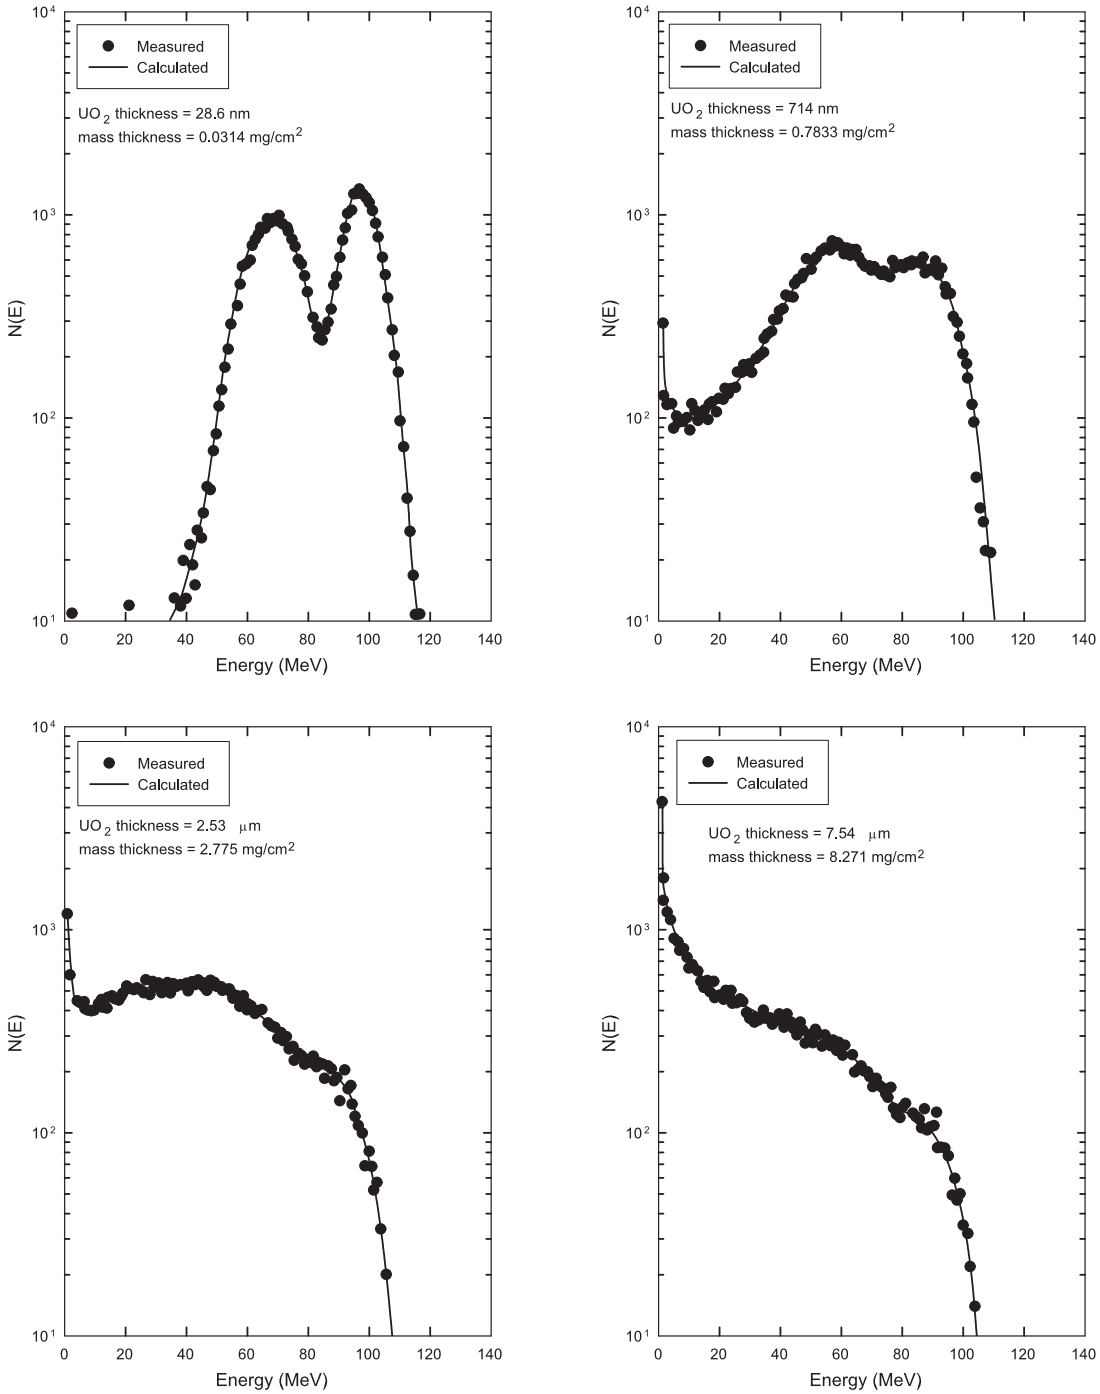

Figure 17.25. Calculated and experimentally measured pulse height spectra of fission fragments from UO_2 film thicknesses of 28.6 nm, 714 nm, 2.53 μm, and 7.54 μm. Data are from [Kahn et al. 1965].

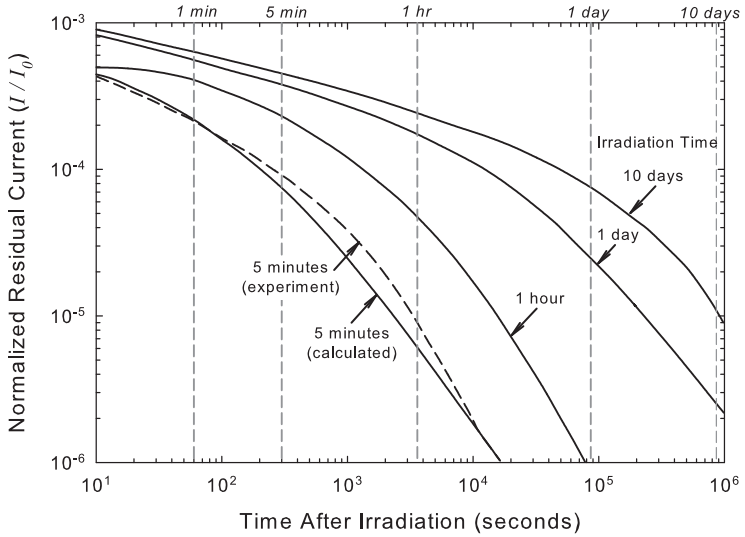

Figure 17.26. Calculated and experimental fission-chamber normalized residual currents from fission products as a function of time after irradiation. Shown are normalized currents for varied irradiation times. Data are from [Roux 1966].

reactor and the subsequent time after irradiation (see Fig. 17.26). A few features can be observed from the Roux results following irradiation: first within a few seconds, the memory current drops by a factor of 10^3, and second it can take many days for the memory current to reduce by a factor of 10^5.

Fission chambers can be operated in pulse-mode, current mode, and Campbelling mode. Because of the multiple operational modes, fission chambers are often used in "wide range" channels in nuclear instrumentation systems. For low flux situations, pulse mode operation offers the advantage that each interaction can be discriminated from background. The disadvantage is that operation is restricted to lower count rates to reduce dead time problems. Pulse mode is used mainly for start-up because it can be used to distinguish between neutrons and gamma rays. At elevated count rates, fission chambers can be operated in current mode, which has the advantage of no longer suffering dead time problems. The measured time-averaged current is proportional to the average power density at the detector location. However, signals from various radiations are no longer distinguishable. The use of Campbelling mode (or mean square voltage mode) does assist with gamma-ray and background discrimination [Campbell and Francis 1946; Vermeeren et al. 2011]. The output signal is still a form of current mode, in which the output is a combination of signals from steady-state and a time varying components. The Campbelling circuit is used to block the steady-state component while squaring the time varying component. The resulting signal is proportional to the square of the charge that is created by each incident particle of radiation, thus enhancing the difference between types of radiation [Geslot et al. 2011]. Hence, the neutron induced portion of the signal is enhanced, while the gamma-ray component is reduced. Thus, Campbell mode operation is useful for neutron measurements in a high gamma-ray background.

Commercial units designed as beam port monitors may have a "pancake" design so that only a small fraction of the neutrons passing through a sensitive volume interact and are detected. Typical diameters of such detectors are about 70 to 115 mm. The purpose of the design is to provide an in-situ neutron measurement of the beam intensity while minimally perturbing the beam.

Cylindrical detectors are fashioned generally in a coaxial-type design, but one in which the inner anode diameter is relatively large, often having nearly the same diameter as the outer cathode. Hence, these detectors are not designed to produce an avalanching field as occurs in common proportional counters. The gap between the anode wall and the cathode wall is typically only a few mm. Consequently, the device performs more as a parallel plate detector rather than a coaxial gas-filled detector (as described in Chapters 10 and 11). Designs may have the cathode or anode coated with the fissile material. In either case, fission fragments are ejected into the small gas volume between the cathode and anode walls and deposit in the gas only a fraction of the total fission product energy. Elevating the gas pressure can increase the energy deposition, although most commercial units are pressurized at only 1 atm. The fill gas is often a combination of Ar and N_2. The argon is more effective at absorbing energy from the fission fragments and serves as the detection gas (see Table 9.1), while the N_2 has a higher electron mobility so as to produce faster pulse rise times (see Fig. 10.10). As shown in Table 9.1, the ionization energy for N_2 is slightly less than that of argon so that charge can be transferred from ionized argon to the nitrogen. The small gas-filled gap limits energy deposition from fission fragments and background radiations. However, because the energy deposited in this gap by fission fragments is significantly larger than that deposited by beta particles, gamma rays, and alpha particles, pulse height discrimination can be used to distinguish between neutron induced events and background.

Sub-miniature fission chambers (SMFC) have been under development for in-core nuclear reactor monitoring for many years [Poujade and Lebrun 1999; Blandin et al. 2003; Lamirand et al. 2014]. These detectors are manufactured with a traditional coaxial design but with the distinction that the outer diameter is approximately 1.5 mm. The anode is also thicker in diameter than that required for proportional counters and is coated with a enriched fissile material such as 97% ^{235}U [Blandin et al. 2003]. The sensitive lengths of such SMFCs are approximately 1 cm. The detectors are backfilled with Ar gas pressurized between 1 to 1.5 atm. Sub-miniature detectors are designed to operate in high neutron fluxes in the core of a nuclear reactor with some designs now under investigation for transient measurements. Commercial variations of the sub-miniature design are available.

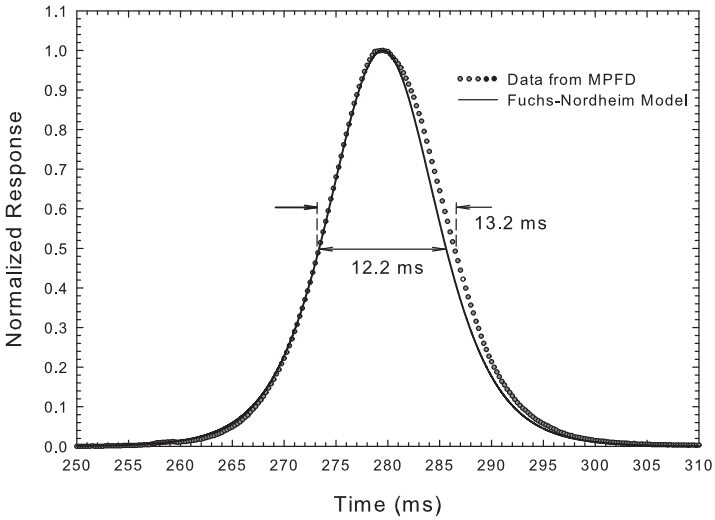

Figure 17.27. Pulse shape comparison of the Fuchs-Nordheim model prediction and measured results from an MPFD for a \$2.77 reactivity insertion. The experiment was conducted in a TRIGA nuclear reactor with thermal peak flux of 9.28×10^{15} cm^{-2} s^{-1}. Data are from [Nichols et al. 2018].

Another type of miniaturized fission chamber is the micro-pocket fission detector (MPFD). These tiny devices are significantly smaller than normal fission chambers and have dimensions of approximately 1 mm with gas volumes of 0.5 mm^3 or less. Although the small volumes are incapable of absorbing the total energy from any of the fission products, the amount of energy absorbed is about 3 to 7 MeV for all fission products, regardless of the branch [McGregor et al. 2005]. The small volume ensures that background gamma-rays and beta particles deposit less than 1 keV, too small to be detected. Alpha particle emission from the reactive coating can deposit more energy, but also is small, typically only 60 keV or less. Hence, simple pulse height discrimination can be used to separate neutron-induced events from the radiation background.

MPFDs are intentionally designed to be inefficient because they are intended as in-core instrumentation for nuclear reactors. Because of their small size, they can be inserted into tiny test ports without causing flux perturbations. Dead time is also less of an issue, mainly because the electron-ion drift times are much smaller for these detectors than traditional fission chambers. These detectors have been operated in pulse mode for neutron fluxes ranging up to 10^{13} n cm^{-2} s^{-1} [McGregor et al. 2005].

Variants of these miniaturized fission chambers are under investigation for different reactor cores and applications [Reichenberger et al. 2016, 2017]. One variant eliminates the need to plate fissile material on an electrode and uses a parallel electrode wire geometry to collect the charges from the miniature gas pocket. With reactor excursion experiments, current mode operation shows that these detectors can track reactor excursions up to a thermal flux of at least 9.28×10^{15} n cm^{-2} s^{-1} as demonstrated in a TRIGA nuclear reactor [Nichols et al. 2018]. When compared to the Fuchs-Nordheim model [Fuchs 1946; Nordheim 1946], the experimental results match well to the model (see Fig. 17.27), showing experimentally a FWHM of 13.2 ms compared to the predicted value of 12.2 ms.

17.4 Scintillator Slow Neutron Detectors

Scintillators used for slow neutron detectors can be categorized into two groups, (1) those composed of a single compound that both fluoresces and also interacts strongly with thermal neutrons and (2) those composed of a mixture of two compounds, one of which fluoresces and the other of which contains neutron reactive material. For instance, LiI and CLYC are in group 1, whereas boron loaded plastic and liquid scintillators are in group 2. Some examples are briefly discussed here. Greater detail about these scintillators is provided in Chapter 13 and also by Van Eijk et al. [2004] and Birowosuto [2007].

17.4.1 Neutron Reactive Scintillators

LiI Scintillator

LiI:Eu crystal, described in Chapter 13, is a highly hygroscopic alkali-metal halide scintillator, recognized by Hofstadter et al. [1951] for its unique properties suitable for thermal and slow neutron detection. It has a density of 4.076 g cm^{-3} and a relative molecular mass of 133.89. The natural abundance of ^{6}Li is 7.59% with a 2200-m/s (n,t) cross section of 938.0 b.[14] It then follows that the macroscopic (n,t) cross section for 2200-m/s neutrons is 1.31 cm^{-1}; hence over 70% of thermal neutrons are absorbed in a crystal 1 cm thick. The attenuation length can be decreased by growing LiI enriched with ^{6}Li. The most probable emission wavelength λ_{max} is approximately 475 nm. As with many Eu activated scintillators, LiI is a relatively slow scintillator with a decay constant of 1.4 μs so that its response rate is somewhat limited. The use of Tl as the activator introduces fluorescence with short decay times [Khan et al. 2015], although a relatively long fluorescence component persists. Further, the light yield decreases compared to LiI:Eu with a most probable emission wavelength λ_{max} remaining near 475 nm for activator concentrations between 0.02% and 0.5% Tl.

Not only is LiI a good neutron absorber, the high iodine content also makes it a good gamma-ray absorber. Consequently, LiI neutron detectors can also have a relatively high sensitivity to background radiation counts. Because the ^{6}Li(n,t)^{4}He reaction releases 4.73 MeV, often simple pulse height analysis is enough to distinguish between gamma-ray and neutron events. However, pulse height discrimination may not be an adequate discrimination technique in the presence of gamma-ray energies of approximately 4 MeV or greater, or in intense gamma-ray environments that induce pulse pile-up [Nicholson and Snelling 1955].

[14] This cross section was often called the *absorption* cross section, a term no longer in wide usage because it includes fission plus 16 reactions in which the neutron disappears such as (n,γ) and 15 reactions that produce positively charged reaction product(s) such as (n,p), (n,t), (n,2α), and (n,t2α). However, here the total 2200-m/s is 938.8 b, an indication that the (n,t) reaction is essentially the only reaction.

LiI:Eu has been reinvestigated in recent years as a compact neutron imager. LiI grown as a microcolumnar scintillator has been developed with the impetus of using the natural fiber optic structure for light segregation [Nagarkar et al. 2001]. Enriched to 96% in ^{6}LiI, crystals were grown on fiber optic substrates to promote light propagation to a light sensing device, in this case, a charged coupled device (CCD). The LiI films were 1.2 mm thick with 30 μm diameter microcolumns. Measurements indicated that a spatial resolution of 110 μm is achievable.

LiI:Eu scintillators attached to either a Si PIN diode [Pausch and Stein 2008] or a SiPM [Foster and Ramsden 2008] have been investigated as compact neutron detectors. The advantage of such a structure is the lower operating voltages required and the smaller overall volume. Pausch and Stein [2008] report results from a 3-mm-thick LiI:Eu detector exposed to a mixed gamma-ray/neutron field, in which a moderated AmBe source and ^{137}Cs and ^{60}Co sources were used. It was found that counts from gamma-rays interacting in the LiI scintillator or directly interacting in the semiconductor diode can be significant and, consequently, lead to misinterpretation of gamma-ray counts as neutron counts. Pausch and Stein [2008] report a pulse processing method that can discriminate between gamma-ray and neutron events. Foster and Ramsden [2008] report the appearance of artifacts in the pulse height spectrum when the LiI/SiPM combination was exposed to a mixed gamma-ray/neutron field, in which a modestly moderated ^{252}Cf source and a ^{137}Cs source were used. It is less likely that the artifacts are from direct gamma-ray interactions in the SiPM, mainly because the depletion region in a SiPM is relatively small (smaller than in a PIN diode). Instead, it is hypothesized that the artifacts result from neutron scattering from Li nuclei [Foster and Ramsden 2008]. Also observed was a strong dependence of the neutron induced pulse height spectrum and the operating temperature. Foster and Ramsden [2008] argue that the thermal dependence is of little consequence, mainly because the pulse height spectrum is only used for a LLD setting and not for spectroscopy, and that bias adjustments to the SiPM can help compensate thermal changes in the pulse height spectrum.

Elpasolite Scintillators

Cesium lithium yttrium chloride (Cs_2LiYCl_6 or CLYC) and other elpasolites containing Li can be used for slow neutron detection [van Eijk et al. 2005]. Lithium-based elpasolites are sensitive to both neutrons and gamma rays, and have been used to detect both. For low count rate measurements, the relatively good energy resolution of CLYC:Ce and also cesium lithium yttrium bromide (Cs_2LiYBr_6 or CLYB) allows pulse height discrimination (PHD) between neutron and gamma-ray counts, just as with LiI:Eu detectors. The α/β ratio for CLYC:Ce is 0.66, an indication that pulse shape discrimination (PSD) could be used to discriminate between gamma rays and neutrons. CLYC:Ce also possesses core valence luminescence (CVL) that produces only a fast component from gamma-ray events. The same is not true for neutron events. Hence, PSD can be performed by simply distinguishing between events with and without CVL. Note that the long decay times characteristic of elpasolites can be a problem in high mixed radiation fields for either PHD or PSD, mainly because pulse pile-up contaminates the neutron-induced spectrum. The elpasolite $Cs_2LiLaBr_6$ (or CLLB) has better energy resolution than CLYC:Ce [Glodo et al. 2011], but apparently lacks core valence luminescence [Bessiere et al. 2005]. However, neutron PSD can be achieved by comparing the decay time of the decay components (as described in Chapter 13), mainly because the slow components differ with the radiation type, where the induced gamma-ray tail has a longer duration than the neutron induced tail.

CLYC:Ce can be obtained commercially and can be coupled to either a traditional PMT or a SiPM. Spectral performance is good with approximately 4.5% FWHM for 662-keV gamma rays. It performs adequately well for gamma-ray spectroscopy and neutron detection. However, for high energy resolution gamma-ray spectroscopy, there are other scintillators that can outperform CLYC:Ce (such as $LaBr_3$). The same is true for compact neutron detectors. Hence, the main novelty of CLYC:Ce is the ability to detect efficiently both gamma rays and neutrons with a single device.

A significant disadvantage to CLYC:Ce is that both ^{133}Cs (100% natural abundance) and ^{35}Cl (75.78% natural abundance) are moderate neutron absorbers that transmute into radioisotopes that emit beta particles. Further, their atomic ratios per molecule are much higher than Li. For natural constituents, approximately 78% of neutron absorptions in CLYC:Ce do not produce a spontaneous neutron reaction, but rather increase the background from emissions of beta particles and gamma rays. Consequently, the intrinsic thermal-neutron detection efficiency of CLYC:Ce is limited to approximately 22%. If natural Li is replaced with enriched ^{6}Li, the thermal-neutron detection efficiency has an upper limit of 80%. To remedy this problem, other elpasolites without Cs and Cl have been explored and a successful candidate was found to be Rb_2LiYBr_6 (or RLYB:Ce) [van Eijk et al. 2005]. Overall, the light output and performance of RLYB:Ce is similar to CLYC:Ce although, at the time of this writing, it is not commercially available. Another introduction to the elpasolite family with promising results is $Cs_2LiLa(Br_{6-x}Cl_x)$ or CLLBC:Ce, which has good gamma-ray energy resolution along with the neutron detection characteristic of CLYC:Ce [Shirwadkar et al. 2012]. The substitution of Br for Cl works to reduce parasitic neutron losses, while the substitution of La for Y works to slightly increase parasitic neutron losses. CLLB:Ce has become commercially available with reported energy resolution for 662 keV gamma rays of approximately 4% FWHM.[15] The popularity of CLLB:Ce is likely to increase in the coming years because of its dual application to neutron and gamma-ray detection.

LGBO Scintillator

Many other scintillators with reactive components have been investigated. For instance, $Li_6Gd(BO_3)_3$:Ce scintillators with varying concentrations of Gd, B, or Li enrichments have been studied [Czirr et al. 1999]. $Li_6Gd(BO_3)_3$:Ce can be produced as a powder or as a transparent crystal [Czirr et al. 1999]. Three of the main constituents react with neutrons, namely, ^{6}Li(n,t)^{4}He, ^{10}B(n,α)^{7}Li, and ^{155,157}Gd(n,γ)^{156,158}Gd. The neutron absorption response of this interesting scintillator can be changed by adjusting the ratios of the neutron absorbing nuclides to their non-reactive isotopes. When using materials of natural abundance, the Gd component dominates neutron absorption. Consequently, the reaction products are mainly gamma-rays and low energy conversion electrons, and the Li and B components contribute little to the response. Recapture of the gamma rays is inefficient and the conversion electrons have short ranges, a property which unfortunately limits the response. Van Eijk [2001] reports that natural $Li_6Gd(BO_3)_3$:Ce produces a low-end average light yield of 14,000 photons/neutron. Note that this average is a compilation of three uniquely different emissions from the four possible reactions. According to Czirr et al. [1999], light emission ratios for Gd, B, and Li per neutron are approximately 2, 11, and 52, respectively. In these results the representative conversion electron energy of 85 keV has been substituted for the Gd emissions (see Schulte et al. [1994]). Hence, the pulse height from ^{6}Li(n,t)^{4}He is significantly higher than those from other reactions.

If the Gd is depleted of ^{155}Gd and ^{157}Gd, then the boron component can dominate the absorption. If the ^{10}B is then also omitted, the Li component dominates neutron absorption even further. Czirr et al. [1999] conclude that a good compromise is to produce $^{6}Li_6{}^{[nat-(155,157)]}Gd(^{11}BO_3)_3$:Ce so as to take advantage of the high energy reaction products from ^{6}Li and the resultant light yield of 56,900 photons/neutron. The reaction product ranges, and subsequent light attenuation lengths, are still problematic in a manner similar to that for coated gas-filled detectors. In an attempt to overcome this problem, Allier [2001a, 2001b] suggest Si diode well-structures backfilled with $Li_6Gd(BO_3)_3$:Ce powder. In summary, Van Eijk [2001] notes that advantages include the low index of refraction of 1.66 and the high neutron absorption efficiency. Disadvantages include the longer decay times that range from 200 ns to 800 ns and the high cost of Gd depleted of ^{155}Gd and ^{157}Gd.

[15] Through Saint-Gobain Crystals.

GSO Scintillator

Gadolinium orthosilicate (Gd_2SiO_5:Ce or GSO) is another gadolinium-based scintillator that has been studied as a possible neutron detector [Reeder 1994a, 1994b; Uozumi et al. 1997]. This scintillator has a fast decay component (56 ns) that is responsible for 85-90% of the light yields and a slow component (600 ns) that is responsible for the remaining 10-15% of the light yield [Melcher et al. 1990]. The maximum wavelength is 430 nm and matches well to bialkali PMTs. However, the light yield is relatively low at only 12,500 photons/MeV. Reeder [1994a] notes that the pulse height spectrum peak is approximately 77 keV equivalent and matches well to the Gd conversion electron spectrum [Schulte et al. 1994]. Because GSO is sensitive to both gamma-rays and neutrons, it can be used to detect both. Reeder [1994a] lists advantages of GSO as simplistic because it has dual detection capabilities as well as compact and efficient because a small crystal readily absorbs neutrons. Disadvantages include competition between low-energy background gamma rays and the Gd conversion electron emissions as well as contamination by characteristic x-rays from the shielding (especially from Pb).

Because conversion electrons, Compton electrons, and photoelectrons produced by neutrons and gamma rays have fundamentally similar properties, discriminating between neutron and gamma-ray events with pulse shape discrimination does not appear to be an option [Uozumi et al. 1997]. Further, the complex nature of the combined spectra makes simple pulse height discrimination difficult. Reeder [1994b] attempts to address this problem by coupling thin GSO crystals to PMTs, so thin that the probability of gamma-ray interactions is significantly reduced below that of thermal-neutron absorptions, all the while retaining the ability to capture the conversion electron reaction product emissions. To demonstrate the concept, Reeder [1994b] compared the response of a 60 μm thick GSO crystal and a 1 cm thick GSO crystal to gamma-ray and neutron emissions from a moderated PuBe source, as well as gamma-ray emissions from a ^{137}Cs source. Although the work qualitatively demonstrates the concept, the sample areas (and solid angles) were different, thereby making quantitative conclusions difficult. Regardless, it is clear that thick crystals of GSO neccessarily have problems with background gamma rays interfering with the neutron-induced pulse height spectrum.

$LiBaF_3$ Scintillator

The scintillator $LiBaF_3$ has also been studied as a neutron detector [Knitel et al. 1996; Combes et al. 1998]. $LiBaF_3$ has multiple emission wavelengths with different decay times, ranging from 1 ns up to 13 μs depending on the doping type and concentration [van Eijk 2001]. The light yields and decay times are significantly different for gamma-ray and neutron interactions. A bright fast component is produced by gamma-ray interactions (about 1,200 photons/MeV with a mean lifetime τ of about 0.8 ns), which is absent for neutron interactions [Knitel et al. 1996]. A method that rejects these high amplitude fast pulses is used to discern between neutron and gamma-ray events [Knitel et al. 1996; Combes et al. 1998]. Van Eijk [2001] argues that the fast emission produced by gamma-ray interactions is due to core-valence luminescence, which is accompanied by the delayed luminescence from self-trapped holes. The fast core-valence luminescence is altogether missing for neutron interactions. Combes et al. [1998] report that the use of radiation damaged $LiBaF_3$ crystals have improved discrimination between gamma-ray and neutron events. Along with co-doping with Ce and Rb, the damaged material produced a fast decay time for the self-trapped hole luminescence, thereby reducing issues with pulse pile-up while improving the signal to noise ratio [Combes et al. 1998].

17.4.2 Scintillators Loaded with Neutron Reactive Materials

Organic Scintillators

Organic scintillators loaded with either ^{10}B, ^{6}Li, or natural Gd are commercially available as neutron detectors. These materials are usually applied to fast neutron measurements, but can also be used for thermal or slow neutron detection. The concept is simple; neutrons are absorbed in the absorber, either ^{10}B or ^{6}Li,

which release energetic reaction products that subsequently cause fluorescence in the scintillator. These detectors can be economically manufactured in large sizes and formed into multiple shapes. The light emission can be significant, mainly because of the high Q-values from the ^{10}B(n,α)^{7}Li and ^{6}Li(n,t)^{4}He reactions.

The amount of boron that can be loaded into an organic plastic scintillator (polyvinyltoluene) is limited by the reduction in scintillator transparency. Loading is usually no more than 5% by weight for commercial boron-loaded organic scintillators, and these scintillators have lower light yields than their unloaded counterparts by approximately 20% [Drake et al. 1986] (see also Table 13.2). Commercial plastic scintillators, such as EJ-254 and BC-454, are loaded with natural boron; hence, the actual ^{10}B loading amounts to approximately 1%. Higher boron loadings are available by special request. Although the Q-value of the boron reaction is high, in Chapter 13 it was mentioned that light yield in organic scintillators is lower for heavy ions than for electrons. The work of Verbinski et al. [1968] can be used to find an approximate light yield for the ^{10}B(n,α)^{7}Li reactions products compared to energetic electrons. For instance, the scintillation signals from ^{10}B(n,α)^{7}Li reactions are approximately equivalent to that of 76-keV electrons [Drake et al. 1986; Eljen 2016a]. Consequently, gamma-ray background can interfere with neutron measurements. For fast neutrons, the initial (n,p) reaction in the plastic produces a prompt light response, followed by a time delay of approximately 2.7 μs before the light response from a ^{10}B(n,α)^{7}Li reaction appears. By measuring both light emission pulses from the proton recoil and the subsequent ^{10}B(n,α)^{7}Li reaction products, fast neutron interactions can be readily identified [Drake et al. 1986].

Liquid Scintillators

Liquid scintillators loaded with neutron reactive absorbers are also commercially available, and, in many ways, are more attractive as slow neutron detectors than are plastic scintillators. For liquid scintillators loaded with boron, pulse shape discrimination methods can be used to distinguish between gamma-ray and neutron events [Chou and Horng 1993]. Commercial products are available loaded with either natural or 90% enriched ^{10}B. Loading is typically 5% by weight, which yields 1% ^{10}B loading by weight for natural boron and 4.6% ^{10}B loading by weight for fully enriched boron. A variety of loadings can be obtained by special request. For electron and gamma-ray events, the light yield is approximately 65% that of anthracene, which is similar to that of other organic scintillators. The pulse height from a ^{10}B(n,α)^{7}Li event is approximately equivalent to a 90-keV electron pulse [Eljen 2016b]. For fast neutrons, the average capture time is a function of the ^{10}B loading, ranging from 0.3 μs for 5% enriched ^{10}B loading to 1.4 μs for 5% natural boron loading. Also, there is on average a 2.7 μs delay between the initial (n,p) reaction emission and the ^{10}B(n,α)^{7}Li emission, a delay which permits neutron identification with delayed time gating methods.

Liquid scintillators loaded with natural Gd rely on prompt gamma rays and conversion electron emissions from the ^{157}Gd(n,γ)^{158}Gd and ^{155}Gd(n,γ)^{156}Gd reactions. These scintillators are used for neutron spectroscopy and neutrino detection. Gd loading for commercial products is typically 0.5% by weight, but special Gd concentrations are available.

Because liquid scintillators are often employed in large containers, the solvents are chosen to have high flash points to reduce the risk of combustion.[16] Also, liquid scintillators can be contaminated with water moisture, a condition that compromises performance. Hence, the user must take care to keep exposure to air at a minimum. Typically these liquid scintillators are packaged under an inert environment (gas).

Ceramic Neutron Sensitive Scintillators

Li Glass Scintillators Cerium activated silicate glasses were introduced in the late 1950s for radiation detection [Ginther and Schulman 1958]. Although boron loaded glasses were also investigated for neutron detection [Bollinger et al. 1959], it is the Li-loaded class of silicate glasses [Voitovetskii et al. 1960a, Voitovetskii and

[16] The flash point of a liquid is the temperature at which the liquid has sufficient vapor pressure in equilibrium with the liquid to just form a flammable atmosphere.

Table 17.2. Properties of Ce activated ^{6}Li-Glass (nat. Li/ 95% enriched ^{6}Li/ 99.99% enriched ^{7}Li).

Property	GS1/GS2/GS3	GS10/GS20/GS30	KG1/KG2/KG3
Total Li by weight	2.4%	6.6%	7.5%
Density g cm^{-3}	2.66	2.5	2.42

Tolmacheva 1960b; Ginther 1960; Bollinger et al. 1962] that have been researched and widely commercialized for neutron detection. The scintillation mechanisms and properties of glass scintillators were briefly covered in Sec. 13.2.3, with more details on the properties of Li-loaded Ce-activated silicate glasses detailed in the literature [Spowart 1976, 1977; Fairley and Spowart 1978].

Li-loaded glass scintillators, activated with Ce, are commercially available in a variety of concentrations and enrichments, as summarized Table 17.2.[17] The absorption characteristics of such glasses are shown in Fig. 17.28. These glass scintillators can be obtained in various sizes, thicknesses, and ^{6}Li doping concentrations. Perhaps the most common of the Li glass materials used by commercial instrumentation companies is GS20 with 6.6% doping of 95% enriched ^{6}Li. GS20 has a maximum emission wavelength of 395 nm with between 20% and 30% of the light yield compared to that of anthracene. The light yield for GS20 glass ranges between 3,270 photons/MeV to 5,550 photons/MeV, depending upon the glass thickness and scintillation yield standard. For full energy absorption within the scintillator, the total light yield per interaction ranges between 15,450 and 26,200 photons/MeV centered about a wavelength of 395 nm. There are other Li glasses available, with a general labeling convention in which '1' designates natural lithium, '2' designates 95% enriched ^{6}Li, and '3' designates 99.99% enriched with ^{7}Li, which is insensitive to neutrons.

The decay constants are a function of radiation type and the Li loading, and generally have fast and slow decay components [Fairley and Spowart 1978]. Yet, from Table 17.2, these decay times vary only small amounts between radition types. There are varied Li loadings, with commercial codes [Spowart 1976, 1977] listed as 2.4% (GS1,GS2,GS3), 6.6% (GS10,GS20,GS30) and 7.5% (KG1,KG2,KG3) by weight. The ranges of the ^{6}Li(n,t)^{4}He reaction products in Li glass, tritons and α particles, are approximately 36.3 microns and 6.3 microns, respectively. Absorptions near the glass surface can lead to reaction products escaping the scintillator and decreasing the light output, an effect known as the "edge effect" [Yamaguchi 1989]. This situation can be remedied by fastening sheets of ^{7}Li-glass, such as GS3, GS30, or KG3, that is depleted of ^{6}Li

[17] The traditional designations for the different Li glass scintillators come from Levy West Laboratories, which became Applied Scintillation Technologies and is now named Scintacor. The 'GS' designation is, presumably, named for Ginther and Schulman.

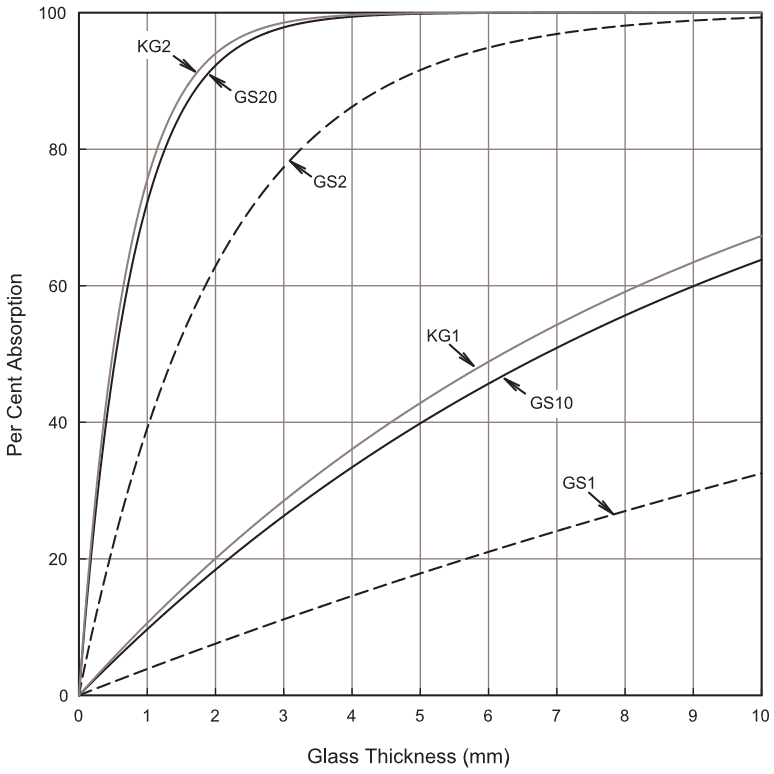

Figure 17.28. Absorption characteristics of 2200 m s^{-1} neutrons in various Ce activated Li glasses.

to 99.99% on both sides of the neutron sensitive Li glass. Reaction products escaping the neutron sensitive region fluoresce the ^{7}Li-glass and, thus, allow emitted photons to be recovered. Lithium glasses provide a convenient way to produce large area sheets of a neutron scintillator and are used to detect both thermal and fast neutrons. They can be used under high pressure and at high temperatures because of their high melting point of 1475 K. Spowart [1977] reports a luminescent thermal dependence that reaches a maximum near 450 K, reducing with either higher or lower temperatures.

Gadolinium Oxysulfide Ceramics Gadolinium oxysulfide (Gd_2O_2S, GOS or Gadox) is used for thin scintillator screens. It is available as a powder, but can be hot pressed into a translucent ceramic [Greskovich and Duclos 1997]. Co-dopants include Pr, Ce, and F, and have a central emission wavelength of 580 nm and emit 40,000 photons/MeV [Lecoq et al. 2006]. The emission decay time is relatively long at 2.1 μs. Gadox is primarily used for digital radiography imaging panels for x-ray excitations. However, its elemental Gd constituent produces a high neutron absorption efficiency; hence, it has been evaluated as a neutron scintillator. Because Gd is a good absorber of photons and neutrons, and the resulting reaction products are nearly indistinguishable (Compton electrons, photoelectrons, conversion electrons), there are difficulties in distinguishing between neutron and background gamma-ray events.

However, because Gd is such a strong thermal-neutron absorber ($\sigma^{\rm nat}_{\rm Gd}(n,\gamma) = 48,610$ b at 2200 m/s), only a thin layer is necessary for adequate performance. For instance, the density of Gadox is 7.34 g cm^{-3} with a corresponding 2200-m/s macrocroscopic cross section of 1,360 cm^{-1}. These values indicate that a layer only 10 μm thick absorbs over 85% of intersecting thermal neutrons. Lindsay et al. [1986] report the use of a thin layer of Gadox on a LIXI (Light Intensifier X-ray Image) scope, in which the background

from gamma-ray interactions is suppressed for real-time neutron radiography. Kardilov et al. [2011] report methods to improve performance of Gadox films for neutron imaging by imbedding the scintillator in sodium silicate (or "water glass") and applying an Al reflective coating. Greskovich and Duclos [1997] report that the hexagonal crystal structure of Gadox limits light collection, a consequence of optical anisotropy, residual porosity, and foreign phases from densification additives. They also report that Gadox is susceptible to x-ray damage, more so than many other ceramic scintillators.

Zinc Sulfide Scintillator Zinc sulfide activated with silver is a bright scintillator (see Chapter 13) with a light yield that is approximately 130% of that of NaI:Tl. This material is often mixed with neutron reactive materials to produce a thermal-neutron detector. For instance, LiF or B_2O_3 mixed with ZnS:Ag make effective scintillating films. ZnS:Ag is available mainly in powder form, and it is also opaque to its own light emissions, a property that limits the working thickness of the material to no more than 25 mg cm^{-2} or about 60 microns. The most probable light emission wavelength is centered at 450 nm and matches adequately well to most PMTs. The index of refraction is 2.36 at 450 nm that can become a significant source of internal reflection if coupled directly to glass or PMMA ($\theta_c = 39.5\,^\circ$). ZnS:Ag is often (incorrectly) stated to be insensitive to gamma rays and beta particles. Actually, ZnS:Ag is sensitive to both gamma rays and electrons; however, the amount of energy deposited in a thin film of only 60 microns or less by an energetic electron is relatively small and easily distinguished from heavy ion reaction products from either ^{6}Li(n,t)^{4}He or ^{10}B(n,α)^{7}Li by pulse height discrimination.

17.5 Semiconductor Slow Neutron Detectors

Semiconductor slow-neutron detectors can be classified as either coated detectors or bulk detectors. Coated detectors are electron devices, usually Schottky or junction diodes, upon which a neutron reactive coating has been applied. Bulk detectors are semiconductors with one or more neutron reactive constituent isotopes. There are variations of both types [Caruso 2010], and a few of the more important structures are described below.

Coated Semiconductor Neutron Detectors

Coated semiconductor neutron detectors are generally fashioned as semiconductor diodes with a neutron reactive coating applied to the rectifying contact.[18] The first such detector was a small Si *pn* junction diode, only a few square milimeters in area, with a ^{10}B film vapor deposited upon the rectifying junction [Babcock et al. 1959]. Although studied for decades, these coated semiconductor neutron detectors were viewed as novel devices for dosimeter packages, primarily because of their inherently low efficiencies. However, recently, with the introduction of microstructured semiconductor neutron detectors (MSNDs), they are receiving renewed attention because of their high neutron detection efficiencies. Overall, there are two main types of coated semiconductor neutron detectors, namely planar diode detectors and MSNDs.

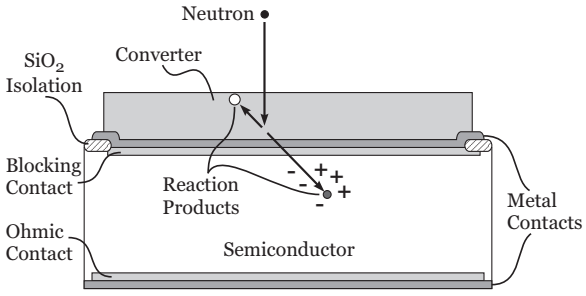

Figure 17.29. The basic construction of a coated planar semiconductor diode neutron detector.

[18] In some of the original literature on these devices, they are called "foil detectors" because a thin foil of the neutron reactive material was positioned adjacent to the semiconductor diode detector. However, almost all detectors of this sort now have the reactive material applied directly to the rectifying junction of the semiconductor diode; hence, "foil detector" is no longer a suitable description.

Planar Diodes Thin film neutron detectors consist of semiconductor diodes, preferably with relatively thin contact layers, upon which a layer (or layers) of neutron reactive material has been deposited. The basic concept has been used by a variety of research groups (see the review by Caruso [2010]). As shown in Fig. 17.29, neutrons absorbed in the neutron reactive film release charged-particle reaction products in opposite directions, one of which may enter the semiconductor diode detector. Charged particles entering the detector lose their energy through Coulombic scattering, thereby creating a high density cloud of columnar ionization in the form of electron-hole pairs. The semiconductor diode detector is voltage biased to separate the electron-hole pairs and drift the charges to their respective contacts. The mobile charges each induce an image charge on the contacts as they move through the device, and the induced charge is integrated and measured by an external preamplifier and accompanying electronics. The basic structure of a planar coated semiconductor neutron detector is depicted in Fig. 17.29 that shows neutron reactive material fastened to the electrical contact adjacent to the diode rectifying contact. Advantages of these detectors include a compact size and low operating voltages and, thus, make possible the production of compact neutron dosimeters [Aoyama et al. 1992; Sasaki et al. 1998; Ndoye et al. 1999] and compact fieldable instrumentation [Schulte and Kesselman 1999]. It is also possible to integrate multiple detectors into an array upon a single substrate to create compact linear neutron imaging arrays [Campbell et al. 1997; Schelten et al. 1997; Petrillo et al. 1999; McGregor 2002b] or 2-dimensional neutron imaging arrays [Mirashghi et al. 1992, 1994; McGregor et al. 1996b; Unruh et al. 2009].

Semiconductor diodes coated with a neutron reactive material have been studied as neutron detectors for well over fifty years and date to the original work by Babcock et al. [1959]. Most of the devices reported in the literature either have a coating of ^{10}B [Rose 1967] or ^{6}LiF [Pospíšil et al. 1993], although Gd [Feigl and Rauch 1968] and pure Li metal coatings [McGregor et al. 2003] have also been explored. Si is the semiconductor substrate most often used as the substrate, mainly because it is relatively inexpensive and has a small thermal-neutron interaction cross section of $\sigma_{(n,\gamma)} = 0.17$ b. However, gallium arsenide (GaAs) [McGregor et al. 2000] and chemical vapor deposited (CVD) diamond [Foulon et al. 1998] have also been explored as semiconductor substrates for coated neutron detectors. Simple semiconductor diodes coated

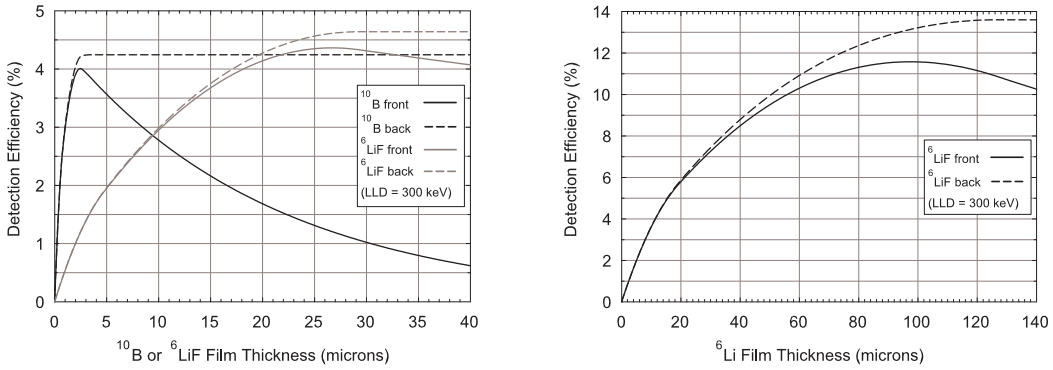

Figure 17.30. (left) Thermal neutron (2200 m s^{-1}) detection efficiency vs. film thickness for front and back irradiation of a Si detector coated with ^{10}B or ^{6}LiF. (right) Thermal neutron (2200 m s^{-1}) detection efficiency vs. film thickness for front and back irradiation of a Si detector coated with ^{6}Li metal. [from McGregor et al. 2003].

with either ^{10}B or ^{6}LiF are limited to approximately 5% thermal-neutron detection efficiency [McGregor et al. 2003], and consequently have received limited application as neutron detectors. Detectors can be stacked in various configurations to improve efficiency [McGregor et al. 2003], similar to stacking gas-filled neutron detectors. The same equations, Eqs. (17.34) to (17.38), used to calculate efficiencies for coated gas-filled

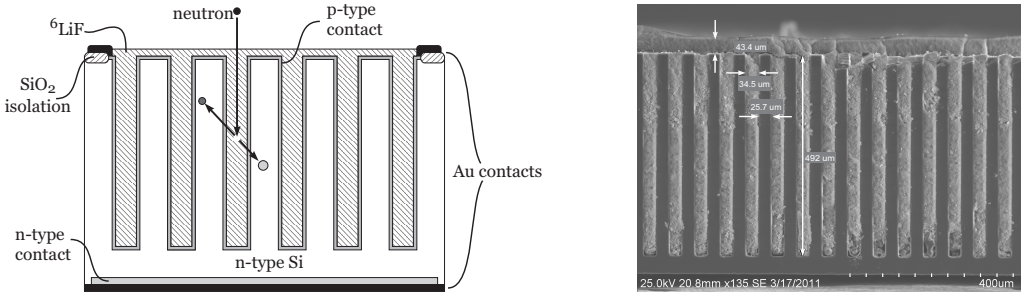

Figure 17.31. (left) The basic structure of an MSND. (right) An MSND with 492 μm deep trenches, each 25.7 μm wide, backfilled with ^{6}LiF nanoparticles. The Si fins are 34.5 μm wide. [from McGregor et al. 2013b; McGregor et al. 2015].

detectors also apply to coated-semiconductor detectors, the results of which are shown in Fig. 17.30. The efficiency can be improved by using pure ^{6}Li metal, in which the thermal neutron detection efficiency can be increased above 13% [McGregor et al. 2003]. However, pure Li metal is reactive and requires moisture proof encapsulation in an inert environment. Semiconductor detectors coated with natural Gd have also been explored [Feigl and Rauch 1968; Schulte et al. 1994; Schulte and Kesselman 1999]. The appeal of using Gd is because of its large thermal-neutron (n,γ) cross section of 48,610 b, but the resulting low-energy conversion-electron and gamma-ray emissions can be difficult to distinguish from background gamma rays in a high radiation field. A compensated detector design can help discern between background gamma rays and neutron signals [McGregor et al. 2002b].

Microstructured Diodes Muminov and Tsvang [1987] suggested that channels etched in a semiconductor substrate backfilled with neutron reactive material might increase the neutron detection efficiency. The first such device was reported by McGregor et al. [2002a], and consisted of an array of holes etched into a GaAs substrate backfilled with enriched ^{10}B nanoparticles. Although these initial detectors exhibited modest efficiencies, they indicated the technology of etching microstructures into the semiconductor held promise. Since that time, these Microstructured Semiconductor Neutron Detectors (MSNDs) have matured into a highly efficient and compact type of neutron detector.

The basic MSND has microcavity features extending into a semiconductor surface. Within and around the microstructures is a rectifying contact [McGregor et al. 2013b]. Many of the first generation devices had simple Schottky barrier rectifying contacts; however, almost all recent generation devices have p-type contacts diffused into high-resistivity n-type Si. Although the first such detectors were backfilled with enriched ^{10}B, the relatively higher energy reaction-products from the ^{6}Li(n,t)^{4}He reaction produces improved detection efficiency with better gamma-ray discrimination [Uher et al. 2007; Shultis and McGregor 2009].

Hence, modern MSNDs are mostly constructed with nanoparticles of enriched ^{6}LiF backfilled into the Si microstructures. The detector configuration and operation are depicted in Fig. 17.31 (left). Neutrons interact in the ^{6}LiF material, which has a macroscopic thermal-neutron (n,α) cross section of 57.4 cm^{-1}. Absorption of a neutron causes the compound nucleus ^{7}Li* to decay into an alpha particle with kinetic energy of 2.06 MeV and a triton with kinetic energy of 2.73 MeV. For thermal neutrons, these reaction products are emitted in opposite directions. With narrow channels, the probability of one or more reaction products emerging from the ^{6}LiF absorber into the adjacent semiconductor can be relatively high. Those reaction products that do enter the semiconductor produce a dense cloud of electron-hole pairs. An applied reverse bias across the detector junction drifts the released electrons and holes to the electrical contacts, which induces a current to flow, and ultimately produces a voltage pulse in the attached preamplifier circuitry. Deep channels, on the order of 400–500 microns, increase the neutron absorption probability. Narrow channels, on the order

of 20 microns wide, improve the probability of capturing and measuring a reaction product in the adjacent semiconductor. The width of the semiconductor region between channels is also generally close to the channel width of about 20 microns.

These microstructured detectors are manufactured with VLSI methods, methods which permit mass production and, thereby lower the cost of the detectors. Si is the preferred substrate, mainly because it has a low neutron interaction cross section and it is inexpensive. Further, the (110) orientation of Si can be easily and rapidly anisotropically etched to form deep narrow trenches on the order of 450 microns (Fig. 17.31 (right)). The *pn* junction contacts are formed with traditional dopant diffusion in high-temperature furnaces, and metallization is applied with physical vapor deposition. The backfilling of the neutron reactive material is economically and rapidly performed by using a centrifuge to push ^{6}LiF nanoparticles in solution into the channels. These detectors are fabricated on the wafer scale, yielding up to fifty 1-cm^2 detectors on a single 100-mm diameter wafer. MSNDs also require little to no applied voltage, mainly because of the deep depletion region in the high purity Si.

In recent years, MSNDs have been fabricated as dual sided devices, with p-type regions on both sides of a high purity n-type substrate [Fronk et al. 2015]. Neutrons that stream through the Si regions on one side of the device encounter the neutron absorber on the other side of the device. The manufacture processing for dual-sided MSNDs is actually easier than the singled-sided design, mainly because there is only one diffusion step [Fronk et al. 2015]. Ochs et al. [2019] explain that the optimum packing fraction of ^{6}LiF in the trenches is approximately 65% rather than solid, a consequence of the combined effects of neutron absorption lengths and reaction product ranges. These new detectors have reached over 69% thermal-neutron detection efficiency $\epsilon_{\rm tn}$, and theoretical models suggest that values of $\epsilon_{\rm tn}$ up to 80% are possible [Ochs et al. 2019]. Both single and dual-sided MSNDs are commercially available, routinely fabricated with $\epsilon_{\rm tn} > 30\%$ and $\epsilon_{\rm tn} > 60\%$, respectively.[19] The detectors are mass produced in compact packages as either 1-cm^2 or 4-cm^2 detectors.

MSNDs have several advantages as alternative neutron detectors. They are rugged and compact, and require less than 2 volts to operate. Under certain conditions, no voltage is required to operate the detector (although it is still required for the coupling electronics). MSNDs are relatively gamma-ray insensitive, with discrimination ratios n/γ greater than 10^6. Because MSNDs are mass produced, they can be purchased inexpensively compared to ^{3}He detectors. They can be arranged in arrays with several different form factors [McGregor et al. 2005], or can be used as single detectors for neutron dosimetry and remote neutron monitoring. The detectors can also be arranged in arrays with form factors of common ^{3}He gas-filled detectors. A device loaded with single-sided MSNDs, having similar dimensions of a 4-atm ^{3}He gas-filled detector, matched the performance of the much more expensive detector [McGregor et al. 2015]. Work with an array of dual-sided MSNDs yielded greater efficiency than a compact 6-atm ^{3}He gas-filled detector of the same size [Ochs et al. 2017], and calculations show that MSNDs can also give comparable performance to small 10-atm ^{3}He gas-filled detectors. Large arrays of MSNDs arranged in blocks of HDPE have been demonstrated as a system to locate and identify fast neutrons sources [Hoshor et al. 2015]. From the average detection location in the 3D array of detectors, an algorithm determines the most probable type of source producing the neutron field as well as the direction of the source.

There are reports of MSNDs with boron backfilling instead of LiF [Nikolic et al. 2008; Huang et al. 2014]. The single advantage to using boron backfilling is the higher neutron absorption cross section, thereby reducing the mean absorption length of 180 microns for ^{6}LiF to only 20 microns for pure ^{10}B. Hence, the microstructures can be 9 times shallower for the boron-filled device than the ^{6}LiF-filled device and produce similar absorption efficiency, provided that the backfilling densities are similar. However, because the reaction product energies and ranges are much less for ^{10}B than ^{6}LiF, there are disadvantages to the use of boron

[19] Through Radiation Detection Technologies, Inc.

[Shultis and McGregor 2009]. These disadvantages include relatively high energy loss from dead layers at the microstructure boundaries, significant count losses from the wall effect, and the requirement of much smaller features to etch and subsequently backfill (about 2 microns for ^{10}B opposed to about 25 microns for ^{6}LiF). Nikolic et al. [2008] have produced MSNDs as"pillar" detectors while Huang et al. [2014] report Si detectors with holes backfilled with boron. Wu et al. [2017] have adopted the single-sided straight trench structure for boron-filled MSNDs, reporting 32% thermal neutron detection efficiency for small devices.

17.5.1 Bulk Semiconductor Neutron Detectors

Semiconductor detectors, in which one of more constituent atoms are neutron reactive, are called *bulk semiconductor neutron detectors*.[20] The obvious advantages of a solid state version of a gas-filled ion chamber is that they should have high-efficiency and a compact form. Bulk solid-state neutron detectors can be divided into two basic categories: those that rely on the detection of charged particle reaction products and those that rely on prompt capture gamma rays. In general, this type of neutron detector is difficult to make reliably and at the time of writing this book is not commercially available. However, for the sake of completeness, a brief discussion of this class of detectors is included.

The bulk materials that rely upon charged particle emissions are based on boron and lithium containing semiconductors. In the search for bulk semiconductor neutron detectors, the boron-based materials, such as BP, BAs, BN, and B_4C, have been investigated more than other potential materials. See, for example, Ananthanarayanan et al. [1974], Kumashiro et al. [1987], Emin and Aselage [2005], Caruso et al. [2006], McGregor et al. [2008], and Doan et al. [2015]. Boron-based semiconductors in cubic form are difficult to grow as bulk crystals, mainly because they require high temperatures and high pressure for synthesis. BP and BAs can decompose into undesirable crystal structures (cubic to icosahedral form) unless synthesized under high pressure. B_4C also forms icosahedral units in a rhombohedral crystal structure [Clark and Hoard 1943], an undesirable transformation because the icosahedral structure has relatively poor charge collection properties [Domnich et al. 2011] which make these icosahedral forms unsuitable for neutron detection.

BN can be formed as either simple hexagonal, cubic (zincblende) or wurtzite crystals, depending on the growth temperature, and it is usually grown by thin film methods. It is the simple hexagonal form of BN that has been most studied as a neutron detector. Thin film chemical vapor deposition methods are usually employed to produce BP, BAs, BN, or B_4C. These boron-based films are often grown upon n-type Si substrates, which can form a *pn* junction with the Si and, therefore, produce a simple coated Si diode as described at the beginning of this section. Consequently, the neutron response from the device can be easily mistaken as a bulk response when it is actually a coated diode response. To date, there is sparse evidence of boron-based semiconductors producing intrinsic neutron signals.[21]

Li-containing semiconductors, categorized as Nowotny-Juza compounds, have also been investigated as bulk neutron detectors. The Nowotny-Juza compound LiZnAs has been demonstrated as a neutron detector [Montag et al. 2016]; however, the material is difficult and expensive to synthesize, and only small semiconductor crystals have been reported. Traditional semiconductor materials with neutron reactive dopants have been investigated, namely, Si(Li) detectors. Neutrons interact with the lithium dopant in the material and produce energetic reaction products. However, the dopant concentration is relatively low in Li drifted Si detectors (or other doped semiconductors), typically less than 10^{19} cm^{-3}. For a degenerate concentration of Li on the order of 10^{19} cm^{-3}, a 5-cm-thick block of natural Si(Li) would have less than 1% thermal-neutron

[20] The expression "solid-form" semiconductor neutron detectors has been used in the past by the authors, but it seems awkward and has thus been abandoned.

[21] The spectral output from many of these boron-based semiconductors grown on Si is often later identified correctly as the spectrum from a boron-coated diode as in Fig. 17.17 [McGregor and Shultis 2004; 2005]. Films grown on insulating substrates also may produce signals from reaction products ionizing the surrounding air.

detection efficiency, while a 5-cm-thick block of a Si(^{6}Li) detector would have only 4.6% thermal-neutron detection efficiency.

Another material currently being studied as a bulk semiconductor neutron detector is lithium indium diselenide ($LiInSe_2$) [Tupitsyn et al. 2012]. Originally studied for its optical properties [Isaenko et al. 2002], $LiInSe_2$ has garnered interest for its semiconductor properties. With a bandgap of 2.85 eV, the material can operate as a room temperature detector. $LiInSe_2$ detectors rely on the ^{6}Li(n,t)^{4}He reaction as the neutron detection mechanism. Energy from these heavy ion reaction products is easily absorbed provided the crystal is reasonably thicker than the combined ion ranges (that are about 80 μm). Lukosi et al. [2016, 2017] demonstrated that $LiInSe_2$ could be used as a neutron detector and a neutron imager. Although there appear to still be problems with producing uniform $LiInSe_2$ crystals, this relatively new neutron detector material shows promise. The relatively high Z value of In suggests that gamma-ray background could be a potential problem; however, pulse height discrimination can help distinguish between gamma rays and neutrons because of the high 4.67-MeV Q-value of the ^{6}Li(n,t)^{4}He reaction.

The mass density of $LiInSe_2$ is 4.25 g cm^{-3} and the atom density is 9.15×10^{21} cm^{-3}. The resulting 2200-m/s macroscopic cross section for the ^{6}Li(n,t)^{4}He reaction is 0.653 cm^{-1}. If 95% enriched ^{6}Li is substituted, the 2200-m/s macroscopic absorption cross section for the ^{6}Li(n,t)^{4}He reaction increases to 8.18 cm^{-1}. The indium in the compound, and to a lesser extent the selenium, combine to parasitically absorb neutrons without producing a useful signal. Consequently, the total 2200-m/s macroscopic absorption cross sections for natural and enriched forms of $LiInSe_2$ are 2.64 cm^{-1} and 10.17 cm^{-1}, respectively. The combined absorption cross sections of the various elements yield a limiting 2200-m/s neutron detection efficiency of 24.6% from the ^{6}Li(n,t)^{4}He reaction. Also, the activation of ^{115}In leads to the gradual buildup of a background beta-particle and gamma-ray signal, which decays with a half-life of 54.2 minutes after irradiation. If 95% enriched ^{6}Li is substituted, the limiting thermal neutron detection efficiency from the ^{6}Li(n,t)^{4}He reaction increases to 80.4%.

Prompt gamma-ray emitting semiconductors, such as CdTe [Vradii et al. 1977], CdZnTe [McGregor et al. 1996a], and HgI_2 [Beyerle and Hull 1987; Bell et al. 2004], have been successfully used as neutron detectors. Both natural Cd and Hg have relatively large thermal-neutron (n,γ) cross sections of 2444 b and 370 b for 2200 m s^{-1} neutrons, respectively. These detectors rely upon the prompt gamma-ray emissions from the ^{113}Cd(n,γ)^{114}Cd reaction (producing 558.6-keV and 651.3-keV gamma rays) and the ^{199}Hg(n,γ)^{200}Hg reaction (producing 368.1-keV and 661.1-keV gamma rays). Because the emissions can be reabsorbed at distances relatively far from the neutron interaction, the spatial information of the original neutron interaction is lost. These semiconductor materials and detectors are best used as gamma-ray spectrometers and, hence, are intrinsically sensitive to the gamma-ray background. The effective neutron detection efficiency is compromised because of the relatively small Compton ratio. In other words, a large fraction of events add to the Compton continuum rather than to the full energy peak, thus, making discrimination between neutrons and background gamma rays difficult. However, with adequate energy resolution, pulse height discrimination can be used to distinguish the prompt gamma-ray emissions from neutron interactions.

CdTe and CdZnTe have mass densities of 5.86 and about 5.8 g cm^{-3} and 2200-m/s macroscopic absorption cross sections of 37.2 cm^{-1} and 34.8 cm^{-1}, respectively. Hence, over 95% of thermal neutrons are absorbed within a 1-mm thickness of either material with most thermal neutrons being absorbed near the detector surface. For detectors of typical thicknesses between 2 and 10 mm, nearly half of the gamma rays are emitted in directions away from the detector bulk. This geometric problem, coupled with the low gamma-ray attenuation coefficients for 558.6-keV and 651.3-keV gamma rays (see Fig. 16.1), mostly from Compton scattering, yields a relatively low neutron detection efficiency. For instance, McGregor et al. [1996a] report a thermal-neutron detection efficiency of only 3.7±1.9% for a 3-mm-thick CdZnTe detector, although the device was capable of absorbing over 99% of the intersecting thermal neutrons. Using Cd starting material

slightly depleted of ^{113}Cd tends to distribute neutron absorption more evenly throughout thick crystals; however, this approach can be costly.

The problem of non-uniform neutron absorption is less pronounced for HgI_2, which has a density of 6.4 g cm^{-3} and a 2200-m/s macroscopic cross section of 3.17 cm^{-1}. Because the neutron absorption is more evenly distributed through the material, it takes approximately 1 cm of material to absorb 95% of thermal neutrons. Further, the prompt gamma-ray emission energy of 368.1 keV has a higher linear attenuation coefficient, with the photoelectric coefficient being slightly higher than the Compton scattering coefficient. Hence, the prompt gamma rays resulting from ^{199}Hg(n,γ)^{200}Hg reactions have a higher probability of reabsorption compared to that for the prompt gamma rays from CdTe and CdZnTe devices. Unfortunately, material problems with HgI_2 have not yet yielded results that support its widespread use for neutron detection. Further, because of the high Z components, interference from background gamma rays becomes more of a problem so that good energy resolution of the full energy peak is important.

17.6 Neutron Diffraction

The concept of wave-particle duality was introduced in Secs. 3.2.5 and 3.2.6, and Bragg diffraction was briefly mentioned in Sec. 12.4. Described here is a method to use the wave nature of neutrons with Bragg diffraction to measure the energy of slow neutrons. Recall from Sec. 3.2.6 that the de Broglie wavelength is

$$\lambda = \frac{h}{p} = \frac{h}{m_n v}. \tag{17.39}$$

where h is Planck's constant, m_n is the neutron rest mass, and v is the neutron speed. Given a neutron energy, then Eq. (17.39) can be rewritten as

$$\lambda = \frac{h}{\sqrt{2m_n E}}. \tag{17.40}$$

At low energies, relativistic effects can be ignored, hence the rest mass of a neutron can be used to find the de Broglie wavelength

$$\lambda_n = \frac{0.286}{\sqrt{E}} \text{ Å} \tag{17.41}$$

where λ_n is in angstroms and E is expressed in electron volts (eV).

The Bragg condition for diffraction is related to wavelength by

$$n\lambda = 2d \sin\theta, \tag{17.42}$$

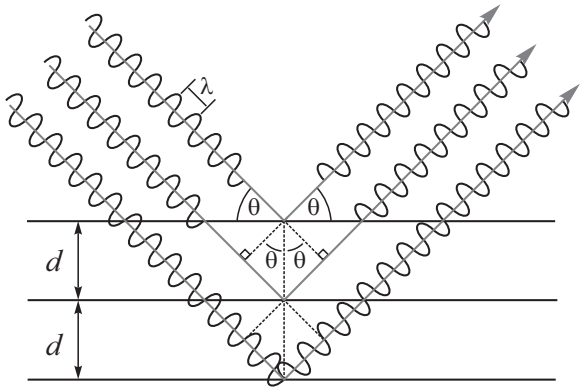

Figure 17.32. Geometry for Bragg diffraction of particles, showing the case for $n = 4$.

where n is an integer, d is the spacing between parallel atomic planes in an ordered crystal, and θ is the angle at which radiation intersects the crystal from the direction parallel to the planes, as depicted in Fig. 17.32. Elsasser [1936] predicted that neutrons could be diffracted from crystal planes, shortly thereafter proven by experiments conducted by Halban and Preiswerk [1936] and Mitchell and Powers [1936]. Substitution of Eq. (17.41) into Eq. (17.42) yields

$$\sin\theta = \frac{0.286n}{2d\sqrt{E}}, \tag{17.43}$$

where d is in angstroms and E is in eV. Consider the fundamental diffraction condition with $n = 1$. Here it is shown that given a distance d between crystal planes there is an lower limit to the neutron energy that can be observed. Also, given a practical working angle θ, an upper energy limit can also be determined.

Example 17.3: Given a lower diffraction angle limit of 1°, what are the neutron diffraction energy limits for $n = 1$ of a Si crystal oriented for diffraction off the {111} planes.

Solution:

For silicon, $a = 5.43$ Å and the distances between planes are found from Eq. (12.4),

$$d = \frac{a}{\sqrt{h^2 + k^2 + l^2}} = \frac{5.43 \text{ Å}}{\sqrt{3}} = 3.135 \text{ Å}$$

where (hkl) refer to the Miller indices of the crystal. The limits must lie between $\sin(1^\circ)$ and 1, hence

$$\sin(1^\circ) \leq \frac{0.286}{2d\sqrt{E}} \leq 1.$$

Rearranging terms yields

$$6.83 \text{ eV} \geq E \geq 0.00208 \text{ eV}.$$

Although reflection and diffraction seem similar, in that the angle of incidence is equal to the angle of emission, they are fundamentally different. First, all atoms in the crystal along the path of the incident beam participate in diffraction, whereas reflection is more or less a surface phenomenon (e.g., reflection of light). Diffraction occurs only if the Bragg condition of Eq. (17.42) is met, while reflection can occur at practically any angle. Reflection is a far more efficient process than diffraction. For instance, practically all photons are reflected from a specular surface, whereas a diffracted beam comprises only a few percent of the incident beam. Neutron diffraction can be used in either reflection or transmission modes [Bacon and Lowde 1948], as depicted in Fig. 17.33. In either case, the effect of diffracted neutrons leaving the beam is called *extinction*. In other words, the strength of the neutron beam diminishes as neutrons are diffracted out, thereby causing the diffracted beam to weaken as the diffraction depth increases.

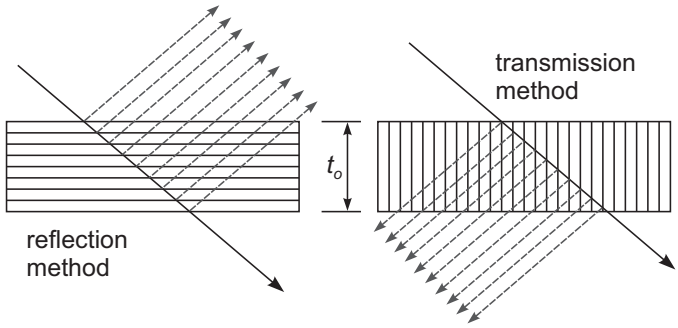

Figure 17.33. Distinction between reflection and transmission cases of diffraction by a parallel crystal slab of thickness t_o. After Bacon [1975].

The method of neutron diffraction can be used to isolate specific energies of neutrons, most effectively for slow neutrons. Such an arrangement is shown in Fig. 17.34. Consider the case in which moderated neutrons from a source are collimated onto a perfect crystal. If the origin of the neutrons is considered a point centered at the collimator entrance, then neutrons

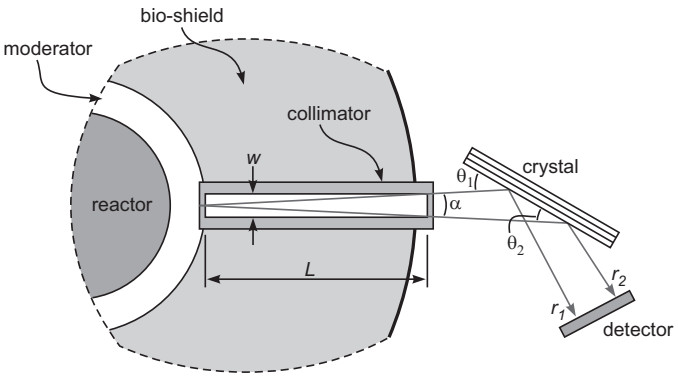

Figure 17.34. Common arrangement for a neutron diffractometer at a nuclear reactor beamport. After Spalek [1965].

may be diffracted at limits defined by rays r_1 and r_2. Consequently, only those neutrons with wavelength (energy) defined by θ_1 in Eq. (17.42) diffract along ray r_1, while only those neutrons with wavelength (energy) defined by θ_2 in Eq. (17.42) will diffract along ray r_2. Obviously, neutrons confined within these limits will diffract only if the Bragg condition is also met. Hence, there is a spread of neutron wavelengths that can diffract from the crystal with this configuration

$$n\ d\lambda = 2d\cos\theta d\theta. \tag{17.44}$$

The angle α defined by the collimator is small, hence

$$d\theta = \alpha \simeq \frac{w}{L} \tag{17.45}$$

where w and L are the collimator diameter and length, respectively. Note that neutrons may enter the collimator at any location along the entrance orifice, which broadens the total spread in angle to 2α. Substitution of these results into Eq. (17.44) yields

$$n\ d\lambda = \frac{4wd}{L}\cos\theta. \tag{17.46}$$

The *resolving power* η is a measure of the diffractometer ability to distinguish between neutron wavelengths, generally defined as

$$\eta = \frac{\lambda}{d\lambda} = \frac{L\tan\theta}{2w}. \tag{17.47}$$

In reality, crystals have numerous imperfections in the structure. In fact, a so-called perfect crystal without point defects will still have structural misorientations of crystal segments on the order of 500 nm long, referred to as the *crystal mosaic*. The magnitude of the angular misorientation of these mosaic blocks, called the *mosaic spread*, can range from a few minutes of arc up to a half a degree. Consequently, neutrons can actually penetrate deeper into the crystal and diffract more efficiently over a range of mosaic angles.[22] This increase in diffracted neutrons is generally proportional to the square of the crystal structure factor ($\boldsymbol{F}_{hkl}^2$) [Bacon 1966].

17.6.1 The Structure Factor for Crystals $\boldsymbol{F}_{hkl}$

The crystal structure factor $\boldsymbol{F}_{hkl}$ is a mathematical method of describing the diffraction of waves in a crystalline solid, which describes the amplitude and phase of the diffracted wave

$$\boldsymbol{F}_{hkl} = \sum_{j=1}^{N} b_j e^{[2\pi i(hx_j + ky_j + lz_j)]}, \tag{17.48}$$

where the sum is over all atoms (N) in a unit cell, x_j, y_j, z_j are the position coordinates of the jth atom, and b_j is the neutron scattering length of the jth atom. From Euler's formula

$$\boldsymbol{F}_{hkl} = \sum_{j=1}^{N} b_j \cos\left[2\pi\left(hx_j + ky_j + lz_j\right)\right] + i\sum_{j=1}^{N} b_j \sin\left[2\pi\left(hx_j + ky_j + lz_j\right)\right]. \tag{17.49}$$

The notation for the structure factor is often abbreviated as simply $\boldsymbol{F}$.

[22] In fact, diffraction crystals are purposely compressed under pressure to produce an optimum mosaic spread in order to increase the strength of the diffracted neutron beam.

Recall from Chapter 12 that the terms hkl refer to the Miller indices. Hence, the structure factor is the result of all waves scattered in the $[hkl]$ direction of reflection by the N atoms contained in the unit cell. The structure factor for neutrons is described in terms of length with units on the order of 10^{-12} cm. When considering a *small* volume of the crystal, dV, the total integrated diffraction under the reflection orientation from this segment is

$$QdV = \frac{\lambda^3 M^2}{\sin(2\theta_B)} \boldsymbol{F}_{hkl}^2, \tag{17.50}$$

where M is the reciprocal of the unit cell volume, θ_B is the Bragg scattering angle, and λ is the de Broglie neutron wavelength.

As neutrons proceed through a *large* crystal at the Bragg angle, the diffracted amplitude is reduced by both neutron absorption and neutron diffraction. Thus, even after allowing for the effect of absorption, the deeper parts of the crystal contribute less than the upper parts, because neutrons corresponding to the Bragg condition of Eq. (17.42) are being removed before reaching lower crystal planes. Consequently, Eq. (17.50) fails to describe the integrated diffraction for thick crystals, the phenomenon referred to earlier as extinction [Bacon and Lowde 1948].

Example 17.4: Determine the structure factor of an FCC lattice.

Solution:

The unit cell has four complete atoms, with one located at the origin and three located at the adjacent faces of the unit cubic cell. Hence, the coordinates for four adjacent atoms in the unit cell can be written as

$$x_1, y_1, z_1 = (0,0,0);\ x_2, y_2, z_2 = \left(\frac{1}{2}, \frac{1}{2}, 0\right);$$

$$x_3, y_3, z_3 = \left(0, \frac{1}{2}, \frac{1}{2}\right);\ x_4, y_4, z_4 = \left(\frac{1}{2}, 0, \frac{1}{2}\right)$$

For integer values of hkl and from Eq. (17.49) the structure factor becomes,

$$\boldsymbol{F}_{hkl} = b\left(1 + \cos[\pi(h+k)] + \cos[\pi(k+l)] + \cos[\pi(h+l)]\right).$$

Consequently, if hkl are *all* even or are *all* odd, then $\boldsymbol{F}_{hkl} = 4b$. However, if hkl is mixed odd and even, then $\boldsymbol{F}_{hkl} = 0$.

17.6.2 Angular Response to a Maxwellian Neutron Distribution

Consider the distribution of slow neutrons in a nuclear reactor, generally described by a Maxwellian distribution

$$dn = K_1 v^2 e^{-v^2/v_o^2}\, dv, \tag{17.51}$$

where dn is the number of neutrons within differential speed dv about v per unit volume, and v_o is the most probable neutron velocity. The flux of neutrons of some speed v is simply the product $v\,dn$ so intensity or flux of neutrons traveling down the beam port is

$$dn_b = v\ dn = K_1 v^3 e^{-v^2/v_o^2}\, dv. \tag{17.52}$$

These neutrons strike the diffraction crystal, as depicted in Fig. 17.34. Neutron diffraction off the crystal varies inversely with the neutron energy E or v^2. Consequently, the diffracted beam (reflection condition) spectrum from the neutron beam becomes

$$dn_d = \frac{v\ dn}{v^2} = K_1 v e^{-v^2/v_o^2}\ dv. \tag{17.53}$$

According to Eq. (17.53), as the neutron velocity increases, the number of diffracted neutrons decreases with v. Given any Bragg angle θ_B, the neutron velocities must satisfy Eq. (17.42) to undergo diffraction. Neutrons that reach the neutron detector for select Bragg angles are of constant velocity. Hence, to map a select neutron energy range, the crystal can be rotated in the neutron beam to change θ_B. The detector position must also be changed by $2\theta_B$ to match the Bragg angle.

From Eq. (17.39) and Eq. (17.44), one can derive

$$-\frac{nh}{mv^2}dv = 2d\cos\theta\ d\theta. \tag{17.54}$$

Considering only the fundamental diffraction ($n = 1$), Eq. (17.54) can be rearranged to find

$$dv = -\frac{2m_n v^2 d}{h}\cos\theta\ d\theta. \tag{17.55}$$

Substitution of Eq. (17.55) into Eq. (17.53) yields

$$\frac{dn_d}{d\theta} = -K_1\frac{2m_n v^3 d}{h}e^{-v^2/v_o^2}\ \cos\theta. \tag{17.56}$$

The collimator geometry defines $d\theta$ and can be regarding as constant. Consequently, the detector response C, or the count rate, is described by

$$C = K_2 v^3 e^{-v^2/v_o^2}\ \cos\theta, \tag{17.57}$$

and when divided by $\cos\theta$ yields

$$\frac{C}{\cos\theta} = K_2 v^3 e^{-v^2/v_0^2}, \tag{17.58}$$

the same relative distribution as the slow neutron distribution in the beamport (Eq. (17.52)). Hence, this outcome yields the thermal neutron *flux* in the nuclear reactor, while dividing by v yields the slow neutron *distribution* in the nuclear reactor.

17.6.3 Measurements with Diffracted Neutron Beams

Diffracted neutron beams can be used to identify neutron energies provided that the Bragg condition under use is well calibrated. Such uses apply to polyenergetic neutron sources, such as from a beamport from a nuclear reactor. Another use of diffracted neutron beams is to study the crystallinity of crystals, where the crystal under study is rotated through the beam about the Bragg angle. The resolution of the response gives a measure of the crystal perfection, the response often referred to as a *rocking curve*. Another common application is as a nearly pure monoenergetic neutron beam for measurements and experiments. Although contamination may be present from higher orders of diffracted neutrons ($n > 1$) and scattered background neutrons, the combined effects of Eq. (17.50) and Eq. (17.53) diminish this effect. This contamination can be reduced further with a second diffraction crystal between the primary crystal and the detector. This second crystal must be set at the same Bragg condition as the first crystal, which produces a somewhat stringent alignment requirement between the two crystals, a tedious process, and comes with the expense of a lower

overall neutron flux at the work location. From Eq. (17.47), the limiting energy resolution dE/E from the beamport is,

$$\left|\frac{dE}{E}\right| = \frac{2d\lambda}{\lambda} = \frac{4w}{L\tan\theta}. \tag{17.59}$$

With simple substitutions and use of trigonometric identities,

$$\left|\frac{dE}{E}\right| = \frac{4wd\sqrt{E}\cos\theta}{nLk} = \frac{4wd\sqrt{E-(k^2n^2/4d^2)}}{nLk}, \tag{17.60}$$

where d is the interplane distance and $k = 0.286$ from Eq. (17.43). If the Bragg angle is well known from the crystal diffractometer, then the neutron energy is also known, and accurate measurements of neutron cross sections can be performed for various intervening materials (between the crystal and detector), limited by the energy resolution of the system.

17.7 Calibration of Slow Neutron Detectors

There are numerous methods used by credible organizations to calibrate and determine the neutron detection efficiency of thermal neutron detectors. These methods can differ significantly with varying degrees of measurement error. The reason for the differing calibration methods stems primarily from the difficulty in securing a calibrated standardized neutron source. For thermal-neutron detection efficiency, a diffracted neutron beam from a nuclear reactor is possibly the best calibration source. However, access to a nuclear research reactor is often inconvenient, and an organization may instead resort to a moderated ^{252}Cf or AmBe source. Fortunately, calibration of slow-neutron detectors can be a relatively straightforward process for $1/v$ absorbers [McGregor and Shultis 2011]. A few of these calibration methods are described here, although they do not represent the many methods used by various organizations. The different measurement protocols, although reproducible, are often not easily related to each other.

According to National Institute of Standards and Technology (NIST), there is no reliable method to produce an omnidirectional thermal neutron source to test a detector in an isotropic flux [McGregor and Shultis 2011]. Monte Carlo codes such as MCNP can be used to understand the experimental conditions and optimize a measurement, but it is inadequate to predict the detection efficiency, mainly because of the uncertainty associated with the code (about 5%) and uncertainty with the neutron measurement (also about 5%) together produce a result that has an unacceptable error for NIST-traceable detector calibrations.

17.7.1 Method of the NIST

The NIST uses a combination of a calibrated neutron current and calibrated neutron detectors to determine the unknown efficiency of a neutron detector [McGregor and Shultis 2011]. The calibration consists of using a ^{252}Cf neutron source placed in a heavy-water moderator pool that approximates the thermal-neutron environment inside a light-water reactor. However, the preferred method for testing a thermal-neutron detector is with a single-crystal diffracted beam, whose spatial profile is determined from activation analysis of a Dy foil, or is measured with a neutron-imaging detector so that the neutron beam profile is documented within the workspace. The neutron flux is then measured with a calibrated fission chamber. Hence, the basic method is to (1) profile the relative thermal-neutron beam intensity as a function of position and then (2) measure the neutron current (or fluence) with a calibrated standard fission chamber. The count rate of the unknown detector is then directly compared to the measured neutron current. Note that fission chambers, typically fabricated with uranium as the neutron reactive material, deviate slightly from the ideal $1/v$ behavior. Hence, knowledge of the diffraction angle, and resulting neutron energy, is important for making thermal corrections to the NIST calibration method.

17.7.2 Method of Reuter Stokes

A calibration method used by some commercial manufacturers of neutron detectors is to archive a so-called "gold standard" for each neutron detector product. For instance, for one such manufacturer, a large box formed by walls of 6-inch-thick high-density polyethylene (HDPE) is used as a moderator. The box has a large open cavity in the center, and a neutron source (^{252}Cf) is inserted into the box, centered near one of the walls. Gold activation foils (see next section) are then used to measure the thermal-neutron flux at various locations in the box after the foil measurements are corrected for neutron self-absorption. In this manner the neutron flux is mapped spatially inside the HDPE box. A detector is then placed inside the box, at an angle, near a wall opposite that of the location of the ^{252}Cf source. A measurement is conducted, correcting for spatial differences in the neutron flux. Afterwards, a NIST traceable detector is placed in the box at the prior location of the test detector, and another identical measurement is conducted.

This measurement method yields relative efficiencies as compared to a NIST-traceable standard. Hence, the method relies upon a fast neutron source moderated in a box that produces a thermal-neutron flux incident on the detector from nearly 4π directions. Due to the nature of the source-detector configuration, the neutron flux intersecting the detector is not uniform in direction or space. The Au foil calibration allows approximate corrections for non-uniform distribution of thermal neutrons. This method is adequate for in-house calibrations, but is not easily used for calibrations at other facilities. Finally, the method is probably adequate for large neutron detectors, but has larger measurement uncertainty for small neutron detectors.

17.7.3 Method of ORNL

A method introduced at Oak Ridge National Laboratory (ORNL) also uses a ^{252}Cf source. The neutron source is placed within a large block of HDPE capable of moderating and minimizing the leakage of neutrons. A blind hole beamport is drilled into the HDPE block that is oriented towards the source, but still leaves enough moderator between the drilled beamport hole and the ^{252}Cf to produce a thermalized neutron beam. A borated shutter, composed of perpendicular jaws, is attached to the moderator block around the beamport opening and is used to reduce the beam cross sectional area. The thermal-neutron flux at the testing location is measured with a calibrated neutron detector. For additional verification, MCNP is used to calculate the expected neutron flux and profile at the testing location and is quoted as having approximately 10% error [McGregor and Shultis 2011]. The observed count rate, per unit area, from the detector being studied is then divided by the measured thermal-neutron flux to determine the intrinsic neutron detection efficiency.

17.7.4 Method of Sampson and Vincent

The method of Sampson and Vincent, introduced primarily as a calibration system for $^{10}BF_3$ detectors, is used to determine the efficiency for a narrow beam geometry of diffracted neutrons [Sampson and Vincent 1971]. Here the BF_3 detector is placed end-on facing into the neutron beam from the diffractometer. The monoenergetic neutron flux from the diffracted beam is calibrated by activation of a NIST-traceable Au foil. The Au foil is placed between the detector and the emerging neutron beam. The beam is set at an arbitrary diffraction angle θ from the monodirectional neutrons incident on the diffractometer. The energy and beam angle are described by the Bragg diffraction condition

$$n\lambda = n\frac{h}{\sqrt{2E_n m_n}} = 2d\sin\theta, \qquad n = 1, 2, 3, \ldots, \tag{17.61}$$

where λ is the neutron wavelength, d is the atomic interplane distance, m_n is the neutron mass, h is Plank's constant, and E_n is the neutron kinetic energy. For a given direction θ, the diffracted beam has neutrons of energy E_1 (for $n = 1$) and also for neutrons of higher energy, the "harmonics" ($n > 1$).

The gold foil is used to measure the neutron flux ϕ incident on the end of the $^{10}BF_3$ detector. If the foil is totally immersed in the beam, the saturation activity of the Au foil A_∞^{Au} is

$$\phi = \frac{A_\infty^{Au}}{N_d \sigma_a^{Au}(E)}, \tag{17.62}$$

where N_d is the total number of Au atoms in the foil, and $\sigma_a^{Au}(E)$ is the Au microscopic absorption neutron cross section at energy E. For negligible absorption in the foil, the detector count rate when exposed to the beam is

$$R = \epsilon_{in}(E)\phi\mathcal{A}, \tag{17.63}$$

where $\mathcal{A}$ is the cross sectional area of the neutron beam incident on the detector and $\epsilon_{in}(E)$ is the intrinsic efficiency of the detector. Combine these last two equations to obtain

$$\epsilon_{in}(E) = \frac{R N_d \sigma_a^{Au}(E)}{A_\infty^{Au} S_b}. \tag{17.64}$$

In this simplistic overview, the details of correcting the gold foil activity for self-absorption, fast neutron flux components, and counter efficiency used to measure the foil activity have been omitted. Sources of uncertainty with the Sampson and Vincent method include flux contamination from higher order diffraction harmonics (mainly from the second-order contamination), uncertainty in the flux calibration due to a sizeable neutron resonance in the Au foil at 4.9 eV, uncertainty in the measurement of the neutron beam area (S_b), and finally uncertainly in the dead region at the end of the detector that reduces the neutron flux before encountering the high-field region of the detector. Sampson and Vincent report a correction for second order effects, and also report a theoretical efficiency that takes into account the end window absorption effects and neutron scattering.

17.7.5 Method of McGregor and Shultis

A method developed by McGregor and Shultis [2011] provides an in-house calibration standard and works especially well for neutron detectors based on $1/v$ absorbers without introducing multiple sources of error. This method requires a moderated neutron beam without contamination from fast neutrons. Isolation of the thermal neutrons is accomplished by diffracting, from a graphite crystal, a neutron beam from a nuclear reactor. The graphite crystal structure destructively interferes with diffraction of even harmonics, thereby eliminating problems with the contamination from second harmonic diffraction. Two $1/v$ neutron detectors are required for the calibration, along with a duplicate, but empty shell, of at least one of the two detectors.

The test detector to be used as the calibration standard is placed in the neutron beam, as shown in Fig. 17.35(b), such that neutrons pass through the container walls and neutron reactive gas. A reference detector is placed in the neutron beam beyond the calibration detector, also shown in Fig. 17.35(b). The reference detector measures a count rate of

$$R_{out} = R_{in} e^{-\Sigma_w t_w} e^{-\Sigma_g t_g} \exp^{-\Sigma_w t_w} = R_{in} e^{-2\Sigma_w t_w} e^{-\Sigma_g t_g}, \tag{17.65}$$

where R_{in} is the neutron count rate from the reference detector before neutrons are attenuated by the test detector and R_{out} is the neutron count rate measured by the reference detector after attenuation through the test detector, Σ_w is the macroscopic cross section of the empty detector shell material, Σ_g is the macroscopic cross section for the detection material (gas) in the test detector, t_w is the shell material thickness, and t_g is the thickness of the neutron reactive material within the test detector. The transmission factor for the test detector is

$$T_d \equiv \frac{R_{out}}{R_{in}} = e^{-2\Sigma_w t_w} e^{-\Sigma_g t_g}. \tag{17.66}$$

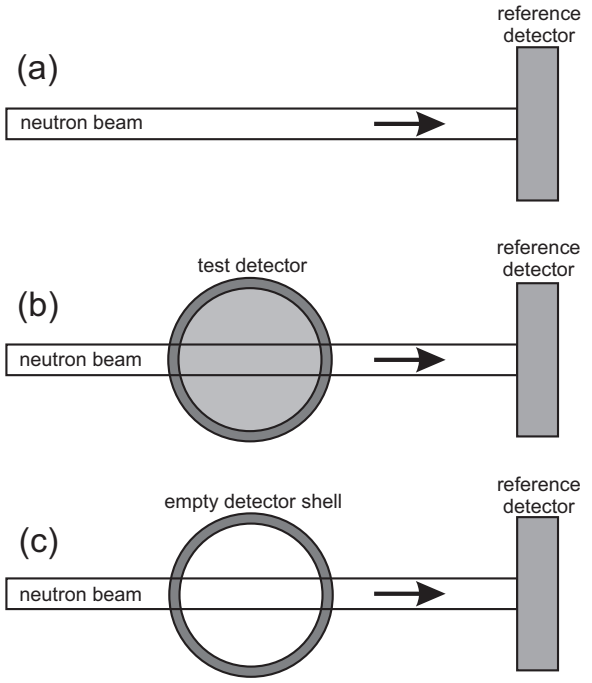

Figure 17.35. Method to produce a calibrated standard detector. After the calibration, the test detector can be used as a calibration standard for other $1/v$ neutron detectors. For the method to function properly, the reference detector must also be a $1/v$ detector [McGregor and Shultis 2011] .

Transmission through the empty shell detector is,

$$T_{2w} = \frac{R_w}{R_{in}} = e^{-2\Sigma_w t_w}, \tag{17.67}$$

where R_w is the count rate from the beam attenuated by the empty detector shell. The transmission factor for neutrons passing through the test detector $1/v$ absorber is,

$$T_g = \frac{R_{out}}{R_w} = e^{-\Sigma_g t_g}. \tag{17.68}$$

The fraction of the neutron beam attenuated by the absorber in the test detector reveals the fraction of interactions in the test detector, but does not yield the detector intrinsic efficiency. The beam attenuated by the neutron absorber was already attenuated by one wall of the detector shell. Hence, the fraction of the neutron beam transmitted through one wall of the detector shell is,

$$T_{1w} = \sqrt{\frac{R_w}{R_{in}}} = [e^{-2\Sigma_w t_w}]^{1/2}. \tag{17.69}$$

The intrinsic slow-neutron detection efficiency is,

$$\epsilon_{in} = \frac{\sigma_{ao}}{\sigma_{to}} e^{-\Sigma_w t_w}(1 - e^{-\Sigma_g t_g}), \tag{17.70}$$

where σ_{ao} is the absorption cross section leading to detectable events in the test detector and σ_{to} is the total cross section at an arbitrary energy E_o. The total cross section σ_{to} is the total probability that a neutron interacts with a target nuclei, including capture, fission, elastic scattering, and inelastic scattering. Because inelastic and elastic scattering usually do not follow a $1/v$ dependence, the ratio of σ_{ao}/σ_{to} deviates from $1/v$ behavior at moderately high neutron energies, and proper corrections must be made to account for the differences. However, at low energies (generally below 10 eV), $\sigma_{ao} \approx \sigma_{to}$ is a good approximation. Therefore, substitution of Eq. (17.68) and Eq. (17.69) into Eq. (17.70) yields,

$$\epsilon_{in} = \sqrt{\frac{R_w}{R_{in}}}\left(1 - \frac{R_{out}}{R_w}\right), \tag{17.71}$$

which is the intrinsic detection efficiency for the test detector. The test detector can be used thereafter as a calibration standard, provided that the totality of the neutron beam intersects within the perimeter of the detector active region.

From the discussion in Section 17.1, the count rates represented by R_{in}, R_{out}, and R_w are independent of neutron energy for materials with $1/v$ cross sections. Because of the σ_{ao}/σ_{to} ratio, corrections may apply for $1/v$ absorbers if the neutrons in the beam have energies exceeding approximately 10 eV. Hence neutron moderation is required for the measurements in order to avoid such corrections. Finally, if the detector under test is composed of non-$1/v$ absorbers for the neutron reactive material, such as, for example, ^{157}Gd, ^{113}Cd, or ^{235}U, then it is necessary to apply the appropriate non-$1/v$ corrections to the calculated efficiency, and generally requires some knowledge of the neutron energies.

17.8 Neutron Detection by Foil Activation

In the early days before modern neutron detectors, measurement of a neutron field was often done by irradiating small samples (usually in the form of foils) composed of elements (or isotopes) whose cross sections varied differently with the incident neutron energy. The radionuclides produced in the sample by neutron absorptions decay with the emission of radiation that can be measured. The rate at which radiation is emitted by an irradiated sample after it was removed from the neutron field depended on the flux used to irradiate the sample, the irradiation time, and the composition of the detecting material.

From the activity produced in the foils and the use of clever unfolding algorithms, the magnitude and energy dependence of the neutron flux could be estimated. The foil activation method is also discussed in Sec. 18.5.7 for fast neutron measurements. Although once widely used, the use of the foil activation method is not as prevalent today as it once was, primarily as a result of better and newer neutron detectors. However, one foil activation method is still in wide use and is the basis of several thermal neutron flux standards. In this method a gold foil is activated and from its resulting activity, both the thermal and fast neutron fluxes can be inferred. This one-foil method is widely accepted and, with appropriate correction factors, can give excellent results.[23] Other foils that have been used to measure the thermal neutron flux with the Cd covered/bare foil technique described in this section are listed in Table 17.3.

If the flux $\phi(E)$ is constant throughout the volume V_d of a bare gold foil, then the rate of production R_b of the radionuclide produced by the absorption of a neutron in gold is

$$R_b = N_d \int_0^\infty \sigma_a(E)\phi(E)\,dE = V_d \int_0^\infty \Sigma_a(E)\phi(E)\,dE, \tag{17.72}$$

where N_d is the number of gold atoms in the foil, $\sigma_a(E)$ the microscopic absorption cross section of gold, $\phi(E)$ the energy-dependent flux density, and E the neutron energy.

[23] One could say, in more ways than one, this foil technique is the "gold standard" for measuring thermal neutrons.

Table 17.3. Some activation foils used for thermal neutron measurements. Only the most abundant gamma rays are listed. Data are extracted mostly from ENDF/B [2017] and LM-KAPL [2002].

In Fig. 17.36 the thermal energy dependence of the neutron flux and of the total cross sections for gold and cadmium is shown. Several features should be noted. Below the so-called thermal cutoff $E_{TC} \simeq 0.2$ eV the neutron flux has a Maxwellian distribution $\phi_M(E)$. As can be seen from the cadmium cross section, a cadmium covered gold foil is activated primarily by neutrons with energies above the *cadmium cutoff energy* $E_{CC} \simeq 0.4$ eV. Further below E_{CC} gold is seen to be almost a perfect "$1/v$" absorber.

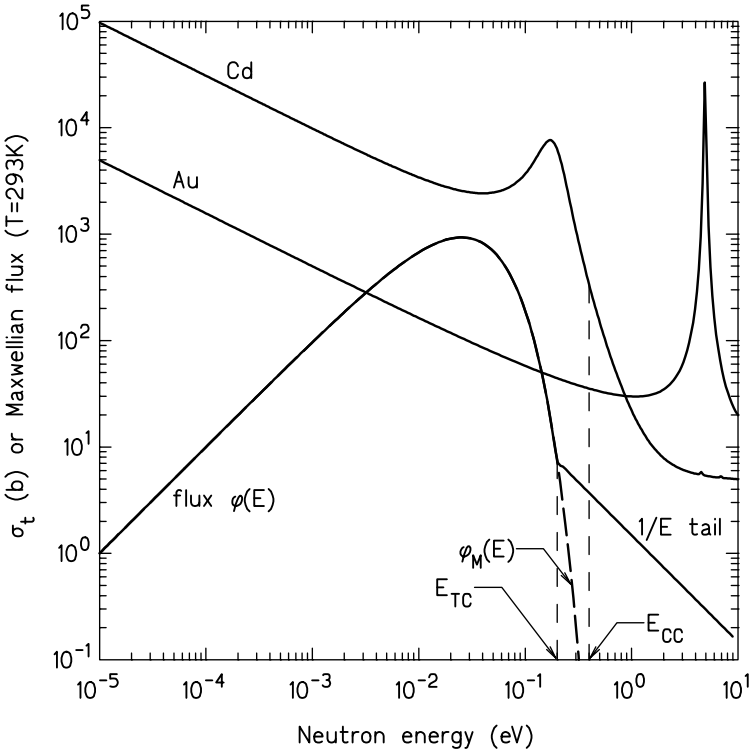

Figure 17.36. The energy dependence of the thermal flux $\phi_M(E)$ for neutrons in thermal equilibrium at room temperature ($T = 293$ K), the idealized epithermal $1/E$ slowing-down flux above the thermal cutoff E_{TC}, and the total (absorption) cross sections for gold and cadmium.

The *total thermal flux density*, or *thermal flux* for short, is defined as

$$\phi_t \equiv \int_0^{E_{TC}} \phi(E)\, dE, \tag{17.73}$$

and the *total fast flux* as

$$\phi_f \equiv \int_{E_{TC}}^{E_{\max}} \phi(E)\, dE, \tag{17.74}$$

where $E_{\max}$ is the maximum neutron energy. Below the *thermal cutoff* E_{TC} the energy distribution of the flux can often be well approximated by the Maxwellian distribution (see Problem 17-1)

$$\phi(E) \simeq \phi_M(E,T) = \phi_t \frac{E}{E_T^2} e^{-E/E_T}, \tag{17.75}$$

where $E_T \equiv kT$ (= 0.0253 eV for a neutron temperature of $T = 293.5$ K) is the most probable neutron energy for the thermal flux density.

For $E > E_{TC}$, the neutron flux in and from a reactor varies as $1/E$ or $\phi(E) = \phi_o/E$, characteristic of a neutron slowing down spectrum. The total fast flux is thus

$$\phi_f \equiv \int_{E_{TC}}^{E_{\max}} \phi(E)\, dE = \int_{E_{TC}}^{E_{\max}} \frac{\phi_o}{E} dE = \phi_o \ln\!\left(\frac{E_{\max}}{E_{TC}}\right). \tag{17.76}$$

For $E_{TC} \simeq 0.2$ eV and $E_{\max} \simeq 20$ MeV, $\phi_f \simeq 18\phi_o$. Below E_{TC} gold is a $1/v$ absorber, i.e., $\sigma_a(E) = \sigma_a(E_o)\sqrt{E_o/E}$ where $\sigma_a(E_o)$ is the gold absorption cross section at an arbitrary thermal reference energy usually taken as $E_o = E_{T=293.5\text{K}} = 0.0253$ eV.

The activation rate for a bare gold foil may then be written as

$$R_b = N_d \left\{ \int_0^{E_{TC}} \frac{\sigma_a(E_o)\sqrt{E_o}}{\sqrt{E}} \phi_M(E,T)\, dE + \int_{E_{TC}}^{E_{\max}} \sigma_a(E) \frac{\phi_o}{E}\, dE \right\} \tag{17.77}$$

or

$$R_b = N_d \overline{\sigma}_a \phi_t + N_d \int_{E_{TC}}^{E_{\max}} \sigma_a(E) \frac{\phi_o}{E}\, dE \tag{17.78}$$

where the thermal-averaged absorption cross section for gold is

$$\overline{\sigma}_a \equiv \frac{\displaystyle\int_0^{E_{TC}} \sigma_a(E_o)\sqrt{\frac{E_o}{E}} \phi_M(E,T)\, dE}{\displaystyle\int_0^{E_{TC}} \phi_M(E,T)\, dE} \simeq$$

$$\frac{\displaystyle\int_0^{\infty} \sigma_a(E_o)\sqrt{\frac{E_o}{E}} \phi_M(E,T)\, dE}{\displaystyle\int_0^{\infty} \phi_M(E,T)\, dE} = \frac{\sqrt{\pi}}{2}\sqrt{\frac{T_o}{T}}\sigma_a(E_o). \tag{17.79}$$

If it is assumed $\phi(E) = \phi_o/E$ for $E > E_{TC}$ then the integral in Eq. (17.78) can be evaluated as

$$\int_{E_{TC}}^{E_{\max}} \sigma_a(E) \frac{dE}{E} = \phi_o \int_{E_{TC}}^{E_{CC}} \sigma_a(E_o) \sqrt{\frac{E_o}{E}} \frac{1}{E}\, dE + \phi_o \int_{E_{CC}}^{E_{\max}} \frac{\sigma_a(E)}{E}\, dE$$

$$= \sigma_a(E_o)\phi_o \sqrt{4E_o} \left(\frac{1}{\sqrt{E_{TC}}} - \frac{1}{\sqrt{E_{CC}}} \right) + \phi_o \int_{E_{CC}}^{E_{\max}} \frac{\sigma_a(E)}{E}\, dE.$$

$$= \overline{\sigma}_a \phi_o \sqrt{\frac{16E_T}{\pi}} \left(\frac{1}{\sqrt{E_{TC}}} - \frac{1}{\sqrt{E_{CC}}} \right) + \phi_o \int_{E_{CC}}^{E_{\max}} \frac{\sigma_a(E)}{E}\, dE. \tag{17.80}$$

Substitution of this result into Eq. (17.78) gives the activation rate of a bare foil as

$$\boxed{R_b = N_d \left\{ \overline{\sigma}_a \phi_t + \phi_o \overline{\sigma}_a \sqrt{\frac{16E_T}{\pi}} \left(\frac{1}{\sqrt{E_{TC}}} - \frac{1}{\sqrt{E_{CC}}} \right) + \phi_o \int_{E_{CC}}^{E_{\max}} \frac{\sigma_a(E)}{E}\, dE \right\}.} \tag{17.81}$$

To measure the thermal flux ϕ_t, one must differentiate between the activation produced by thermal neutrons and by fast neutrons. One way to do this experimentally is to make two measurements, one with a bare foil and one with a detector foil covered with cadmium of sufficient thickness to absorb all thermal neutrons below the cadmium cutoff energy E_{CC} from reaching the gold foil. However, neutrons with energies above E_{CC} reach the gold foil and activate it at a rate

$$\boxed{R_c = N_d \phi_o \int_{E_{CC}}^{E_{\max}} \sigma_a(E) \frac{dE}{E} \equiv N_d \phi_o I_d.} \tag{17.82}$$

The integral in this expression is called the *resonance integral* I_d of a detector foil element. Values of the resonance integral for many elements have been measured and tabulated [ANL 5800]. For example, the resonance integral for gold is 1558 b. From the rate of activation of the cadmium-covered foil, the value of ϕ_o can be obtained. However, it must be recognized that the detector foil absorption cross section generally has many resonances and there can be significant self-shielding in the foil at these resonance energies. Thus the assumption that the flux is constant throughout the foil may be a poor assumption for the fast-neutron activation of the foil. Correction for this and other non-ideal effects are considered later.

The difference between the activation rate of the bare and cadmium-covered foils is thus

$$\boxed{R_b - R_c = N_d \overline{\sigma_a} \left\{ \phi_t + \phi_o \sqrt{\frac{16E_T}{\pi}} \left(\frac{1}{\sqrt{E_{TC}}} - \frac{1}{\sqrt{E_{CC}}} \right) \right\}.} \tag{17.83}$$

For $E_T = 0.03$ eV, $E_{TC} = 0.2$ eV, and $E_{CC} = 0.4$ eV, the coefficient of ϕ_o is about 0.25. The value of ϕ_o is often sufficiently small that the second term on the right-hand side of Eq. (17.83) can be neglected. However, one should, in principle, distinguish between the *thermal flux* contribution and the *subcadmium flux* contribution from epithermal neutrons, even if, in practice, the thermal flux is assumed to be proportional to $R_b - R_c$.

17.8.1 Cadmium Ratio

In flux measurements, one often encounters the term *cadmium ratio* (CR). This ratio is simply the specific activation rates of bare and cadmium-covered foil detectors, i.e.,

$$\mathrm{CR} \equiv \frac{\widehat{R_b}}{\widehat{R_c}} \tag{17.84}$$

where the specific activation rate $\widehat{R} \equiv R/m$ with the foil mass denoted by m. From the results of Eqs. (17.81) and (17.82), the CR is

$$\mathrm{CR} = 1 + \frac{\overline{\sigma}_a}{I_d} \left\{ \frac{\phi_t}{\phi_o} + \sqrt{\frac{16E_T}{\pi}} \left(\frac{1}{\sqrt{E_{TC}}} - \frac{1}{\sqrt{E_{CC}}} \right) \right\} \simeq 1 + \frac{\phi_t}{\phi_o} \frac{\overline{\sigma}_a}{I_d}. \tag{17.85}$$

where the last simplification is obtained by ignoring the usually very small subcadmium epithermal activation. From this result, it is evident that the larger the measured value of the CR, the larger is the proportion of thermal neutrons in the total neutron population reaching the detecting foils.

17.8.2 Measuring Activation Rates

Thus far, only the rates of production of radioactive foil atoms have been considered. In this section production rates are related to measurable quantities. After irradiation, it is the activity of the foil that is actually measured, which usually persists some time after the irradiation procedure. Thus it is necessary to relate the foil activity A to the production rate R of radionuclides in the foil during the irradiation process.

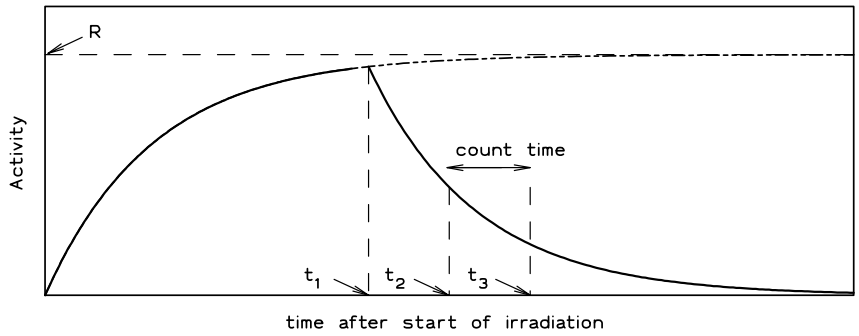

Figure 17.37. Activity of a foil that is irradiated by a constant flux between times 0 and t_1. At time t_1 the foil is removed from the neutron beam. The foil is subsequently counted between times t_2 and t_3.

The buildup of radionuclides in a foil during irradiation is described by

$$\frac{dN(t)}{dt} = R - \lambda N(t), \tag{17.86}$$

where $N(t)$ is the number of radionuclides (with decay constant λ) in the foil at time t after the commencement of irradiation. Burnup of the parent and daughter nuclides can usually be neglected. If the foil was "clean" at the time ($t = 0$) irradiation began, then the number of radionuclide daughters at a later time t is

$$N(t) = \frac{R}{\lambda}\left(1 - e^{-\lambda t}\right), \tag{17.87}$$

and the foil activity at time t is

$$A(t) \equiv \lambda N(t) = R\left(1 - e^{-\lambda t}\right). \tag{17.88}$$

If the foil remains in the neutron flux for a time much greater than the half-life of the daughter radionuclide, the activity reaches its saturation value $A_\infty = R$, the sought quantity. After removal of the foil at time t_1, the activity exponentially decreases as

$$A(t) = A(t_1)e^{-\lambda(t-t_1)} = R\left(1 - e^{-\lambda t_1}\right)e^{-\lambda(t-t_1)}, \quad t > t_1. \tag{17.89}$$

By counting the radiation emitted by the radioactive foil we can determine R. Suppose, the radionuclide emits a gamma ray of energy E_0 with a frequency f per decay. A gamma-ray spectrometer with known

efficiency $\epsilon(E_0)$ at gamma-ray energy E_0 is used to measure the activity of E_0 emitted from the foil between times t_2 and t_3 (from Fig. 17.37). The total observed counts in the photopeak is

$$\begin{aligned} C = f\epsilon \int_{t_2}^{t_3} A(t)\,dt + BG &= f\epsilon \int_{t_2}^{t_3} A(t_1)e^{-\lambda(t-t_1)}\,dt + BG \\ &= \frac{f\epsilon A(t_1)e^{\lambda t_1}}{\lambda}\left(e^{-\lambda t_2} - e^{-\lambda t_3}\right) + BG \\ &= \frac{f\epsilon R}{\lambda}\left(e^{\lambda t_1} - 1\right)\left(e^{-\lambda t_2} - e^{-\lambda t_3}\right) + BG \end{aligned} \tag{17.90}$$

where BG is the background count that occurred between t_2 and t_3. From this result the production rate R (equal to the saturation activity A_∞) is found to be

$$R = A_\infty = \frac{\lambda(C - BG)}{\epsilon f(e^{\lambda t_1} - 1)(e^{-\lambda t_2} - e^{-\lambda t_3})}. \tag{17.91}$$

To obtain R from the above expression, it is necessary to first obtain the counter efficiency ϵ for the counting geometry and radiation emitted by the foil's radionuclides.

Foils used in a neutron flux measurement usually have different masses. To correct for the different masses, the *specific* foil activity is calculated, i.e., the activity per unit mass of the foil. From Eq. (17.91) the specific activity is

$$\widehat{R} \equiv \frac{R}{m} = \frac{\lambda(C - BG)}{m\epsilon f(e^{\lambda t_1} - 1)(e^{-\lambda t_2} - e^{-\lambda t_3})}. \tag{17.92}$$

Finally, the confidence limits on the variance of $\widehat{R}$ are obtained from the variances of the foil and background counts, and the uncertainties in the times t_1, t_2, and t_3.

Natural gold consists of only the stable ^{197}Au isotope. Upon absorption of neutrons, radioactive ^{198}Au is produced. This isotope has a half-life of 2.696 d and decays by β^- emission. In the decay process a 0.4118-MeV gamma ray is emitted with a frequency of 95.51%. Other emitted gamma and x-ray photons have frequencies of less than 2%. Activity measurements of the gold foils are performed with a gamma-ray spectrometer (usually a high-resolution HPGe detector) by measuring the counts in the 411-keV full energy peak. The absolute spectrometer efficiency ϵ at this energy and the sample position must be obtained by using calibration sources.

17.8.3 Flux Correction Factors

The theory presented so far has neglected some minor effects which require corrections to obtain accurate flux values. Specifically, the following facts have been neglected:

1. Gold is not exactly a $1/v$ absorber at the high end of the Maxwellian spectrum (see Fig. 17.36).
2. Some neutrons with $E < E_{CC}$ pass through the cadmium cover and activate the covered gold foil.
3. The cadmium cover also stops some neutrons with $E > E_{CC}$, so fewer fast neutrons activate a covered gold foil compared to a bare foil.
4. If the detector foils are measuring the flux in a medium through which neutrons are diffusing, the presence of the foil with its relatively high absorption cross section causes the flux around the foil to be depressed. For neutrons streaming through a void or in air, no such flux depression occurs.

5. At neutron energies for which the gold foil has a large cross section, the outer layer of the foil shields the inner foil volume, i.e., the activation per unit volume is not uniform throughout the foil. This is particularly important for the fast neutron activation of gold foils.

A detailed discussion of these complicating factors is beyond the scope of this book. Here only a brief description of how these effects can be investigated is presented. Greater detail for the theory and methods used to correct experimental data for these complicating factors are given in the references.

17.8.4 Correction for Non-$1/v$ Absorption

To account for the first effect, a corrected thermal averaged cross section is used. The thermal averaged cross section of Eq. (17.79) is more correctly defined as

$$\overline{\sigma}_a \equiv \frac{\displaystyle\int_0^\infty \sigma_a(E)\phi_M(E,T)\,dE}{\displaystyle\int_0^\infty \phi_M(E,T)\,dE} = \frac{\sqrt{\pi}}{2} g_a(T)\sqrt{\frac{T_o}{T}}\sigma_a(E_o), \tag{17.93}$$

where $g_a(T)$ is the Westcott non-$1/v$ correction factor (see Eq. (17.13)) obtained by evaluating the above integrals numerically. For a perfect $1/v$ absorber $g_a = 1$, and for a gold foil in a Maxwellian neutron energy distribution at room temperature ($T = 293$ K), $g_a(293\text{ K}) = 1.005$ [ANL 5800]. However, as the neutron temperature T increases the Maxwellian "hardens" as it shifts towards the gold absorption resonance at $E = 4.90$ eV (see Fig. 17.36) and $g_a(T)$ increases as gold becomes more non-$1/v$. However, near room temperature one can set $g_a(T) \simeq 1$ for gold without introducing significant error.[24]

17.8.5 Correction for Cadmium Filter Effects

Ideally, a high-pass neutron filter would absorb all neutrons below a sharp cutoff energy and be transparent to neutrons with energies above the cutoff. A cadmium cover with a thickness of between 0.5 to 1 mm comes close to this ideal, absorbing almost all neutrons below about 0.4 eV and only a few above about 0.6 eV.

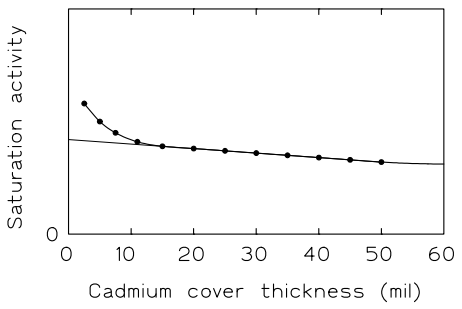

Figure 17.38. Foil saturation activity for different thicknesses of cadmium covering the foil.

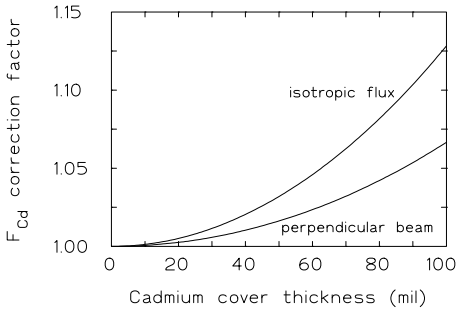

Figure 17.39. Epithermal cadmium correction factor F_{Cd} for covers of different thicknesses.

The effect of a cadmium filter covering a gold foil can be investigated by irradiating detector foils with different thicknesses of the cadmium cover. A typical plot of such results is shown in Fig. 17.38. The actual

[24] Data for $g_a(T)$ and the resonance integral needed for other foils used in activation analyses can be found in ANL [2003], Mughabghab [2003], and on-line at wwwnde.jaea.go.jp/j40/j40.htm.

shape of the curve depends on several factors such as the detector foil material, foil size, the medium in which the measurements are made, and the cadmium ratio. From Fig. 17.38, the rapid rise below approximately 20 mil ($\sim$ 500 microns) of cadmium indicates that a significant number of subcadmium neutrons reach the foil. More than 20 mils ($\sim$ 500 microns) of cadmium seems to reduce the subcadmium transmission enough so that the curve has only a small slope (caused by the cadmium absorption of epi-cadmium neutrons). For cadmium thicknesses greater than about 20 mils, one can correct for the absorption of epi-cadmium neutrons by extrapolating to zero cadmium thickness (the straight line in Fig. 17.38).

If a cadmium cover of thickness 500 microns or more is used, negligible thermal neutrons reach the gold foil. However, this cover absorbs some epithermal neutrons. To correct for this, a cadmium filter correction factor F_{Cd} is defined as

$$F_{Cd} \equiv \frac{R_{epi}}{R_c}, \tag{17.94}$$

where R_{epi} is activation rate in a bare foil by epithermal (above thermal) neutrons and R_c is the measured activation rate in a cadmium covered foil by epithermal neutrons. For a gold foil most of the epithermal activation is caused by neutrons absorbed in the gold resonance at $E_r = 4.91$ eV. If α represents the probability a 4.91-eV neutron passes through a cadmium cover of thickness t_c

$$F_{Cd} \equiv \frac{R_{epi}}{R_c} = \frac{R_{epi}}{\alpha R_{epi}} = \frac{1}{\alpha}. \tag{17.95}$$

For a beam of 4.91-eV neutrons normally incident on the cadmium cover, $\alpha = \exp[-\Sigma_{Cd}(E_r)t_c] \equiv \exp[-\tau_c]$. Then for a normally incident beam of neutrons

$$F_{Cd} = \exp[\tau_c]. \tag{17.96}$$

For a covered foil placed in an isotropic flux, it can be shown [Profio 1976], $\alpha = 2E_3(\tau_c)$ so that

$$F_{Cd} = \frac{1}{2E_3(\tau_c)}, \tag{17.97}$$

where $E_3(x)$ is the exponential integral function of order 3. These factors for a gold foil are shown in Fig. 17.39. Thus, to correct for epithermal-neutron absorption in the cadmium covered foil, we should use $R_{epi} = F_{Cd}R_c$ in place of R_c in Eqs. (17.81) to (17.83) which are used to calculate the fast and thermal flux densities.

17.8.6 Correction for Flux Perturbation and Self-Shielding

The complicating effects of foil self-shielding and the depression of the neutron field around the foil can be investigated by irradiating foils with the same area but different thicknesses. A typical result is shown in Fig. 17.40. The shape of such a plot depends on the area of the foil, the foil material, and the medium in which the measurements are made. The effect of flux depression and self-shielding can be eliminated by extrapolating the experimental results to zero foil thickness. Previous investigators have analyzed these complicating factors both analytically and experimentally, and several semiempirical correction factors have been developed [ANL 5800].

When an absorbing foil is used to measure the flux (fast or thermal) at some point in a moderator, the foil causes a depression in the flux around the foil. Moreover, the flux is depressed in the center of the foil because of self-shielding. A typical flux-profile is shown in Fig. 17.41. The average flux $\overline{\phi}$ is found through the through measuring the foil activity. However, it is the unperturbed flux ϕ_∞ that is sought. These two

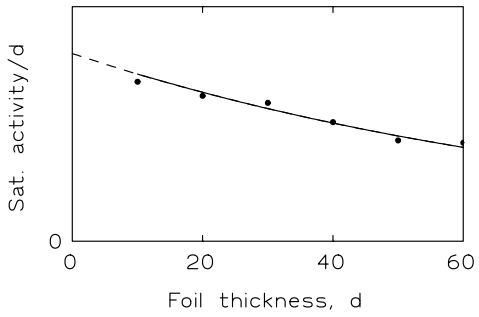

Figure 17.40. Saturation activity per unit volume for different thicknesses of foil.

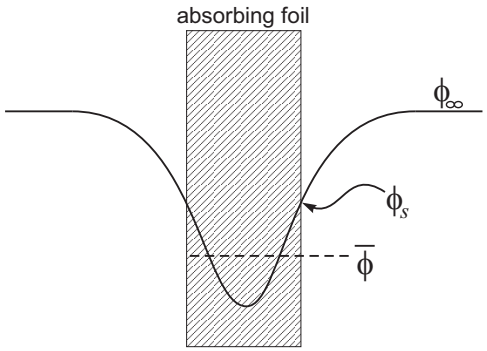

Figure 17.41. The depression of the flux and the self-shielding effect produced by an absorbing foil in a moderator.

flux densities are related by

$$\overline{\phi} = \left(\frac{\overline{\phi}}{\phi_s}\right)\left(\frac{\phi_s}{\phi_\infty}\right)\phi_\infty \qquad \text{or} \qquad \phi_\infty = \frac{1}{F_1 F_2}\overline{\phi}, \tag{17.98}$$

where the *self-shielding factor* $F_1 \equiv (\overline{\phi}/\phi_s)$ and the *flux-depression factor* $F_2 \equiv (\phi_s/\phi_\infty)$. In general, these correction factors depend on the angular distribution of the flux density, foil size and thickness, and on the scattering and absorption cross sections of the surrounding material. Two extreme cases of angular distribution of the flux are considered below.

Perpendicular Beam in Air

In this geometry, the foil is placed in a non-diffusing medium and irradiated by a perpendicular beam of neutrons. The flux of the beam is not affected by the foil so that $F_2 = 1$ and $\phi_s = \phi_\infty$.

Thermal Flux-Density Self-Shielding: For a foil with $\Sigma_a \gg \Sigma_s$ whose radius is much greater than its thickness d, and which is irradiated by a perpendicular beam of thermal neutrons with a Maxwellian energy distribution, the position dependent neutron flux is,

$$\phi(x) = \phi_s e^{-\overline{\Sigma}_a x}, \tag{17.99}$$

where x is distance into the foil. For a thin foil, there is negligible spectrum hardening of the Maxwellian as the neutrons pass through the foil so that $\overline{\Sigma}_a = (\sqrt{\pi}/2)\Sigma_{ao}$. Then the average flux in the foil to the incident flux is

$$F_1 \equiv \left(\frac{\overline{\phi}}{\phi_s}\right) = \left(\frac{\overline{\phi}}{\phi_\infty}\right) = \frac{1}{d}\int_0^d e^{-\overline{\Sigma}_a x}dx = \frac{1}{\tau}[1 - e^{-\tau}], \tag{17.100}$$

where $\tau \equiv \overline{\Sigma}_a d$.

Epithermal Flux-Density Self-Shielding: In the epithermal region, the absorption cross section is divided into two portions (see Eq. (17.80)): a $1/v$ component between the thermal and cadmium cutoff energies, and the component above E_{CC} whose absorption is dominated by absorption resonances. The self-shielding in the $1/v$ region is negligible compared to that in the resonance region. In gold most of the fast absorption occurs in the large resonance at 4.91 eV with a peak value of $\sigma_{ar}^{\max} \simeq 30,600$ b. In the case of an isolated resonance

without significant Doppler broadening, the fast self-shielding factor for a thin foil without appreciable scattering can be approximated by [Profio 1976]

$$F_1 = e^{-\tau_r/2}[I_0(\tau_r/2) + I_1(\tau_r/2)], \tag{17.101}$$

where τ_r is the thickness of the foil in mean-free-path lengths evaluated at the peak resonance energy, i.e., $\tau_r = N_d \sigma_{ar}^{\max} d$, and I_0 and I_1 are the modified Bessel functions of the first kind of the zeroth and first order, respectively.

Nearly Isotropic Flux Density

In this geometry, the foil is placed in a diffusing medium where the neutron field has an angular distribution that is well described by just the P_0 and P_1 Legendre components, i.e., is nearly an isotropic field. In such a field the volume averaged neutron absorption in the foil is nearly independent of the foil orientation.

Thermal Flux-Density Self-Shielding: The self-shielding correction factor for a nearly isotropic thermal flux is given by [ANL 5800]

$$F_1 = \frac{1}{\tau}\left[\frac{1}{2} - E_3(\tau)\right], \tag{17.102}$$

where E_3 is the exponential integral function of order three.

Resonance Self-Shielding: For isotropic neutron incidence on the foil, the self-shielding correction factor for resonances is [Profio 1976]

$$F_1 = \frac{\tau_r}{2}\int_{\tau_r/2}^{\infty} y^2 e^{-y}[I_0(y) + I_1(y)]\, dy. \tag{17.103}$$

Other expressions for F_1 are [ANL 5800]

$$F_1 = \frac{4}{3\sqrt{\pi}}\frac{1}{\sqrt{\tau_r}} \qquad \text{“thick foils”} \tag{17.104}$$

and

$$F_1 = 1 + \frac{\tau_r \ln \tau_r}{4} - 0.3274\tau_r \qquad \text{“thin foils”}. \tag{17.105}$$

Thermal-Neutron Flux-Density Depression: The thermal-neutron flux can be severely depressed in the vicinity of a strong absorber and thermal neutrons absorbed in the foil can no longer pass through the foil and subsequently be reflected back to the foil and increase the foil activity. By contrast, fast neutrons passing through a foil at resonance energies are degraded below the resonance energies in the moderator before they are reflected back to the foil. Thus, for fast neutrons, the flux depression factor correction is close to unity, i.e., $F_2^{\text{fast}} = 1$.

For thermal neutrons, the flux-depression correction factor can be expressed as [ANL 5800]

$$F_2^{\text{th}} = \left\{1 + \left[\frac{1}{2} - E_3(\tau)\right] g(R,\gamma)\right\}^{-1}, \tag{17.106}$$

where $\gamma \equiv \overline{\Sigma_s}/\overline{\Sigma_t} \simeq 1$ for the moderator. Several expressions for the g-factor have been derived [ANL 5800]. One expression for $g(R,\gamma)$ is [Profio 1976]

$$g(R,\gamma) = \left\{\frac{3}{2}\left(\frac{L}{\lambda}\right) S\left(\frac{2R}{L}\right) - K\left[\left(\frac{2R}{L}\right), \gamma\right]\right\} r_g. \tag{17.107}$$

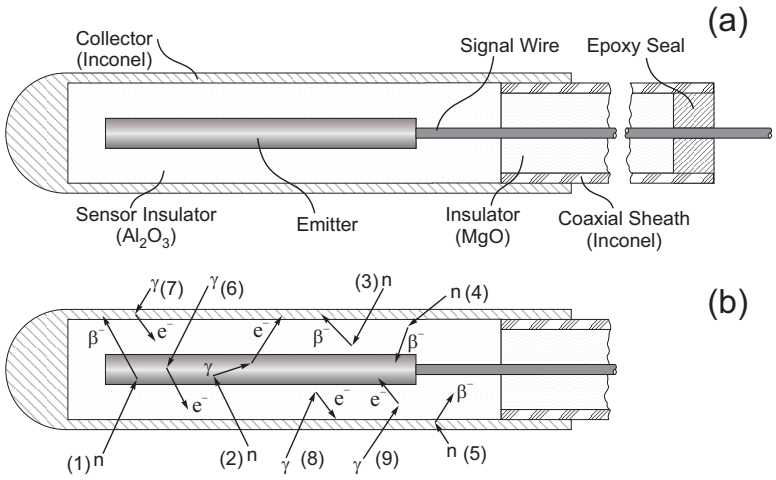

Figure 17.42. (a) The basic components of an SPND; (b) Various radiation interactions that can occur in an SPND.

Here S is the Skyrme function,

$$S(x) = 1 - \frac{4}{x}\int_0^1 e^{-xt}\sqrt{1-t^2}\,dt, \tag{17.108}$$

K is a small transport correction that can be approximated by

$$K \simeq \begin{cases} \dfrac{1}{15}\dfrac{2R}{\lambda_s} & 2R \le \lambda_s \\ 0.15 & 2R > \lambda_s \end{cases}, \tag{17.109}$$

and r_g is a factor depending on L/λ and varies between 0 and 0.9 [Ritchie and Eldridge 1960]. The moderator parameters L, λ, and λ_s are the diffusion length, total mean-free-path length, and the scattering mean-free-path length for thermal neutrons, respectively, in the moderator.

17.9 Self-Powered Neutron Detectors

The self-powered neutron detector (SPND) was originally introduced by J.W. Hilborn [1964].[25] The name "self-powered" is appropriate because these detectors operate without the need for an applied bias. Indeed, they provide a current that is proportional to the neutron absorption rate, a current that can be easily read with a femtoammeter. They are designed as in-core instrumentation for nuclear reactors, usually for operation under steady-state conditions. SPNDs operate on the same principle as neutron activation analysis, except the radioactive decay is rapid and the resulting activation is recorded in real time.

The construction of a basic SPND is shown in Fig. 17.42(a). The components include a neutron absorbing emitter, an electrically conductive collector, and an insulating medium between them. Because these detectors are inserted directly into the core of a nuclear reactor, the materials of choice must be radiation hard in order to survive the total radiation fluence over their operating lifetime. The insulator is typically composed of either aluminum oxide or magnesium oxide, both of which have relatively small neutron interaction cross

[25] In some older texts and publications, they are referred to as Hilborn detectors.

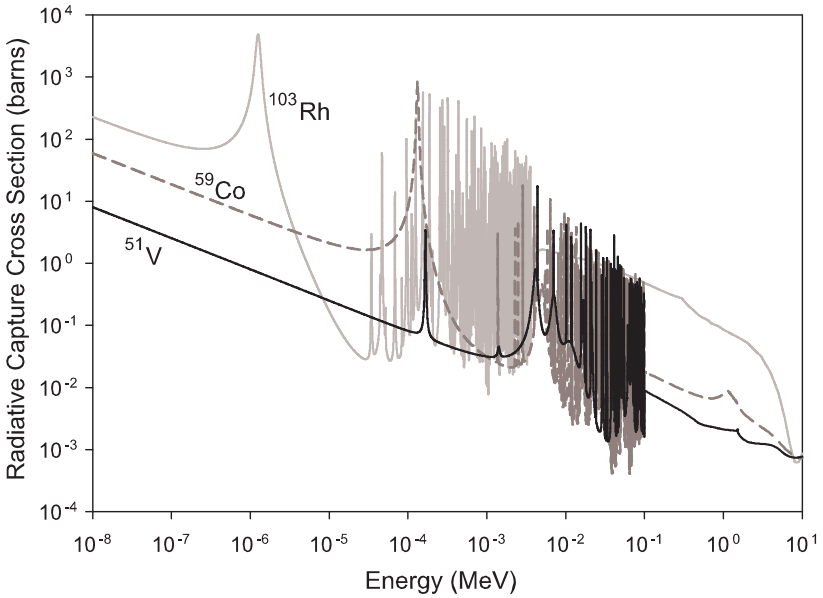

Figure 17.43. Radiative capture cross sections for ^{103}Rh, ^{51}V, and ^{59}Co. Data are from [ENDFPLOT, 2015].

sections. Both insulators have high resistivity at room temperature and at the usual operating temperature of a nuclear reactor core, where the resistivity varies from 10^{12} Ω-cm at room temperature to 5×10^8 Ω-cm at 300 °C. The resistivity of the insulating material will change over time with radiation damage, yet these changes are comparable for both Al_2O_3 and MgO for high purity materials [Angelone et al. 2014]. The neutron cross section is lower for MgO than Al_2O_3 and is typically used for the signal cable insulator. Both Al_2O_3 and MgO are used for the emitter insulator [Stevens 1973].

The conductive metal sheath is usually fabricated from Inconel, a relatively oxidation and corrosion resistant austenite metal alloy of Ni, Cr, and Fe. Different Inconel alloys may include other elements to improve specific properties. Inconel 600 is a common collector choice because of its resistance to corrosion by high purity water, excellent oxidation resistance, high tensile strength, and resistance to stress cracking at high temperatures. The emitter is a neutron activation material that produces daughter products with relatively short decay times. These emitter materials must have thermal-neutron (n,γ) cross sections large enough to be useful for activation, yet small enough so that burnup does not cause large changes in the activation rate over time. The emitter sensitivity should be selective for neutrons or gamma rays. Further, the preferred decay products are beta particles or conversion electrons, although gamma-ray emissions can be used. Typical choices include rhodium, vanadium, and cobalt as emitter materials (whose cross sections are shown in Fig. 17.43), although several other candidate materials have been studied [Hilborn 1964; Ramírez and David 1970; Goldstein and Todt 1979; Amu and Petitcolas 1989; Imel and Hart 1996]. SPNDs are available with short emitter active lengths of only 3 to 4 cm up to long active lengths greater than 20 cm.

For activated beta particle emitters, such as ^{103}Rh and ^{51}V, the emission of beta particles from the emitter creates an electron current, i.e., the electrons that leave the emitter induce charge to flow through the emitter lead and thus produce a current that can be monitored by a femtoammeter. For activated gamma-ray emitters, the gamma rays can interact in the emitter and produce energetic electrons (photoelectric, Compton), which also leave the emitter and produce an induced current. These beta particles, which are

electrons, may strike the collector; however, it is not necessary that these particles reach the collector to produce a current. The mere action of the electrons leaving the emitter produces the induced current. Recall from Sec. 8.5 that mobile charge moving between electrodes induces an image charge to appear on the electrodes. Throughout much of this text, charges were influenced into motion by an electric field. However, in the case of an SPND the electron velocity is produced by the kinetic energy imparted through the decay process. Because beta particles are emitted as a continuous spectrum, with each decay sharing energy with the recoil nucleus and an antineutrino, some beta particles have nearly zero energy while others retain the maximum allowable energy. Consequently, some beta particles will not emerge from the emitter. Regardless, the amount of current produced is a function of the emitter activity and, hence, the measured current is a function of the neutron interaction rate in the emitter.

An analysis on the operation of SPNDs by Warren and Shah [1974] takes into consideration the influence of space charge. Electrons do not freely conduct across the insulator between the emitter and collector. Consequently electrons that come to rest in the insulator build up space charge over time, which ultimately can produce an electric field. Already proven in Sec. 8.6.1 is the fact that space charge does not change the induced current of an electron as it passes through a medium. However, the negative space charge can work to produce a repulsive force that slows down the beta particle. Warren and Shah [1974] calculate that a toroidal electric field maxima will appear in the insulator at some distance $(d_\rho - d_l)/2$ from the emitter surface, where d_l and d_p are the diameter of the emitter and the electric field maxima, respectively. Hence, the amount of current induced by the beta particles and electrons can be reduced if the linear pathlength is reduced. Also, electrons that are coulombically repelled backwards will produce a net induced current representative of the net distance traveled between the emitter and collector. Electrons repelled back to the emitter surface will, consequently, produce a net induced current of zero. A similar situation can be expected for electrons emerging from the collector into the insulator.

Given a thermal-neutron, free-field, flux ϕ_∞, the average thermal flux $\overline{\phi}$ in the emitter is given by Eq. (17.98) or $\overline{\phi} = F_1 F_2 \phi_\infty$. For this simplistic analysis, the nuances of thermal neutron absorption and non $1/v$ cross section behavior discussed in Section 17.1 are ignored. The rate, per unit volume, of production of the radioactive transmutation product from the emitter material is given by

$$R_1(t) = N_e \sigma_e \overline{\phi} \exp[-\sigma_e \overline{\phi} t], \tag{17.110}$$

where N_e is the atomic density of emitter atoms and σ_e is the microscopic *activation* cross section of the emitter material. Here it is assumed there is negligible burnup of the emitter atoms, i.e., N_e remains constant. The atomic density $N_1(t)$ of the radioactive transmutation product accounting for both radioactive decay and transmutation is described by

$$\frac{dN_1(t)}{dt} = R_1(t) - \sigma_1 \overline{\phi} N_1(t) - \lambda_1 N_1(t), \tag{17.111}$$

where σ_1 is the thermal absorption cross section of the radioactive transmutation product and λ_1 is its radioactive decay constant.

Substitution of Eq. (17.110) into Eq. (17.111) and use of the initial condition $N_1(0) = 0$ yields the following result for the activity of the daughter

$$\lambda_1 N_1(t) = \frac{\lambda_1 N_e \sigma_e \overline{\phi}}{\lambda_1 + (\sigma_1 - \sigma_e)\overline{\phi}} \left(\exp[-\sigma_e \overline{\phi} t] - \exp[-(\lambda_1 + \overline{\phi}\sigma_1)t] \right). \tag{17.112}$$

The amount of current produced is also a function of the escape probability of beta particles and electrons from the emitter. A correction constant K is often used to account for this escape probability, which is

an intrinsic function of the emitter geometry and the beta particle emission spectrum. The current is then determined by multiplying the above activity by the emitter volume V_e and by the unit charge constant, i.e.,

$$I(t) = \frac{q\bar{n}KV_e\lambda_1 N_e\sigma_e\overline{\phi}}{\lambda_1 + (\sigma_1 - \sigma_e)\overline{\phi}} \left(\exp[-\sigma_e\overline{\phi}t] - \exp[-(\lambda_1 + \sigma_1\overline{\phi})t]\right), \tag{17.113}$$

where $\bar{n}$ is the average number of radiation quanta emitted per decay of N_1. Typically the emitter material is relatively thin, on the order of 0.5–2 mm in diameter so as to reduce the neutron self-shielding. If emitters with low absorption cross sections for both the initial and transmuted materials are used, then both the neutron self-shielding and flux depression are negligible. Hence, Eq. (17.113) reduces to

$$I(t) \simeq q\bar{n}KV_eN_e\sigma_e\phi_\infty \left(1 - e^{-\lambda_1 t}\right). \tag{17.114}$$

The time response of an SPND is strongly dependent upon λ_1, with a large λ_1 producing a rapid response and a small λ_1 yielding a delayed response. Properties of several emitters are listed in Table 17.4. As t increases to relatively long operating times ($t \to \infty$), the saturation current is reached and Eq. (17.114) becomes

$$I_{sat}(t) \simeq q\bar{n}KV_eN_e\sigma_e\phi_\infty. \tag{17.115}$$

For practical applications, $0.984I_{sat}$ is reached at six half lives of the activated material. Hence, after a step change in nuclear power, it takes 4 min 14 sec for a Rh emitter and 22 min and 36 sec for a vanadium emitter to reach 98.4% of the new steady-state condition.

Shown in Fig. 17.42(b) are several possible reactions that can occur in an SPND [Moreira and Lescano 2013]. Events (1) through (5) are from neutron captures and events (6) through (9) are from direct gamma-ray interactions. For events (1), (2), and (6), the loss of an electron or beta particle from the emitter causes a net positive charge on the emitter, which causes electrons to flow towards the emitter from the signal cable, thereby producing a positive current on the electrometer. For events (5) and (7), the loss of electrons or beta particles from the collector produces a net positive charge on the collector, which causes negative current to flow in the circuit. Events (3) and (8) add negative charge to the collector, which causes positive current to flow in the signal cable, while events (4) and (9) produce negative charge in the emitter and cause negative current flow in the signal cable. Ultimately, all of these events are possible, and the overall measured signal is the net induced current response. If the emitter is designed such that most neutron interactions occur in it while reducing gamma-ray interactions in the surrounding insulator and collector, then most of the measured signal is from neutron absorptions in the emitter, and the neutron flux can be determined from Eq. (17.115).

Neutron activation and gamma-ray interactions in the signal cable may cause background current, which would overestimate the actual neutron flux at the emitter. To remedy this situation, many SPNDs are available with twin leads in which both extend the distance of the entire cable, but only one is connected to the emitter. The second lead produces a compensating signal, which can be subtracted from the primary emitter lead signal in a similar fashion as in a compensated ion chamber.

Rhodium SPNDs are the most popular version in commercial use, mainly because of their higher sensitivity to neutrons than other emitter materials (see Table 17.4). Increased sensitivity, consequently, also means higher burnup at a rate of $\approx 3.5\%$ per month in a thermal-neutron flux of 10^{14} cm^{-2} s^{-1}. Rhodium emitters have a relatively short half-life of 42.3 seconds for approximately 92.4% of the emissions, but also have a longer delayed component for the remaining 7.6% of emissions. These delayed emissions are a consequence of neutron captures producing an excited state of ^{104m}Rh with a decay to ground state half-life of 261.6 seconds [Lederer and Shirley 1978].[26] After this decay to ground, the ^{104}Rh decays by beta emission, with

[26] This half-life of 4.4 minutes is sometimes incorrectly presented as beta emission decay, which it is not. It is the half-life of the metastable state ^{104m}Rh to decay to the ground state of ^{104}Rh, which then subsequently decays by beta particle emission

Table 17.4. Properties of several SPND emitter materials with 508-μm diameters. The type of reaction refers to how current is induced in the emitter, i.e., [n,β^-] indicates the daughter nuclide undergoes beta decay and [n,γ] indicates capture gamma rays produce recoil electrons from scatters in the SPND. The monthly burnup is for the SPND exposed to a flux of 10^{14} cm^{-2} s^{-1}. Data are from Hilborn [1964]; Böck [1976]; Goldstein and Todt [1979].

$T_{1/2} = 42$ seconds, to stable ^{104}Pd. The expected activity, and therefore current, is depicted in Fig. 17.44 for a step increase in reactor power at $t = 0$ and a subsequent step decrease to zero power at $t = 30$ min. Prompt increases in reactor power cannot be monitored with Rh-SPNDs because of these delayed signals. Further, a step decrease in reactor power as shown in Fig. 17.44 serves to illustrate the issue; however this scenario is somewhat artificial because reactor power cannot be reduced in a step-like manner but decreases at its fastest with an 80 s period because of delayed neutrons. In short, Rh-SPNDs, like most SPNDs, are good for steady-state power monitoring, but not for measuring power transients.

Vanadium SPNDs are also commercially available. With a half-life of 226 seconds, V-SPNDs have a slower response than Rh-SPNDs. V-SPNDs are also less sensitive to neutrons and produce a much lower output current. Although the lower sensitivity produces lower signal strengths, it serves to reduce burnup and extend the SPND life to over 30 times that of a Rh emitter of the same size. For longevity, V-based SPNDs have become popular in power reactors, mainly because they can be operated over a long period of time with minimal burnup. As with Rh-SPNDs, V-SPNDs are good for steady-state power measurements, but are not useful for monitoring power transients.

Emitters fashioned from Co perform as prompt flux monitoring devices. The prompt reaction ^{59}Co(n,γ)^{60}Co produces energetic gamma rays between 58 keV and 7.49 MeV, with predominant emissions at 230 keV, 277 keV, 447 keV, 556 keV [see Lone et al. 1981; Tuli 1997]. The activation gamma rays can be reabsorbed or scattered in the emitter material, both processes producing energetic electrons, although these reabsorptions are relatively inefficient (1–2%) in such a small device [Goldstein and Todt 1979]. If the electron exits the emitter, the net positive condition of the emitter causes charge to flow in the signal wire, thereby producing current. The main advantage of Co-SPNDs is the prompt response that allows them to follow better reactor transients and step changes in power.

However, the gamma rays can also interact in the sheath material and the insulator material. If energetic electrons exit the sheath from gamma-ray interactions, then the result opposes the desired emitter emissions. The same is true if a Compton or photo-electron enters the emitter from reactions in the insulator. Another problem with SPNDs that rely upon (n,γ) reactions is the large gamma-ray background of a nuclear reactor.

with a half life of 42 seconds. The two half lives are not additive. The beta particle activity is determined by simultaneously solving the differential equations of the decay scheme.

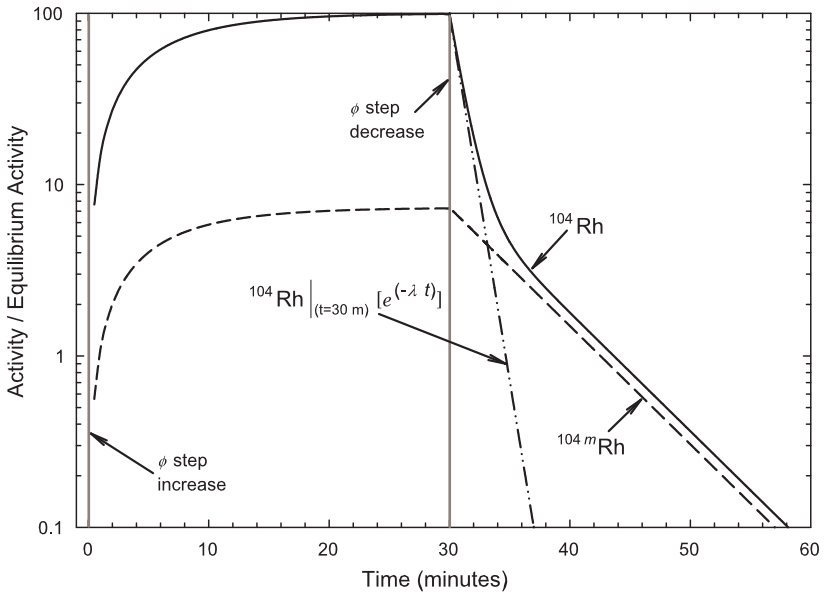

Figure 17.44. Percent ratio of activity from ^{104}Rh and ^{104m}Rh to that of the activity of ^{104}Rh at steady-state equilibrium. The left side of the graph depicts the increase to saturation for an *immediate* step increase in power from zero, and the right side of the graph depicts the activity for an *immediate* step decrease to zero. See text for details regarding issues with this simple model.

These background gamma rays can also interact in the emitter, insulator, or collector, adding either to the emitter or collector currents. Hence, Co-SPNDs are designed such that the net current signal is produced from emitter absorptions, which may be only 10–20% of the total interaction rate [Goldstein and Todt 1979]. Consequently, the inefficiency of capturing the prompt gamma-rays along with the competing interaction processes in the SPND cause the mass sensitivity to be much lower for Co-based SPNDs than for Rh-based SPNDs. Over time the transmutation product ^{60}Co builds up, gradually producing a radioactive product that may require special handling when the SPND is removed from the reactor core. Also, ^{60}Co is a beta particle emitter with $T_{1/2} = 5.27$ years. The result is an increasing background signal with neutron fluence. Some modern systems have compensating electronics for this gradual increase in background current while shielded emitter designs have been proposed to limit the number of ^{60}Co beta particles emerging from the emitter [Goldstein and Todt 1979].

Platinum has also been investigated as an emitter material [Shields 1973; Lynch et al. 1977], although the name SPND is misapplied because it is not strictly a neutron detector.[27] However, for completeness the use of Pt as an emitter is discussed here. Instead of neutron activation, Pt emitters rely directly upon gamma-ray interactions. Further, it is actually desirable that it is insensitive to neutrons because the measurement relies on gamma-ray interactions. Platinum is a candidate because of it high atomic number (78), relatively low average neutron absorption cross section ($\sim$ 10 b), and high density (21.45 g cm^{-3}). Gamma rays interact in the emitter by either photoelectric or Compton events, which eject energetic electrons from the emitter. As with the Co-SPND, gamma rays also interact in the insulator and the collector, giving rise to opposing

[27] Shields named them "self-powered flux detectors".

current to the emitter current. Also as with the Co-SPND, the measured current is the net response from the summed emitter and collector currents. A Pt-SPND has a prompt response to power step changes in a reactor and reportedly a higher sensitivity than Co [Goldstein and Todt 1979]. However, it is assumed with Pt-SPNDs that the gamma-ray flux scales proportionally with the neutron flux, which may not be exact, especially at the reactor core boundaries.

There are additional drawbacks to using Pt as an emitter material; mainly, it does in fact respond to both gamma-rays and neutron interactions [Lynch et al. 1977]. Neutron capture by ^{195}Pt, with a thermal-neutron capture cross section of $\sigma_\gamma = 29$b, produces prompt high-energy gamma-rays of 5.9 MeV and 6.1 MeV [Tuli 1997]. The thermal neutron capture cross section for ^{196}Pt is relatively small at $\sigma_\gamma = 0.4$b; however, the resonance integral capture cross section is $\sigma_{I,\gamma} = 5$ b, producing predominantly 333 keV and 356-keV gamma rays [Lone et al. 1981]. Finally, neutron capture by ^{198}Pt, with $\sigma_\gamma = 3.7$b and $\sigma_{I,\gamma} = 56$b, produces a undesirable beta particle emission response ($T_{1/2} = 30.8$ min). Lynch et al. [1977] report that as much as 55% of the total signal can result from neutron interactions for some emitter geometries, but also provide a method to discern between neutron and gamma-ray induced signals.

17.10 Time-of-Flight Methods

Another method used to measure the energy of a neutron involves the use of timing circuitry (covered in Chapter 22) with which the speed of a neutron is recorded. Suppose that a finite package of neutrons is released from a source, where the starting time gate is linked in coincidence with a neutron detector some distance from the source. Then the detector can be connected to record pulse height events as a function of arrival time. Usually this time spectrum is recorded with a multichannel analyzer where the channels are increments in time. For low energy neutrons, relativistic effects are negligible. The arrival time is a direct measure of the speed, or energy,

$$t = \frac{d}{v} = d\sqrt{\frac{m_n}{2E}}, \tag{17.116}$$

where t is the time duration between pulse initiation and detection, v is the neutron velocity, d is the distance between the neutron source and detector, m_n is the neutron mass, and E is the neutron energy. Given any velocity v or energy E, it becomes clear from Eq. (17.116) that the time spread increases with distance d.

To produce a simulated pulse from a neutron source, a device named a *chopper* is generally used.[28] The first such devices consisted of a large spinning disk with open spaces for neutrons to pass through, while the remaining portions of the disk were composed of a neutron absorber [Amaldi et al. 1935, Frisch and Sorenson 1935, Dunning et al. 1935b, Fink 1936]. The device described by Frisch and Sorenson [1935] was a 50-cm diameter wooden wheel that was 2 cm thick, and relied on neutron collisions with protons in the wood to attenuate slow neutrons. The upgraded design by Dunning et al. [1935b] used an aluminum wheel with portions blocked by Cd. In the Dunning et al. [1935b] design, and also the Fink [1936] design, a second stationary Cd collimator, adjacent to the neutron detector, was used downstream from the rotating disk to accept only those neutrons that emerged from chopper opening.

An improved design, shown in Fig. 17.45 and conceived by Fermi et al. [1947], has a series of parallel slots arranged in a rotating cylinder (or drum). These collimator slots need not be voids, but are usually thin plates of Al clamped between layers of Cd. Notably, the Cd works well for low-energy neutrons with energies below approximately 0.5 eV, but because neutron absorption reduces tremendously above 0.5 eV, it is less effective for higher energies of neutrons. The chopper is rotated at high speeds, where the slots align with the source every half-rotation of the chopper. When the slots are aligned with the neutron stream, a burst of neutrons from the source passes through the chopper and heads towards the detector. The start time is

[28] These devices were originally named *velocity selectors*, but by the mid-1950s the name *chopper* had been largely adopted.

measured by producing a gate signal when the chopper is aligned with the detector, often performed with a magnetic or optical actuator. If it is assumed that the uncertainty in d is relatively small, the uncertainty in the energy calculation can be approximated with Eq. (17.116)

$$\Delta E = \left[\left(\frac{dE}{dt}\right)^2 (\Delta t)^2\right]^{1/2} = 2E\frac{\Delta t}{t} = \sqrt{\frac{8}{m}}\frac{\Delta t}{d}E^{3/2}, \tag{17.117}$$

where Δt is the uncertainty in the flight time.

As shown in Section 17.7.5, the interaction rate in a $1/v$ absorbing detector is independent of neutron energy for slow neutrons with energies in the $1/v$ region. Hence, the number of counts recorded as a function of time yields a measure of the energy distribution of slow neutrons emerging from the chopper. To reduce neutron scattering effects, a beam collimator that is either evacuated or backfilled with ^{4}He or oxygen should be positioned between the chopper and the detector (see Fig. 17.46).[29]

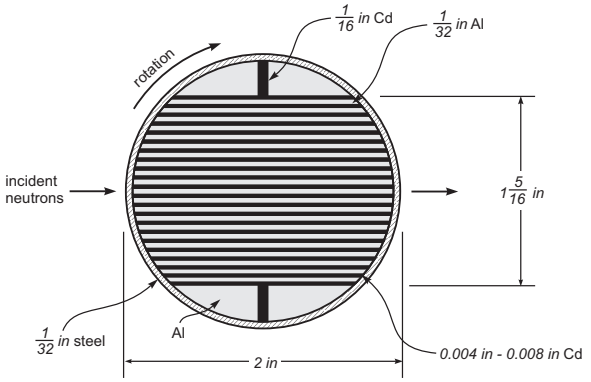

Figure 17.45. Cross section view of the chopper design from Fermi et al. [1947].

Seidl et al. [1954] describe a fast neutron chopper with eight pairs of collimated channels on a relatively large wheel (30-inch diameter). The device was designed for neutron energies ranging between 10 eV up to 10 keV, where the stopping material is phenolic laminate. The chopper was designed to operate at about 12000 rpm with a temporal emission distribution that appears approximately as an isosceles triangle with FWHM of 0.7 μs. The distance between the chopper and a bank of $^{10}BF_3$ detectors was 20 meters, between which was a large plastic helium-filled "balloon".

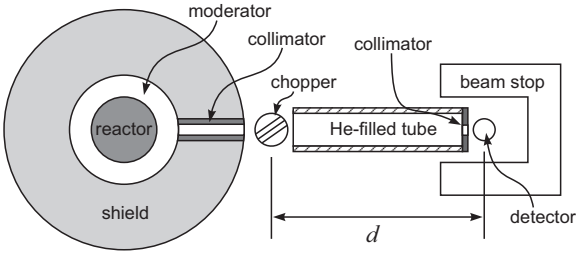

Figure 17.46. One method to arrange a TOF neutron energy measurement from a nuclear reactor.

[29] One of the earliest applications of neutron beam choppers was to measure the neutron lifetime. An alternative method is to place neutrons in a cryogenic bottle, whose walls are perfect neutron reflectors, and measure how many remain after a period of time. At first both methods gave slightly different results, a difference in the mean lifetime of 9-s that persists to this day and is well outside experimental errors. One explanation could be a neutron decay mode that does not produce a proton, in which case the beam method would overestimate the neutron lifetime.

PROBLEMS

1. For an infinite homogeneous medium with weak sources and absorption, the flux of thermal neutrons in thermal equilibrium with the thermal motion of the ambient atoms is given by the Maxwellian distribution

$$\phi_M(E) = \frac{2\pi n}{(\pi kT)^{3/2}}\sqrt{\frac{2}{m_n}}Ee^{-E/kT}.$$

Here n is the total neutron density, k is Boltzmann's constant, T is the neutron temperature (K), and m_n is the neutron mass. Show (a) the most probable energy (the energy at which $\phi_M(E)$ has a maximum is $E_T \equiv kT$) and (b) the average energy is $2E_T = 2kT$.

2. Other forms of the Maxwellian distribution include
(a) *neutron number density energy distribution*

$$n_M(E) = \frac{2\pi n}{(\pi kT)^{3/2}}\sqrt{E}e^{-E/(kT)}$$

(b) *neutron flux velocity distribution*

$$\phi_M(v) = 4\pi n\left(\frac{m_n}{2\pi kT}\right)^{3/2} v^3 e^{-m_n v^2/(2kT)}$$

(c) *neutron number density velocity distribution*

$$n_M(v) = 4\pi n\left(\frac{m_n}{2\pi kT}\right)^{3/2} v^2 e^{-m_n v^2/(2kT)}$$

Sketch these three distributions and that of Problem 1. Find the average and most probable speed or energy for each.

3. Determine the thermal-neutron absorption length for a ^{3}He gas-filled detector pressurized to 4 atm. If the detector has a diameter of 1 inch (2.54 cm), what is the maximum attenuation for a beam of neutrons intersecting perpendicular the tube cross section?

4. You have a $^{10}BF_3$ detector built from a 25-mm diameter (I.D.) Al tube, backfilled with 0.2 atm of $^{10}BF_3$ and 2 atm of Ar gas. If a 0.5 cm diameter thermal-neutron (2200 m s^{-1}) beam intersects the detector mid-section, what is the expected intrinsic thermal-neutron detection efficiency?

5. Given a thermal-neutron beam (0.025 eV) intersecting a 10-mm-thick sample of CLYC:Ce, determine the intrinsic thermal-neutron detection efficiency of the CLYC:Ce sample. If the natural Li is replaced with 96% enriched ^{6}Li, what is the new thermal-neutron detection efficiency?

6. A monoenergetic beam of neutrons is normally incident on a thin sheet of material. Confining your attenuation to a single atom in the material, how long must you wait, on the average, before a neutron interacts with the atom? The beam intensity is 10^{10} neutrons cm^{-2} s^{-1} and the total microscopic cross section for the atoms is 10 barns.

7. Determine the intrinsic (2200 m s^{-1}) thermal-neutron detection efficiency for a neutron beam normally incident on the front surface of a Si diode coated with 1.5 microns of 96% enriched ^{10}B. In the coating, the range of the ^{4}He ion is 2.3 microns and that for the Li ion is 0.8 microns. Assume absorption in the contact layer is negligible.

8. Sketch the expected pulse height spectrum from a thermal-neutron beam intersecting the midpoint of a P-10 gas-filled detector with inner walls coated with (first) 1 micron 90% enriched ^{10}B over which a 10-micron layer of 95% enriched ^{6}LiF layer has been applied.

9. Explain the possibilities and limitations of operating ^{3}He and $^{10}BF_3$ detectors as ion chambers, Geiger-Müller counters, or proportional counters. What practical consideration dictates using the latter (proportional) operation?

10. The sensitivity or efficiency of a BF_3 tube or a boron lined tube decreases with use because of the burnup of the ^{10}B. If such a tube is exposed to a constant thermal flux ϕ, show that the tube sensitivity decreases in time as $\exp[-\sigma_a \phi t]$, where σ_a is the absorption cross section for ^{10}B.

11. A young engineer decided that it was time for change with present day neutron detectors and designed a $^{10}BF_3$ proportional tube with ^{6}LiF-coated walls. Sketch the expected pulse height spectrum if the LiF is very thin. Sketch the expected pulse height spectrum if the LiF is as thick as the maximum range of the highest energy reaction product from the ^{6}Li(n,t)^{4}He reaction. Discuss advantages and disadvantages of the design.

12. Why can't the counting efficiency of a boron-lined proportional counter be increased indefinitely by simply increasing the coating thickness?

13. The government of the rogue nation Haides seeks to develop an atomic bomb. But enriching its abundant natural uranium reserves to extract ^{235}U is beyond the technical and financial abilities of the nation. However, Haides' chief nuclear scientist, Prof. Lou Cipher, thinks there is another way to acquire sufficient ^{235}U. Because fission chambers contain 93% enriched U, they could provide an easy, commercially available, alternative to obtaining the needed ^{235}U. One such chamber with an active cylindrical region of length 35 cm and diameter of 18 cm has a 93% enriched UO_2 coating of thickness 0.015 μm. Prof. Cipher has learned from his spies that a reflected sphere of 15 kg of 93% enriched ^{235}U is needed for a nuclear weapon. How many fission chambers must Haides acquire?

14. In what situations is a ^{3}He tube preferred over a BF_3 tube for counting thermal neutrons?

15. What is the expected activity of an 1 cm^2 Au foil 500 microns thick irradiated in a thermal neutron beam of 10^6 cm^{-2} s^{-1} for 30 minutes?

16. Although the gold foil activation technique is designed for thermal neutron measurements in which the neutrons have a Maxwellian energy distribution, it can also be used in other situations involving slow neutrons. For example, a neutron diffractometer is sometimes used to extract neutrons of (almost) a single energy from the neutrons with thermal Maxwellian distribution leaving a beam port of a nuclear reactor. This monodirectional monoenergetic beam can then be used to calibrate a slow neutron detector as described in Sec. 17.6.5. Modify the analysis of Sec. 17.7 to obtain an expression for the activation of a gold foil in such a beam to determine the intensity (flux) of the monoenergetic beam.

17. Show that Eq. (4.146) for a relativistic heavy charged particle reduces to Eq. (17.28) for a non-relativistic heavy ion.

18. Derive Eq. (17.112).

19. Consider an SPND with ^{103}Rh as the emitter with an atom density of N_o. Let the subscripts "1" and "2" refer to ^{104m}Rh and ^{104}Rh, respectively. The atom density, decay constant, and activation cross

section are denoted by $N_i(t)$, λ_i, and σ_i, respectively, $i = 1, 2$. A new SPND is inserted into a reactor operated at a constant flux of ϕ_o. Show that the buildup to equilibrium of the two daughters is given by

$$N_1(t) = \frac{N_o \sigma_1 \phi_o}{\lambda_1}(1 - e^{-\lambda_1 t}),$$

and

$$N_2(t) = -\frac{N_o \phi_o (\sigma_1 + \sigma_2)}{\lambda_2}[1 - e^{-\lambda_1 t}].$$

20. Consider the ^{103}Rh SPND of the previous problem. Show that the transients from equilibrium as $\phi_o \to 0$ at $t = 0$ are given by

$$N_1(t) = \frac{N_o \phi_o \sigma_1}{\lambda_1} e^{-\lambda_1},$$

and

$$N_2(t) = N_o \phi_o \left\{ \frac{\sigma_1 + \sigma_2}{\lambda_2} e^{-\lambda_2} + \frac{\sigma_1}{\lambda_2 - \lambda_1} \left(e^{-\lambda_1 t} - e^{-\lambda_2 t} \right) \right\}$$

21. Given a Rh SPND operating continuously in a BWR for 6 months at a thermal-neutron flux of 10^{14} cm^{-2} s^{-1}, what is the expected percent decrease in observed current?

22. A beam chopper is used to select neutrons with speeds of 300 m/s. After traveling down a 30-m beam line, 3.40% fewer neutrons reached the detector than left the chopper. Estimate the mean lifetime of neutrons.

Chapter 18

Fast Neutron Detectors

These results, and others I have obtained in the course of the work, are very difficult to explain on the assumption that the radiation from beryllium is a quantum radiation, if energy and momentum are to be conserved in the collisions. The difficulties disappear, however, if it be assumed that the radiation consists of particles of mass 1 and charge 0, or neutrons.

Sir James Chadwick

18.1 Detection Mechanisms

Because interaction cross sections for neutrons in the epithermal to fast region are generally relatively small (except in narrowly defined resonance regions) compared to thermal-neutron cross sections, detectors designed for fast neutrons must rely on alternative approaches to those traditionally used for thermal-neutron detectors that rely on a select few isotopes with large reaction cross sections. An additional difficulty is encountered in the detector design if the goal is to distinguish between thermal and fast neutrons.

Fast neutron detection can be divided into three basic methods. First, fast neutrons can be detected by moderating them into the thermal or epithermal energy region for which a traditional thermal-neutron detector can be used as the sensor. Second, fast neutrons, upon scattering, can introduce recoil atoms into a detecting medium, which is either attached to the detector or is part of the detector material. Third, a fast neutron may undergo in the detector material a nuclear reaction that can, by some means, be distinguished from those produced by thermal neutrons.

18.1.1 Neutron Moderation and Scattering

A common method of detecting fast neutrons is through neutron moderation. This technique places low atomic number materials close to a traditional thermal-neutron detector. Neutrons scatter in the moderator material and lose energy with each scatter, until, ultimately, they lose enough energy such that absorption in the thermal-neutron detector becomes likely.

The kinematics of inelastic neutron scattering are discussed in Sec. 4.3.4. In this chapter only elastic scattering ($Q = \Delta = 0$ and $\gamma = 1/A$) is considered and the results of Chapter 4 are considerably simplified. In particular, the interrelationships among the cosine of the scattering angles are repeated here for convenience.[1] From Eq. (4.47)

$$\omega_s = \frac{1 + A\omega_c}{\sqrt{1 + 2A\omega_c + A^2}}, \qquad -1 \le \omega_c \le 1. \tag{18.1}$$

From Eq. (4.48)

$$\omega_c = -(1 - \omega_s^2)/A + \omega_s\sqrt{1 - (1 - \omega_s^2)/A^2}, \quad -1 \le \omega_s \le 1. \tag{18.2}$$

[1] Here the subscript c and s refer to the center-of-mass and laboratory systems, respectively. The scattering angle is θ_i and its cosine is $\omega_i = \cos\theta_i$, $i = c, s$.

For the special case of $A = 1$ in which $\omega_s \geq 0$ this result reduces to $\omega_c = -1 + 2\omega_s^2$, which implies $\theta_c = 2\theta_s$. The cosine of the angle of the recoil nucleus for elastic scattering is given by Eq. (4.55) as

$$\omega_r = \sqrt{\frac{1-\omega_c}{2}} = \sin(\theta_c/2), \quad 0 \leq \omega_r \leq 1, \tag{18.3}$$

and, from Eq. (4.54), the recoil energy of the nucleus is

$$\frac{T}{E} = \frac{2A}{(1+A)^2}(1-\omega_c) = \frac{4A}{(1+A)^2}\omega_r^2. \tag{18.4}$$

This result indicates that the maximum energy transfer occurs when the laboratory scattering angle of the recoil nucleus θ_r is 0, or when $\theta_s = \theta_c = \pi$.

For a given incident neutron energy E, any one of ω_s, ω_c, ω_r, E', or T is independent, i.e., specification of one determines values of the other parameters. Because scattering is azimuthally symmetric about the direction of the incident neutron in polycrystalline materials, the singly differential scattering cross sections in terms of the different scattering parameters are related by

$$\frac{d\sigma_s(E,\omega_c)}{d\Omega_c}2\pi d\omega_c = \frac{d\sigma_s(E,\omega_s)}{d\Omega_s}2\pi d\omega_s = \frac{d\sigma_s(E,E')}{dE'}dE' = -\frac{d\sigma_s(E,T)}{dT}dT. \tag{18.5}$$

Notice the minus sign in the last term, an indication that as T decreases, ω_c, ω_s, and E' all increase.

Example 18.1: Determine the maximum fractional energy transfer for neutron scattering off H and ^{4}He.

Solution:
From Eq. (18.4) for hydrogen, in which $A = Z = 1$,

$$\frac{T}{E} = \left[\frac{4A\cos^2\theta_r}{(1+A)^2}\right] = \left[\frac{4(1)\cos^2(0)}{(1+(1))^2}\right] = 1.$$

This result shows that the total energy E of the neutron can be transferred to the proton in a single collision, provided $\theta_s = \pi$. For elastic scattering from ^{4}He,

$$\frac{T}{E} = \left[\frac{4A\cos^2\theta_r}{(1+A)^2}\right] = \left[\frac{4(4)\cos^2(0)}{(1+(4))^2}\right] = 0.64,$$

which indicates that a maximum of 64% of the neutron energy can be transferred to a ^{4}He nucleus in a single scatter.

18.1.2 Multiscattered Neutrons

Although a single scatter with hydrogen can transfer a fast neutron to the thermal region, generally several scatters are required. On average, the number n of scatters required to degrade a neutron with initial energy E_o to a lower energy E is [Lamarsh 1966]

$$n = \frac{1}{\xi}\ln\frac{E_o}{E}, \tag{18.6}$$

Table 18.1. Elastic slowing down parameters. Data are from [Lamarsh 1966].

Nucleus	Mass No.	ξ
^{1}H	1	1.000
H_2O		0.920
^{2}H (or D)	2	0.725
D_2O		0.509
Be	9	0.209
C	12	0.158
O	16	0.120

where ξ is[2]

$$\xi = 1 - \frac{(A-1)^2}{2A} \ln\left(\frac{A+1}{A-1}\right). \tag{18.7}$$

For example, using the data of Table 18.1, to thermalize a neutron from 2 MeV to 1 eV requires 14.51, 15.77, 28.5, and 91.83 scatters in H, H_2O, D_2O, and C, respectively.

18.1.3 Absorption

Epithermal and fast neutrons can also be absorbed in materials, although the probability of this is usually lower than that observed for slow neutrons in most materials. However, fast neutrons must pass through the absorption resonance energies of materials as they slow down. The rate at which these slowing neutrons are absorbed is defined by the *resonance integral* which, for a $1/E$ slowing down spectrum is defined as

$$I = \int_{E_{CC}}^{E_{\max}} \sigma_a(E) \frac{dE}{E}. \tag{18.8}$$

where $E_{\max}$ is the maximum neutron energy or energy at which absorption resonances can be resolved. Thus the fast neutron absorption rate in a foil, for example, is given by Eq. (17.82).

There are several select isotopes that absorb neutrons only at energies above a specific threshold energy. Discussion of these threshold reactions is deferred to later in this chapter where foil activation methods are discussed.

18.2 Detectors Based on Moderation

A simple method used to detect fast neutrons is to provide a means to moderate the neutrons and slow them to thermal energies so that a traditional thermal-neutron detector can be used, such as a ^{3}He gas-filled detector. The methods may include simply detecting the presence of neutron or may include complicated unfolding algorithms used to determine the neutron energy spectrum. Some of these moderation detection methods are described in the following sections.

18.2.1 Bonner Spheres

A small thermal-neutron detector is placed in the center of a sphere of high density polyethylene (HDPE). Fast neutrons entering the HDPE sphere lose energy through scattering and, thus, increase the probability of interacting in the thermal-neutron detector. Usually the thermal-neutron detector is a ^{6}LiI:Eu scintillator, although $^{10}BF_3$ and ^{3}He gas-filled detectors have been used [Rotondi and Geiger 1968; Goldhagen 2011], as well as activation foils [Thomas et al. 2002a].

The spheres can be obtained commercially in a set of different diameters, often referred to as a *Bonner sphere set*, named after one of the pioneering authors of the method [Bramblett et al. 1960; Bonner 1961]. A set of commercial Bonner spheres usually has between 6 to 10 different sizes so that several different measurements of the neutron field can be made including one with the bare detector. The main components to a Bonner sphere detector are shown in Fig. 18.1, along with a depiction of a few fast neutron trajectories. Also shown in Fig. 18.1 is a photograph of a commercial Bonner sphere set.

For a small sphere, there is little moderation and it is unlikely that a high energy neutron loses enough energy to be efficiently detected by the neutron detector should it enter that sphere. As the size of the

[2] A neutron of energy E has a *lethargy* $u(E) \equiv \ln(E_{\max}/E)$ where $E_{\max}$ is the maximum energy of a neutron in a system. As E decreases, u increases, i.e., the neutron moves more lethargically, and hence the name *lethargy*. Here ξ is the average gain in lethargy per scatter averaged over all scattering angles.

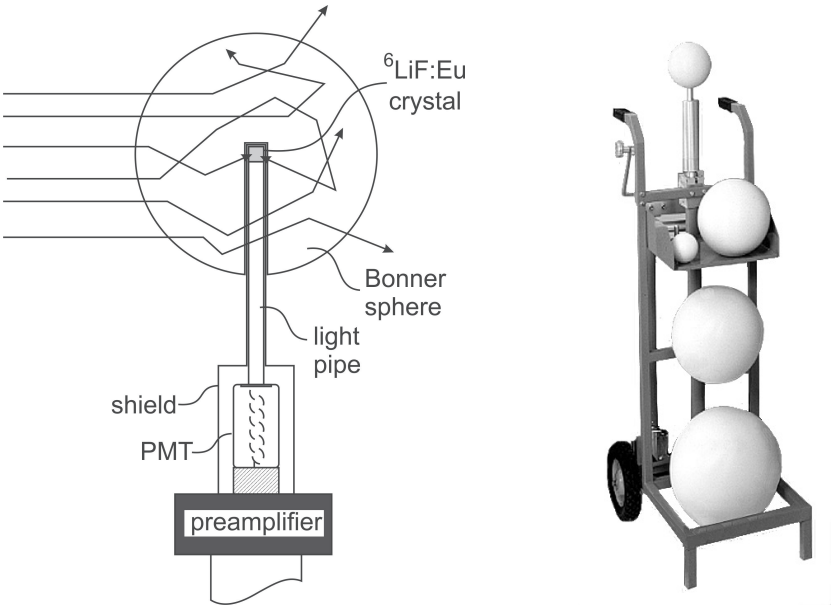

Figure 18.1. (left) Depiction of the main Bonner sphere components. Also shown are several possible neutron trajectories along which some neutrons scatter out of the Bonner sphere, some neutrons are absorbed by the Bonner sphere, and some neutrons are detected by the ^{6}LiF:Eu scintillator. (right) The Ludlum model 42-5 is a commercial Bonner sphere set and rack with 6 different Bonner sphere sizes. Courtesy of Ludlum Measurements.

sphere is increased, the moderation becomes more pronounced for fast neutrons, but overly so for low energy neutrons. Hence, epithermal neutrons may lose too much energy before reaching the detector and be absorbed in the moderator. As the size of the sphere increases further, moderated neutrons with sufficient range to reach the detector may miss it entirely and either be absorbed in the moderator or even escape from the Bonner sphere. Overall, the detector response is a complex function of how the neutrons enter a sphere, the detector absorbing medium (such as ^{6}Li or ^{10}B), the detector absorber mass thickness, the Bonner sphere size, and the distance in air (or other medium) between the neutron source and the detector. Thomas and Alevra [2002b] discuss many of these points in a review on the operation of Bonner spheres for neutron spectroscopy [see also the results of Burgett et al. 2009].

Slow neutrons interact readily with the thermal-neutron detector and, therefore, need no moderation. For each sphere under test, neutrons interacting in the spheres undergo scattering reactions that lead to some moderation. Thermal neutrons may be completely absorbed in even the smallest moderator sphere, usually 2 inches (5 cm) in diameter, and thus go undetected. However, slow neutrons in the low eV range have a relatively high probability of being detected because this sphere is optimized for 1 eV neutrons as can be seen from Fig. 18.2. The next size up is optimized for a slightly higher neutron energy, and so on for the remaining spheres. Most sets have a 12-inch (30.5 cm) diameter sphere as the largest size, although some sets have spheres as large as 18 inches (45.7 cm).

The response function for the ith sphere, $R_i(E)$, such as those shown in Fig. 18.2, gives the average number of counts per incident neutron of energy E. The response function depends on the size and type of thermal-neutron detector at the center of each sphere and how the sphere is illuminated by neutrons. For example, a 1-in diameter incident neutron beam has a different response function than that for broad beam illumination. In such cases the response functions depend on what portion of a sphere is illuminated

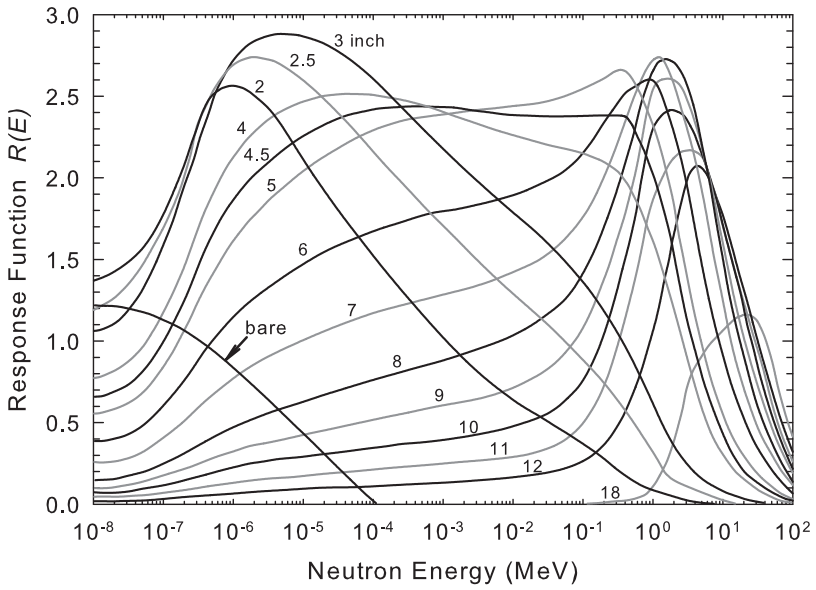

Figure 18.2. Calculated response functions for different sized Bonner spheres over a thermal-neutron detector (^{6}LiI scintillator). Data extracted from Jacobs and van den Bosch [1980].

and the intersecting location on the sphere (centered, off-centered, etc.). Likewise, response functions for a point neutron source near the sphere differs from that for the source placed far from the sphere. Most often reported response functions are for spheres uniformly illuminated by a plane parallel beam of monoenergetic neutrons. In this case $R_i(E)$ gives the average count rate per unit intensity of the beam, i.e., counts per neutron cm^{-2}.

For a particular neutron energy, the probability that the detector records a count can be determined with Monte Carlo techniques [Braga and Dias 2002; Bedogni et al. 2007]. The response functions calculated by Monte Carlo simulations have associated statistical errors and are also obtained for only discrete incident neutron energies. These results are then subjected to some smoothing procedure to make each $R_i(E)$ a smooth continuous function of E.

The neutron field incident on a Bonner sphere is characterized by its energy-dependent intensity or flux $\phi(E)$ (cm^{-2} MeV^{-1} s^{-1}), which here is assumed to be monodirectional and constant in time over a sphere. The detector response function $R_i(E)$ is the count rate obtained with the ith sphere per unit incident beam intensity of energy E. Hence the count rate observed the ith of N spheres is given by the Fredholm equation

$$c_i = \int_{E_{\min}}^{E_{\max}} R_i(E)\phi(E)\,dE, \qquad i = 1, \ldots, N, \tag{18.9}$$

where $E_{\max}$ and $E_{\min}$ are the maximum and minimum neutron energies in the neutron spectrum. Given the N measured c_i and the response functions $R_i(E)$, the unfolding problem is to solve these equations for the neutron energy spectrum $\phi(E)$.

Neutron spectra are usually plotted versus the logarithm of energy. Thus to accurately fit the data, the unfolding problem is better handled in terms of the logarithm of energy. Equivalently, the neutron lethargy

u can be used. The lethargy is defined as

$$u \equiv \ln\left(\frac{E_{max}}{E}\right), \tag{18.10}$$

whose derivative with respect to energy is simply

$$\frac{du}{dE} = -\frac{1}{E}. \tag{18.11}$$

The maximum lethargy $u_{\max}$ corresponds to the minimum energy, and Eq. (18.9) can be written as

$$c_i = \int_0^{u_{max}} du\, R(u)\, \phi(u), \qquad i = 1, \ldots, N, \tag{18.12}$$

where $R(u) = R(E(u))$ and $\phi(u) = E(u)\phi(E(u))$.

Typically, the Bonner sphere response functions are determined by using Monte Carlo methods, which with cubic spline or some other method for smoothing result in a set of curves such as those shown in Fig. 18.2. These response function calculations can be verified by using known fast neutron sources (see Tables 5.6 and 5.7 for examples of neutron sources). The next step in unfolding an unknown spectrum is to convert the Fredholm equations, Eq. (18.9) or Eq. (18.12), into linear algebraic equations by using some numerical quadrature method. The simplest such discretization is to assume $\phi(E)$ is constant over each energy interval formed by a contiguous grid of energies (or lethargies) E_j and E_{j+1}, $j = 1, \ldots, M$. Thus, Eq. (18.9) or Eq. (18.12) are transformed to

$$c_i = \sum_{j=1}^{M} R_{i,j}\phi_j, \qquad i = 1, \ldots, N. \tag{18.13}$$

where M is the total number of assigned flux groups. In matrix form these equations can be written compactly as

$$\mathbf{c} = \mathbf{R}\bullet\boldsymbol{\phi} \tag{18.14}$$

where $\mathbf{c}$ and $\boldsymbol{\phi}$ has elements c_i and ϕ_j and the response matrix $\mathbf{R}$ has elements R_{ij}.

Many unfolding methods and algorithms have been developed since the introduction of the Bonner sphere method by Bramblett et al. in 1960. Some of these unfolding techniques take various types of neutron source spectra into consideration, and can identify the most probable source [Matzke 2002; Goldhagen 2011]. However, the method is time consuming and relatively cumbersome because between 6 or more measurements, depending on the set, must be made with long enough measurement times to ensure reasonable counting statistics. Further, during the measurement process, the user assumes that the neutron flux environment is unchanging. Finally, although the result is a neutron spectrum, it is usually of relatively low resolution. Hence, Monte Carlo codes and archived data are often used as a comparison to the measured results to determine the most probable neutron source (or spectrum) [Thomas and Alevra 2002b].

If the number of Bonner spheres N is greater than or equal to the number of energy groups M, then Eqs. (18.9) can be solved outright. The resolution of the solution increases with the number of Bonner spheres (and energy groups). However, if the number of energy groups exceeds the number of Bonner sphere measurements, then one must deal with an underdetermined set of equations, which, generally, have an infinity of solutions, most of which are physically unrealistic such as negative or complex fluences. Two basic approaches for solving Eqs. (18.13) have evolved over time [Ryan 1998]. The oldest is one based on some iteration scheme wherein some initial spectrum guess is modified to give better agreement with Eqs. (18.9). The second and more recent approach is to add constraints (such as positivity) to the possible solutions and obtain as many equations as there are unknowns so as to *regularize* the unfolding problem. The bases of both of these approaches are outlined below.

The Iterative Method of Doroshenko

An iterative algorithm developed by Doroshenko et al. [1977] is used in many commercial unfolding codes for the Bonner sphere system and is the basis of comparison for the Backus-Gilbert method in this study. The Doroshenko method utilizes a simple recursion relationship to infer the approximate solution from the measured data. The algorithm requires an initial guess of the neutron spectrum $\mathbf{\Phi}^0$, which produces estimated count data given by $c_i^0 = \mathbf{r}_i \bullet \boldsymbol{\phi}^0$, where $\mathbf{r}_i$ is ith row vector of $\mathbf{R}$ for moderator i. Successive estimates of the flux $\boldsymbol{\phi}^{k+1}$ are found by iterating the relation

$$\boldsymbol{\phi}^{k+1} = \boldsymbol{\phi}^k \left[\sum_{i=1}^{N} \frac{\mathbf{r}_i}{c_i^k} \Bigg/ \sum_{i=1}^{N} \frac{\mathbf{r}_i}{c_i} \right], \qquad k = 0, \ldots, k_{max}, \tag{18.15}$$

where k_{max} is the maximum number of iterations and $c_i^k = \mathbf{r}_i \bullet \boldsymbol{\phi}^k$. Essentially, this method attempts to bring the estimated count data c_i^k into agreement with the measured count data c_i by adjusting the estimated neutron spectrum $\boldsymbol{\phi}^k$.

A measure of error ϵ in the iteration is the root mean squared difference between the estimated and measured count rates

$$\epsilon^2 = \frac{1}{N} \sum_{i=1}^{N} \left[\frac{(c_i^k - c_i)}{c_i} \right]^2. \tag{18.16}$$

Although this outcome does not actually reflect the error between the true and measured solutions, ϵ does reflect the convergence rate of the method. In most problems ϵ decreases rapidly and approaches a fixed value, making ϵ a poor cutoff criterion for iteration. Therefore, it is more useful to observe the change, for the k-th iteration, $\delta\epsilon^k = \epsilon^k - \epsilon^{k-1}$, which approaches a uniform value more slowly than ϵ.

Provided that the response functions $\mathbf{r}_i$ and the estimate $\boldsymbol{\phi}^0$ are both positive, positivity of solutions is guaranteed by Eq. (18.15). Good numerical stability is demonstrated for solutions that are similar to the initial estimate. Most importantly, the method gives places more importance on regions where R_i is large, or where each detector combination is the most sensitive. Unfortunately, the method is limited in its ability to handle unknown neutron spectra, where no estimate of $\boldsymbol{\phi}^0$ is possible. Because $\boldsymbol{\phi}^0$ is modified by Eq. (18.15) so as to agree with the measured count rates, it has a strong influence on the final solution $\boldsymbol{\phi}^{k_{max}}$. Secondly, the cutoff criterion k_{max} is an arbitrary parameter that also depends on $\boldsymbol{\phi}^0$. For small values of k_{max} the estimated solution closely resembles $\boldsymbol{\phi}^0$. For large values, numerical instabilities yield non-realistic results.

The Regularization Method

The neutron spectrum $\phi(u)$ can be recovered by minimization principles, using numerical methods as outlined in Press et al. [1992]. To utilize *a priori* information in calculating a solution, one might choose two positive functionals $\mathcal{A}[\boldsymbol{\phi}] > 0$ and $\mathcal{B}[\boldsymbol{\phi}] > 0$, such that $\boldsymbol{\phi}$ can be determined by minimization of $\mathcal{A}[\boldsymbol{\phi}]$ or $\mathcal{B}[\boldsymbol{\phi}]$. $\mathcal{A}$ can be chosen to estimate the accuracy of the solution, and $\mathcal{B}$ to estimate some fixed solution property, such as smoothness.

One obvious functional to minimize that quantifies how good a possible solution $\widehat{\phi}$ is the χ^2 statistic

$$\chi^2 = \sum_{i=1}^{N} \left[c_i - \sum_{j=1}^{M} R_{ij} \widehat{\phi}_j \right]^2, \tag{18.17}$$

where the variances are neglected in this brief discussion. In many regularization schemes $\mathcal{A}$ is taken as χ^2. For the Bonner sphere problem (and many other inverse problems) $M \gg N$ (more unknowns than equations) there are an infinity of solutions some of which make χ^2 very small, if not zero. However, such solutions almost always oscillate widely and otherwise are physically unrealistic (negative or complex values of $\widehat{\phi}$). To

obtain realistic solutions, some additional information or constraints on ϕ (contained in the functional $\mathcal{B}$) are specified.

Thus, the goal is to minimize $\mathcal{A}[\boldsymbol{\phi}]$ subject to the constraint that $\mathcal{B}[\boldsymbol{\phi}] = b$. The method of Lagrange multipliers allows this type of minimization problem to be solved by introducing a multiplier μ. The Lagrange functional to be minimized is given by

$$\mathcal{L} = \mathcal{A}[\boldsymbol{\phi}] + \mu_1(\mathcal{B}[\boldsymbol{\phi}] - b), \tag{18.18}$$

The minimum of Eq. (18.18) is found by setting its first derivative with respect to $\boldsymbol{\phi}$ equal to zero,

$$\frac{\partial}{\partial \boldsymbol{\phi}}\{\mathcal{A}[\boldsymbol{\phi}] + \mu_1(\mathcal{B}[\boldsymbol{\phi}] - b)\} = \frac{\partial}{\partial \boldsymbol{\phi}}(\mathcal{A}[\boldsymbol{\phi}] + \mu_1\mathcal{B}[\boldsymbol{\phi}]) = 0. \tag{18.19}$$

Alternately, $\mathcal{B}[\boldsymbol{\phi}]$ can be minimized subject to the constraint that $\mathcal{A}[\boldsymbol{\phi}] = a$ using Lagrange multiplier μ_2.

$$\frac{\partial}{\partial \boldsymbol{\phi}}\{\mathcal{B}[\boldsymbol{\phi}] + \mu_2(\mathcal{A}[\boldsymbol{\phi}] - a)\} = \frac{\partial}{\partial \boldsymbol{\phi}}(\mathcal{B}[\boldsymbol{\phi}] + \mu_2\mathcal{A}[\boldsymbol{\phi}]) = 0. \tag{18.20}$$

In either case, the inverse problem is changed to

$$\text{minimize} \quad \mathcal{A} + \mu\mathcal{B}. \tag{18.21}$$

As $\mu = \mu_1 = 1/\mu_2$ varies between 0 and ∞, the solution $\boldsymbol{\phi}(\mu)$ varies along a trade-off curve between minimizing $\mathcal{A}$ (small μ) and minimizing $\mathcal{B}$ (large μ). Thus any solution along this trade-off curve can be interpreted as (1) minimizing $\mathcal{A}$ subject to constraint $\mathcal{B} = b$, (2) minimizing $\mathcal{B}$ subject to constraint $\mathcal{A} = a$, or (3) minimizing the sum $\mathcal{A} + \mu\mathcal{B}$.

A benefit of this minimization scheme is that a unique solution $\boldsymbol{\phi}$ can be obtained even where $\mathcal{A}[\boldsymbol{\phi}]$ is degenerate. The general theory and several methods for regularizing underdetermined problems are given by Press et al. [1992]. Application of this method to unfolding Bonner sphere data is given by Ryan [1998] who used the Backus-Gilbert approach in which $\mathcal{A}$ and $\mathcal{B}$ are chosen so as to maximize the stability of the solution $\widehat{\phi}$. Reginatto et al. [2002] used the maximum entropy method in which $\mathcal{B}$ is taken as the negative of the entropy, or negentropy, and the inverse problem becomes

$$\text{minimize} \quad \chi^2(\widehat{\boldsymbol{\phi}}) + \mu \sum_{j=1}^{M} \widehat{\phi}_j \ln(\widehat{\phi}_j). \tag{18.22}$$

18.2.2 REM Counters

The REM counter is a special Bonner sphere that is 10 inches (25.4 cm) in diameter, and is a common device used to measure neutron dose equivalent H. The detector used with many commercial units is a ^{3}He detector embedded in the ball, the entire detector/sphere combination attached to a handheld survey unit. The reason for the chosen 10-inch diameter is that the detector response is close to that for an average human dose equivalent [Hankins 1962; Bramblett et al. 1960].

Hankins [1962, 1965] compares the calculated response of a 10-inch Bonner sphere with a central ^{6}LiF:Eu detector with the inverse radiation protection guide (RPG) response.[3] This comparison is shown in Fig. 18.3.

[3] This quantity is more frequently called the fluence-to-dose conversion factor or dose response function. It is the dose rate per unit neutron flux in units of dose per neutron.

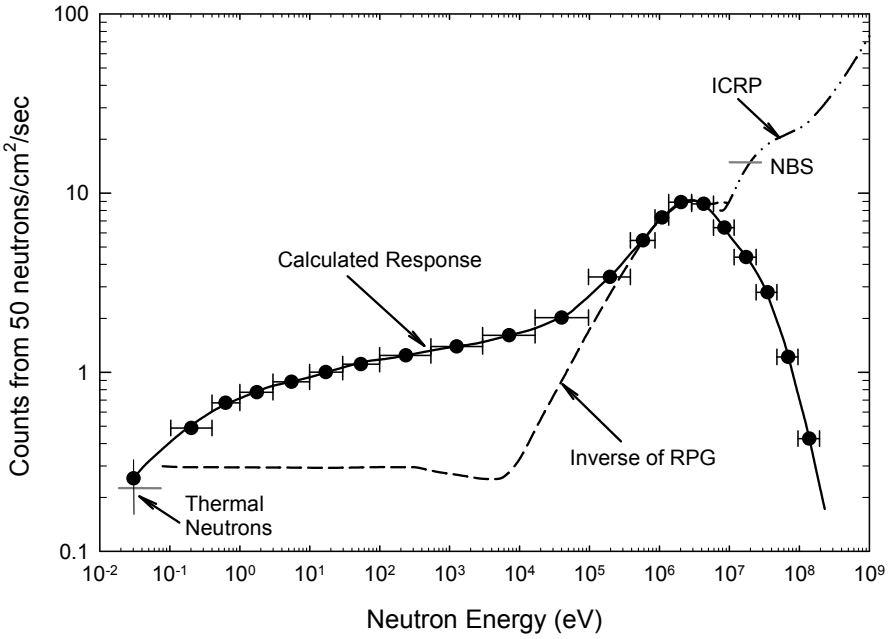

Figure 18.3. Calculated responses from a 10-inch Bonner sphere rem counter compared to (the then) recommended inverse RPG curve. Data are from Hankins [1965]. Also shown are results from the International Commission on Radiological Protection (ICRP) and the National Bureau of Standards (NBS) which is now the National Institute of Standards and Technology (NIST).

At energies below 200 keV, the instrument overestimates the neutron dose by as much as a factor of 5 for some energies. At energies above 7 MeV, the instrument severely underestimates the neutron dose. For these reasons, Hankins [1965] recommends that neutron dosimetry with the basic 10-inch Bonner sphere be restricted to the 200 keV to 7 MeV range. However, modifications to the rem counter design permits the use of smaller diameter spheres, usually ranging between 7 inches and 9 inches, to obtain results that adequately match the inverse RPG curve for energies between thermal and 7 MeV.

A cylindrical neutron dosimeter instrument based on the same concept as the Bonner sphere was introduced by Andersson and Braun [1964]. The detector is designed with $^{10}BF_3$ gas-filled detector with a diameter of about 30 mm and an active length of 60 mm placed inside cylinders of polyethylene. There is an inner annulus of polyethylene with a 0.63 inch (16 mm) wall thickness encapsulated by a perforated 5-mm-thick blanket of boron-loaded polyethylene. Surrounding the entire configuration is another annulus of polyethylene with a 2.56 inch (65 mm) wall thickness and length of 9.6 inches (244 mm). Lastly, a 43-mm-thick plug of polyethylene is placed inside the outer annulus in front of the $^{10}BF_3$ detector. The detector design has several basic features in common with the first long counter designs (discussed in the next section).

Although the response to neutrons above 7 MeV is similar to that determined by Hankins [1965] for the 10-inch Bonner sphere, the energy region below 200 keV gives a better fit to the RPG curve. However, this response improvement comes at the expense of a heavier instrument, reportedly 8.5 kg. These types of detectors are commercially available, which still use the basic cylindrical design and gas-filled neutron detector.[4] In some cases, the $^{10}BF_3$ detector has been replaced with a ^{3}He detector. Modern designs have

[4]The Canberra SNOOPY and the Thermo-Fisher Wendi-2 (see Fig. 18.4) are based on the Andersson-Braun design.

replaced the boron loaded polyethylene with a boron doped synthetic rubber layer. The introduction of heavy elements sheets into the Andersson-Braun design have extended the useful energy range of the instrument. Mares et al. [2002] report a variation that includes a lead layer encapsulating a perforated boron doped rubber layer, both surrounding the polyethylene encapsulated $^{10}BF_3$ detector, a change that extends the neutron detection range beyond 1 GeV. This increase in response is due to (n,xn) fast reactions in the lead.

Leake [1966] modified the Andersson-Braun design to improve the detector response with respect to the RPG curve while reducing the weight of the instrument. The first such modification was styled much like the Hankins [1962] device, but included concentric spheres around the $^{10}BF_3$ detector. A smaller Cd-covered polyethylene sphere encapsulated the detector, while a larger 8.2 inch diameter polyethylene concentric ball surrounded the device. The Cd covered ball suppressed the over-response of neutrons in the low energy region (below 0.5 eV) while reducing the overall weight by eliminating boron-loaded polyethylene sections. Overall, the device response is similar to the inverse RPG curve and weighs only 5 kg.

Another improvement reported by Leake [1968] was to replace the $^{10}BF_3$ detector with a spherical ^{3}He detector. The change reduced background gamma-ray counts while improving the efficiency, and the entire device weighed approximately 6.6 kg. This *Leake detector*, as it became known, was for many years a standard commercially available instrument.[5] Because of changes made by the International Commission on Radiological Protection (ICRP) in their fluence-to-dose conversion factors, minor alterations in the Leake design have been implemented over the years [Leake 1999; 2004] to remain in compliance. These commercial units are usually designed to follow the inverse RPG curve from thermal neutron energies up to 7 MeV. They also detect neutrons up to 10 MeV, although the results are not dose equivalent. Additional modifications have been explored to increase the detection range of neutron energies. For instance, Hsu et al. [1994] report the responses of a lead shell surrounding the detector, within various polyethylene ball sizes, yielding up to

[5]For instance, Ludlum Measurements, Inc., produces a wide variety of Leake-style handheld units (see Fig. 18.5).

a 5 times increase in sensitivity to 800 MeV neutrons. The use of Cu, Pb, and W to extend the neutron energy range was also explored by Burgett et al. [2009].

18.2.3 Long Counter

Early measurements of the number of neutrons emitted from fast sources were performed by Amaldi and Fermi [1936] and Amaldi et al. [1937] by immersing a neutron source in a water bath and measuring the thermal-neutron signal at various locations in the bath. The technique was later adopted by O'Neal [1946] to measure the neutron energy spectra of different photo-neutron sources. The radiation detector used in the former (Amaldi et al. 1937) case was an ion chamber, while activation foils were used in the latter (O'Neal) case. Although the methods proved useful, the inconvenience of the water bath and the time consuming approaches led Hanson and McKibben [1947] to seek a practical and portable solution, called the long counter.

The first long counter was based on the concept introduced by Amaldi and Fermi [1946], but replaced the water bath with paraffin and the detector with a $^{10}BF_3$ gas-filled proportional counter. The original device had a 1-inch diameter $^{10}BF_3$ detector, with a sensitive length of 8 inches, centrally inserted into a 12-inch long cylinder of paraffin. Slow neutrons could enter the detector front (one end of the $^{10}BF_3$ tube) or the adjacent paraffin. The escape probability for slow neutrons from the paraffin is high near the front of the device but decreases for higher energy neutrons that penetrate further into the paraffin cylinder. Overall, the probability of a neutron being moderated and absorbed somewhere along the length of the $^{10}BF_3$ detector is nearly independent of the neutron energy so a flat energy response is achieved. Through experimentation, it was determined that an 8-inch-diameter paraffin cylinder produced the most uniform counting response from a wide spectrum of neutron energies.

The design was modified to exclude neutrons scattered in air surrounding the device by including a shield surrounding the inner portion. The shield consisted of a B_2O_3 blanket and another thick encapsulating blanket of paraffin, as shown in Fig. 18.6. Holes were drilled into the inner paraffin cylinder to assist with the detection of the lower energy fast and epithermal neutrons. Further, the $^{10}BF_3$ detector active length was 10.5 inches. The basic design of the shielded long counter, as developed by Hanson and McKibben [1947], is still used today, although there have been modifications and improvements over the years [Allen 1960; De Pangher and Nichols 1966; East and Walton 1969].

McTaggart's device [see Allen 1960] implemented a few design modifications to optimize the long counter response. The holes were drilled deeper to a length of 6 inches. McTaggart's experiments demonstrated that the flatness of the long counter response would deteriorate if the detector was pushed from its flush position further into the paraffin moderator (see Fig. 18.7). Hence, the $^{10}BF_3$ detector was inserted such that the front end was flush with the paraffin moderator. Also, a 1.5-inch-long boron sleeve was placed over the $^{10}BF_3$ detector with the front edge 3 inches from the paraffin front face. Finally, the inner moderator length was extended to 14 inches, while the outer moderator length was extended to 20 inches. These changes produced a flat response within 5% for neutrons with energies of 25 keV to 5 MeV. The optimized shielded long counter of McTaggart has become known as the *standard long counter*.

Other changes, such as those described by De Pangher and Nichols [1966] rendered additional improvements. A reported problem with the standard long counter was the response reproducibility between different counters [Tagziria and Thomas 2000]. De Pangher and Nichols [1966] sought to remedy this problem with many changes to the standard long counter design aimed at regularizing the components. The paraffin was replaced with high density polyethylene (HDPE), the B_2O_3 glass thermal neutron shield was replaced with boron-loaded polyethylene, and the outermost housing was fabricated from aluminum. The 1-inch diameter holes were replaced with an annular trench and thicker Cd shields were positioned on both ends of the device. According to Marshall [1970], the De Pangher design, also called the *precision long counter*, rendered reproducible results superior to the standard long counter. Harvey et al. [1976] report that the precision

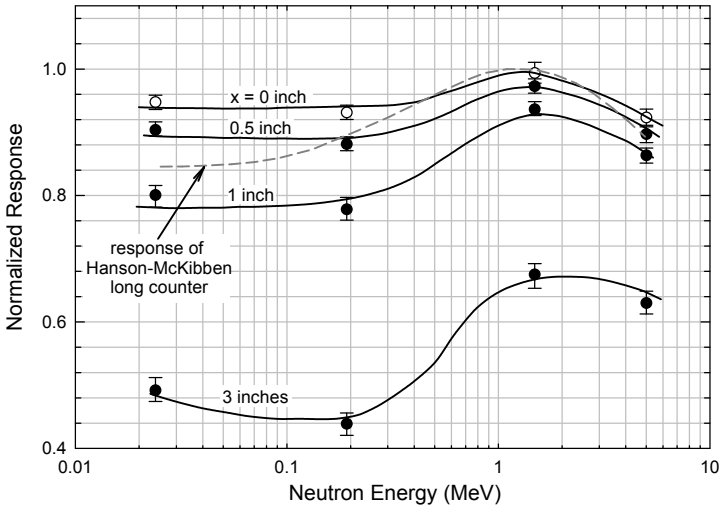

Figure 18.7. The response of McTaggart's long counter as a function of the axial location of the $^{10}BF_3$ detector end (as x) from the paraffin face. Also shown is a comparison between the optimized McTaggart detector (x = 0 inch) and the original Hanson-McKibben detector. Data are combined from Allen [1960].

long counter response was relatively independent of neutron energy. Various researchers have calibrated both the standard long counter and the precision long counter [Slaughter and Rueppel 1977; Hunt and Mercer 1978; Tagziria and Thomas 2000], and found that both long counter designs perform well for neutrons with energies up to about 10 MeV.

Another design called the *modified long counter* and reported by East and Walton [1969] replaced the $^{10}BF_3$ detector with five ^{3}He gas-filled proportional counters in an attempt to increase the overall neutron detection efficiency. This detector has the usual cylindrical shape, but has incorporated many changes to

the moderator. The inner moderator is HDPE with a diameter of 9 inches, while the outer moderator is boron-loaded paraffin. Instead of 8 holes drilled into the inner moderator, there are 12 holes, each 1-inch in diameter and 3.5 inches deep in the HDPE. Although the hole pattern is symmetric, they are no longer on a single radial axis, but rather staggered around a radius of approximately 3.5 inches. Another torus of HDPE, approximately 0.75 inch thick, covers most of the hole openings on the device. The resulting device did show improved detection efficiency with a near constant value of $11.5 \pm 0.5\%$ for neutron energies between 25 keV and 4 MeV. However, because the Q value of the ^{3}He(n,p)^{3}H is much lower than the Q value of the ^{10}B(n,α)^{7}Li reaction, the authors report that background gamma-ray interference is worse than with a standard long counter, and recommend the standard long counter for neutron measurements in a high gamma-ray field.

18.2.4 Directional Neutron Spectrometer

First introduced by Oakes et al. [2010], and Cooper et al. [2011; 2012], the directional neutron spectrometer is a relatively new device that uses the fundamental concept of the Bonner sphere. However, instead of having to change several spheres, one for each measurement, the unit has numerous slices of moderators arranged as a cylinder. Between each moderator slice is an array of compact thermal-neutron detectors, usually of the MSND variety (see Sec. 17.5). A single spectral measurement is performed with all detectors in place, and does not require the removal or replacement of moderators [Oakes et al. 2013]. The output data is processed and template-matched to the most probable neutron source from a library containing hundreds of environment conditions and neutron source spectra. A depiction of the first prototype detector arrangement is shown in Fig. 18.8.

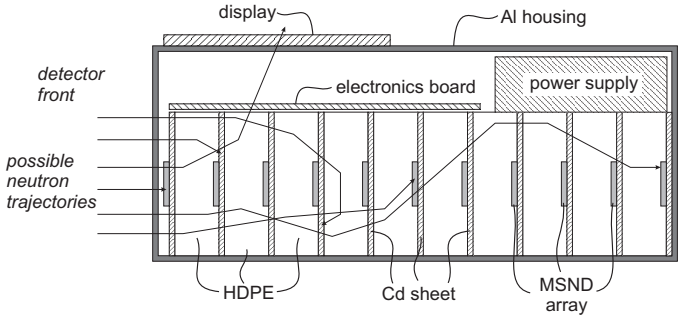

Figure 18.8. The basic arrangement of a sectioned neutron spectrometer from Cooper et al. [2011, 2012].

The initial sectioned neutron spectrometers had up to 20 HDPE layers with a fourplex array of dual-stacked MSNDs between each layer, and a bare MSND array at the front of the stack [Cooper et al. 2011]. In later experimental versions, the small fourplex array was increased to as many as 108 detectors per layer with 30 moderator layers to give a total of 3240 detector channels [Hoshor et al. 2015]. With a mass of nearly 50 pounds (22.7 kg), this large device pushed the limits of portability. Commercial models are considerably lower in weight and have approximately 16 MSNDs per layer. The total number of detectors varies with the number of moderator slices, usually between 7 to 12 slices per unit. The response of an eight-layer device to an AmBe and ^{252}Cf source is shown in Fig. 18.9. Commercial handheld devices range in weight from approximately 8 pounds (3.62 kg) to 20 pounds (9.1 kg). The detector can rapidly identify the neutron spectrum from numerous fast neutron sources under a variety of environmental circumstances [Hoshor et al. 2015; 2017].

This neutron spectrometer also doubles as an imaging device, capable of locating the general direction(s) of the fast neutron source(s). Although the direction finding algorithm can be complicated, it fundamentally operates by tallying counts from the MSNDs in the total array and identifying an imaginary vector drawn from the lowest average count rate per device to the highest average count rate per device. The vector is used to point towards the most probable source location and is usually accurate to within a few degrees.

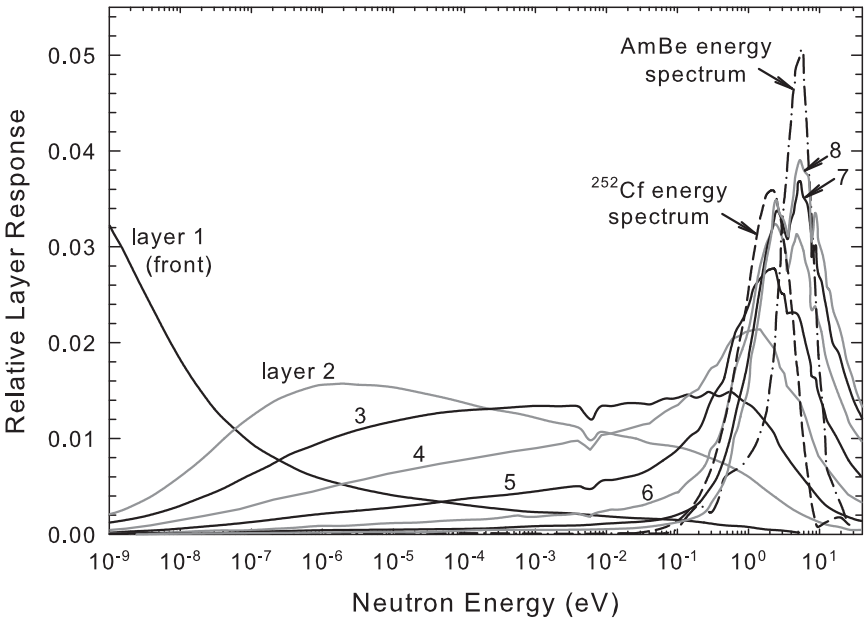

Figure 18.9. Calculated relative response functions for an eight-layer sectioned neutron spectrometer. Also shown for comparison are energy spectra from ^{252}Cf and AmBe neutron sources. Data from Hoshor et al. [2015].

18.2.5 Other Moderated Detectors

There are other types of detectors that take advantage of the moderation detection method. In fact, practically any thermal-neutron detector can be inserted into a moderator material, usually HDPE, to improve overall sensitivity to fast neutrons. The gas-based neutron detectors described in Chapter 17 are commonly inserted into HDPE blocks to improve fast neutron responses. Along with the gas-filled devices already described in this chapter, other examples include moderated ^{3}He detectors reported by Kamboj et al. [1978], and moderated $^{10}BF_3$ detectors reported by Barrett et al. [1969] and Sekharan et al. [1976]. The system reported by Kamboj et al. [1978] has several ^{3}He detectors in a layered block of polyethylene with the goal of producing another neutron source calibration device similar to the long counter. They report a linear neutron energy response between 2.1 and 4.5 MeV. The system described by Barret et al. [1969] has numerous BF_3 detectors embedded in a large single block of paraffin all positioned radially about a neutron source. The method is based on the analysis by Thies [1963] and provides a relatively flat response for neutron energies ranging from 30 keV to 5 MeV. A similar 4π system reported by Sekharan et al. [1976] was designed to measure the cross sections for various neutron producing reactions. The performance of moderated ^{6}Li-foil detectors were described by Nelson et al. [2014; 2015]. High densities of MSNDs have been inserted into moderators with reportedly similar performance as high-pressure ^{3}He gas-filled detectors [Ochs et al. 2017].

18.3 Detectors Based on Recoil Scattering

Detectors based on recoil scattering rely on the recoil atoms transferring energy to a detection device. For gas detectors, the recoil ion generates electron-ion pairs that can be measured as the output. Scintillators generally rely either on scattered recoil ions that are a part of the scintillator to fluoresce the scintillator, such as an organic scintillator, or rely on recoil products entering and fluorescing an adjacent scintillator,

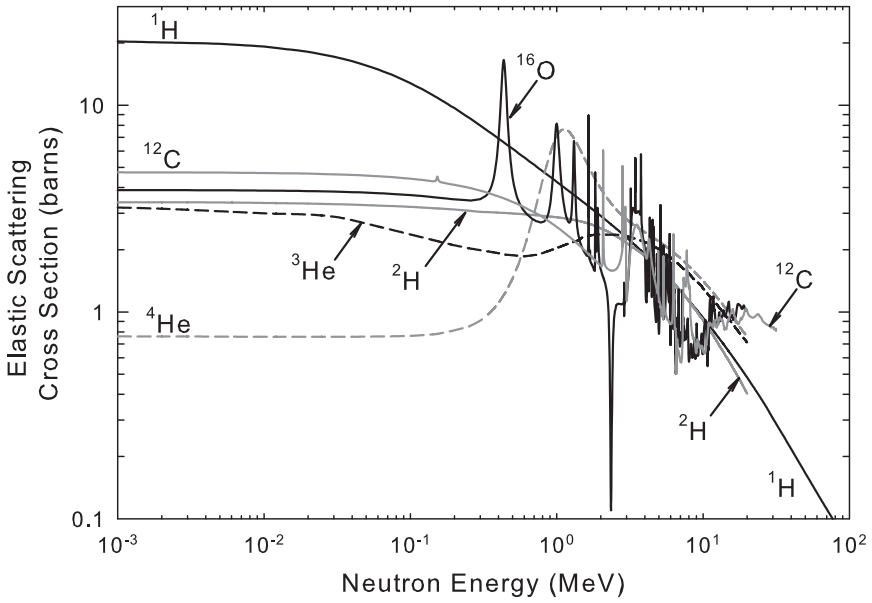

Figure 18.10. Elastic scattering cross sections for many materials used for recoil detectors. Data are from [ENDFPLOT 2017].

such as a ZnS:Eu scintillator. Semiconductors can also be used, whose constituent elements in the material recoil and produce electron-hole pairs. From Eq. (18.4), it becomes clear that more energy is transferred per scatter from low A recoil materials than from high A materials. Consequently, most detectors based on recoil ion scatter are manufactured from the lighter elements. The neutron elastic scattering cross sections for several isotopes used for recoil detectors are shown in Fig. 18.10.

Differential Scattering Cross Sections

The differential scattering cross section quantifies how likely a neutron is to scatter into some new direction from its initial direction. With this information the energy and angular distribution of a recoil nucleus can be determined. This topic is explored in this section.

Of course all scattering cross section measurements are performed in the laboratory coordinate system but, primarily for historical reasons, scattering information was often converted to the center of mass system, fitted to a sum of Legendre polynomials, and the resulting expansion coefficients were then archived in the early cross section libraries. To use such data, the results, upon extraction, had to be reconverted to the laboratory system. This cumbersome approach was used because generally much less scattering data needed to be saved. For low energy neutron scattering in which a compound nucleus is formed, which is at rest in the center of mass system, the subsequent neutron decay occurs isotropically because information about the incident neutron direction is "forgotten" during the relatively long lifetime of the compound nucleus. Thus, the differential scattering cross section would appear almost constant in the center of mass system and only one Legendre coefficient had to be saved.

Today, computer memory and data storage is much less expensive and data from scattering in the laboratory system can readily be archived. The many cross section libraries available from nuclear institutions around the world, now generally have a mixture of scattering data in the two coordinate systems and one must be careful in the use of retrieved scattering data as to which coordinate system was used for the data.

The conversion of the differential scattering cross section from the laboratory system into the center of mass system is found from Eq. (18.5) as

$$\frac{d\sigma_s(E,\omega_c)}{d\Omega_c} = \frac{d\sigma_c(E,\omega_s)}{d\Omega_s}\frac{d\omega_s}{d\omega_c}, \tag{18.23}$$

where $\omega_s = \cos(\theta_s)$ and $\omega_c = \cos(\theta_c)$. Differentiation of Eq. (18.1) with respect to ω_c and substitution of the result into Eq. (18.23) gives

$$\frac{d\sigma_c(E,\omega_c)}{d\Omega_c} = \frac{d\sigma_s(E,\omega_s)}{d\Omega_s}\frac{A^2[A+\cos(\theta_c)]}{[1+2A\cos(\theta_c)+A^2]^{3/2}}. \tag{18.24}$$

Energy Distribution of the Recoil Nucleus

The probability that a neutron of initial energy E transfers energy into dT about T to the scattering nucleus is

$$P(E,T)\,dT = \frac{1}{\sigma_s(E)}\frac{d\sigma_s(E,T)}{dT}\,dT, \tag{18.25}$$

which, from Eq. (18.5), can be written as

$$P(E,T)\,dT = \frac{1}{\sigma_s(E)}\frac{d\sigma_s(E,\omega_c)}{d\Omega_c}\left(-\frac{2\pi d\omega_c}{dT}\right)dT. \tag{18.26}$$

Differentiation of Eq. (18.4) with respect to ω_c gives

$$\frac{d\omega_c}{dT} = -\frac{(1+A)^2}{2AE} = -\frac{2}{(1-\alpha)E}, \tag{18.27}$$

where $\alpha = (A-1)^2/(A+1)^2$. Substitution of this result into Eq. (18.26) gives the energy distribution of the recoil nucleus

$$P(E,T) = \frac{1}{\sigma_s(E)}\frac{d\sigma_s(E,\omega_c)}{d\Omega_c}\frac{4\pi}{(1-\alpha)E}, \qquad 0 \le T \le (1-\alpha)E. \tag{18.28}$$

Thus the ideal pulse height spectrum from a single scatter is proportional to the differential scattering cross section in the center of mass coordinate system.

Example 18.2: In some cases scattering in the center of mass system is isotropic, i.e., $d\sigma_s(E,\omega_c(E,T))/d\Omega_c$ is simply $\sigma_s(E)/(4\pi)$. For this case, derive an expression for $d\sigma_s(E,T)/dT$.

Solution:

From Eq. (18.2) one finds

$$\frac{d\omega_c}{dT} = \frac{-2}{(1-\alpha)E}$$

so that, from Eq. (18.5),

$$\frac{d\sigma_s(E,T)}{dT} = -\frac{d\sigma_s(E,\omega_c)}{d\Omega_c}\frac{4\pi}{(1-\alpha)E},$$

which upon substitution of $d\sigma_s(E,\omega_c(E,T))/d\Omega_c \simeq \sigma_s(E)/(4\pi)$, gives the desired result

$$\frac{d\sigma_s(E,T)}{dT} \simeq \frac{\sigma_s(E)}{(1-\alpha)E}.$$

18.3.1 Gas Detectors Based on Recoil Scattering

The most popular backfill gases are low mass gases, usually ^{1}H, ^{3}He, ^{4}He, and CH_4. The reaction cross sections for these gases are shown in Fig. 18.11. Except for ^{3}He detectors, detectors filled with these gases all respond in similar manners. All gas-based recoil detectors function with a gas composed, at least in part, of a low Z material. The usual candidates include pure hydrogen, CH_4, and helium, although other hydrogenous gases can work. Energetic neutrons scatter from the detector gas and transfer some kinetic energy to the recoiling atom, as described by Eq. (18.4).[6] Typically these detectors are designed as a type of proportional counter, although gridded ion chambers can also work. Gas recoil detectors can in principle detect relatively low energy scatters, yet the practical lower energy threshold is near 20 keV [Ferguson 1960]. The detector cavity should be of adequate dimensions beyond the expected range of the recoiling ions in order to reduce wall effect distortions in the pulse height spectrum. The ion ranges can be reduced by increasing the gas pressure; however, as reported in Chapter 10, increasing the gas pressure reduced the charge carrier velocity and can reduce the response proportionality. At operating pressures up to 20 atm, these detectors can respond to neutron energies up to 20 MeV.

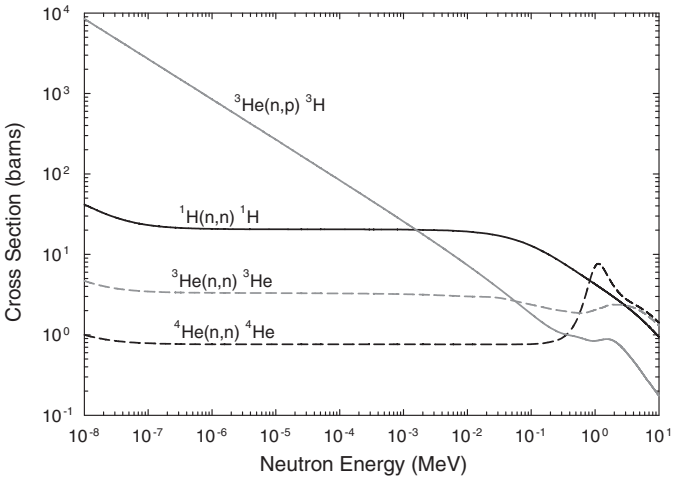

Figure 18.11. Neutron reaction cross sections for ^{1}H, ^{3}He, and ^{4}He. Data are from [ENDF VIII 2018].

The possibility of carbon scattering is high in a CH_4 chamber, and the differential scatter cross section for carbon is not at all uniform. Also, the maximum energy transfer for carbon is only 28%, significantly less than proton recoil contributions. Further, the pulse height spectrum of the recoil energy becomes even more complicated when the proton recoil wall effect is included. Detectors based on the use of ^{4}He are a commercial alternative. These detectors do not have the complications of multiple nuclides, but the differential scattering cross section is not isotropic. Hence, the pulse height spectrum is not a simple step function, although the endpoint energies for monoenergetic neutrons should be near 64% of the initial neutron energy (see Example 18.1).

Typical commercial units are pressurized between 0.526 atm (400 torr) up to 10 atm (7600 torr). Advantages of the high pressure tubes include increased detection efficiency and extended energy range. However, the operating voltage must also be increased, usually to several thousand volts. Further, the gamma-ray background is higher for the pressured recoil detectors. Detectors with lower pressures respond faster to neutrons, require much lower operating voltages (often less than 1000 volts), and suffer less background contamination. However, the recoil particle ranges are longer such that the recoil range increases approximately inversely proportional to the gas pressure. Because of the importance of hydrogen as a moderator and a source of recoil ions, these detectors are considered first.

[6] The recoil atom may be an ion having lost one or more shake-off electrons. As the speed of the recoil atom increases above the speed of K-shell electrons, it becomes increasingly likely the recoil atom has shed one or more electrons.

Proton Recoil Detectors with Hydrogen

Neutron scattering from hydrogen is nearly isotropic in the center-of-mass coordinate system. Hence, the differential scattering cross section $d\sigma_s^H(E,\omega_c)/d\Omega_c$ for hydrogen can be well approximately as $\sigma_s^H(E)/(4\pi)$ for neutron energies well beyond 20 MeV. From Eq. (18.28) with $\alpha = 0$ for H, the ideal recoil energy distribution $P(E,T)$ is a constant or step function ranging from $T = 0$ to $T = E$, the incident neutron energy.

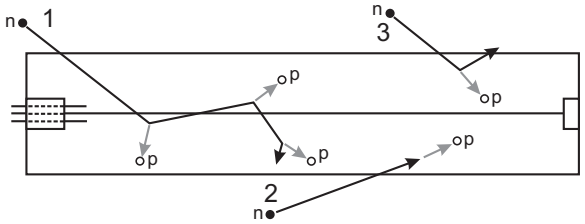

Figure 18.12. Three possible ways in which neutrons can interact in a $^1H_2$ gas detector.

To preserve energy information, these detectors are generally fashioned as cylindrical proportional counters. The interaction efficiency for a given neutron energy can be estimated by a simple exponential approximation,

$$\epsilon(E) = 1 - \exp[-N_H \sigma_s^H(E)], \tag{18.29}$$

where N_H is the atomic density of hydrogen in the detector, σ_s^H is the elastic scatter cross section of hydrogen, and w is the detector effective width. Three possible neutron trajectories are depicted in Fig. 18.12. For trajectory 1, multiple scatters cause the neutron to pass nearly all of its energy to hydrogen in the detector. For trajectory 2, the neutron escapes the detector after leaving partial energy behind. Finally, in trajectory 3, the neutron imparts all of its energy to a proton in a single scatter. Because the range of energetic protons in hydrogen gas is relatively long, the recoil protons often strike the wall or enter the dead regions of the counter (see end effect in Sec. 17.3.1) so as to produce a type of wall effect. These effects distort the pulse height spectrum from the expected step function. Although hydrogen seems to be an obvious choice for a recoil detector gas, it is usually not used in spectroscopic applications because of the wall-effect distortions.

Several types of gas-filled recoil detectors use high purity hydrogen gas, which would be an obvious choice considering the previously reviewed kinematics for scattering from ^{1}H. Shown in Fig. 18.13 are the differential elastic scattering cross sections in the laboratory system for different incident neutron energies on ^{1}H. The results of combining the differential scattering cross section for hydrogen in Fig. 18.13 at a few select energies with the conversion of Eq. (18.24) are shown in Fig. 18.14. Note that when $A = 1$ that Eq. (18.2) reduces simply to $\theta_c = 2\theta_s$. It is seen that the differential elastic scattering cross section for hydrogen is remarkably constant (isotropic) at all scatter angles in the center of mass system, i.e., $d\sigma_s(E_c,\omega_c)/d\Omega_c = \sigma_s(E)/4\pi$.

With A equal 1 and isotropic center-of-mass scattering, Eq. (18.28) reduces to $P(E,T) = 1/E$, $0 \le T \le E$ so the expected pulse height spectrum from hydrogen scattering is simply a rectangular step function terminating at $T = E$, the energy of the incident neutron. There are a few notable points when dealing with ^{1}H as the scattering medium. First, the neutron scatter angle in the laboratory system is restricted between angles $\pi/2 \le \theta_s \le 0$, i.e., there is no neutron backscatter. Second, the neutron can transfer its entire energy to the recoil proton. Third, the probability of scattering through any angle between $\pi \le \theta_c \le 0$ in the center-of-mass system is practically constant.

Although it would seem that ^{1}H is the ideal gas for a recoil spectrometer, there are some problems with the use of ^{1}H as the recoil gas. The range of the recoil proton can be significant in hydrogen gas, approximately 163 ± 2.13 mm for a 2 MeV proton in 2 atm of $^1H_2$ gas. Even if the detector is oriented longitudinally to the fast neutron source, there is still a significant probability that the recoil proton collides with the chamber wall before expending all of its energy, thus producing a wall effect (see Section 17.3.1). The wall effect can be reduced by increasing the gas pressure, but this remedy comes at the expense of longer response time and increased gamma-ray background. Recall from Chapter 10 that gamma-rays primarily interact in the detector shell and not directly in the gas. Hence, the energy deposited by photoelectrons or Compton electrons entering the gas increases approximately linearly with gas pressure. Consequently, the LLD must be increased as the pressure is increased and, hence, reduces the epithermal neutron response

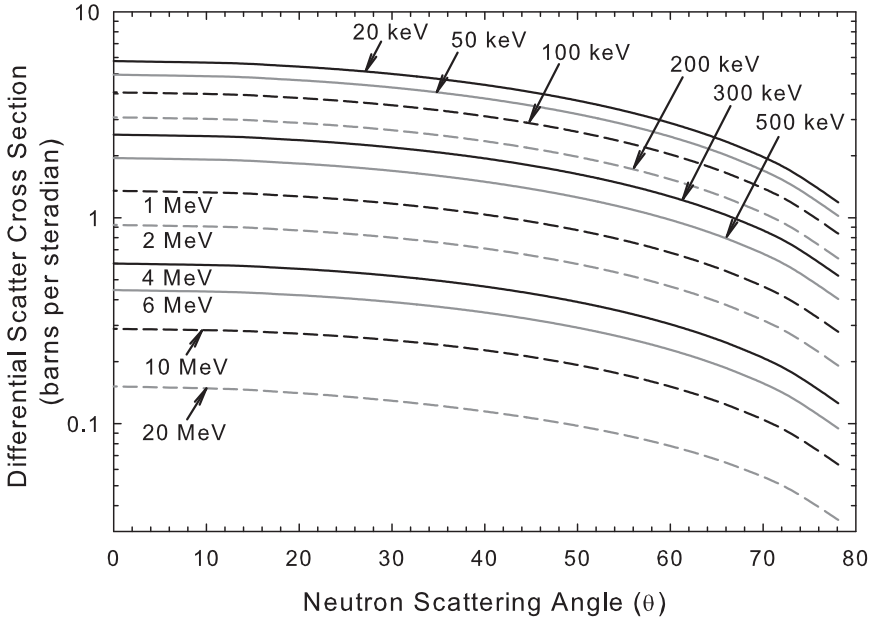

Figure 18.13. The laboratory system ^{1}H differential scattering cross sections in barns per steradian ($d\sigma/d\Omega$) for several incident neutron energies. Data are from [ENDF VIII 2018].

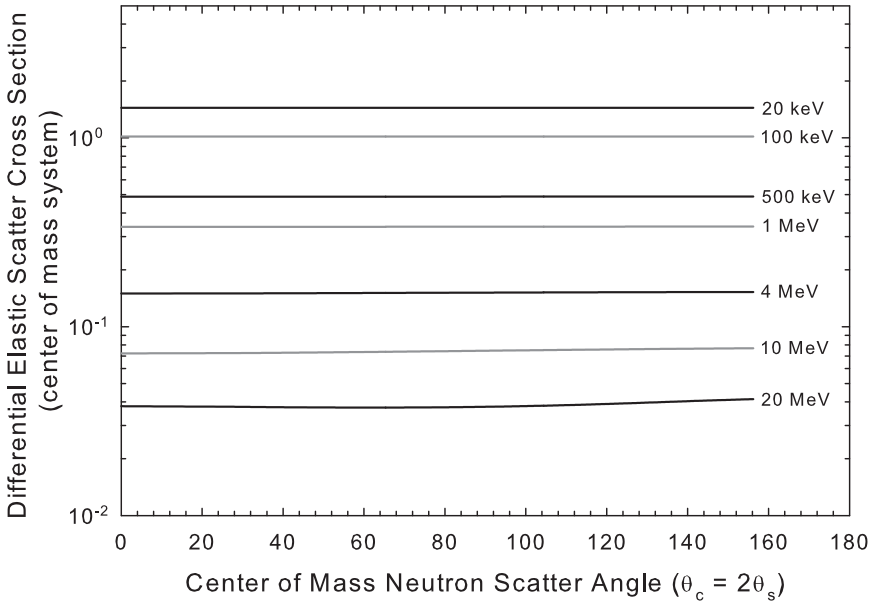

Figure 18.14. The center-of-mass system ^{1}H differential scattering cross sections converted from data of Fig. 18.13 with Eq. (18.24). That the resulting plots are lines parallel to the abscissa is confirmation that scattering is isotropic in the center-of-mass system.

of the detector. Further, the total interaction cross section is relatively constant over a large energy range from 0.1 eV up to approximately 10 keV (see Fig. 18.10). Beyond 10 keV, the elastic scattering cross section decreases, dropping from 18 barns at 20 keV eventually to 0.48 barn at 20 MeV. To counter this reduction in the microscopic cross section at fast neutron energies, the pressure in the detector container may be increased; however, the interaction efficiency for gamma-rays increases as well. Many of these effects are discussed in detail in the literature [Snidow and Warren 1967; Gold and Bennett 1968; Benjamin et al. 1968; Weise et al. 1991].

Proton Recoil Detectors with Non-Hydrogen Gases

There are other gases of interest for proton recoil detectors, mainly CH_4 and ^{4}He. Note that ^{3}He gas can also be used, but because it also has a considerable neutron absorption reaction cross section, is covered in a latter section. To overcome the range problem, in part, methane can be used instead of pure hydrogen [Fink et al. 1980], or at least a partial pressure of methane can be added to the detector chamber [Bennett 1962]. Consequently, the recoil proton range is reduced and allows the detector to respond to higher energy neutrons. For instance, the range of a 2-MeV recoil proton in 2 atm of methane is 39.7 ± .6 mm, less than a quarter of that in 2 atm of $^1H_2$. Benjamin et al. [1968] describe a spherical proportional counter backfilled with P-10 gas that has reduced wall and end effects. However, neutron scattering from carbon, which transfers at most only 28% of its energy per scatter, distorts the pulse height spectrum [Bennett 1962]. Although the carbon may leave some residual energy in the gas that appears in the low energy region of the spectrum, it is the energy reduction of the scattered neutron that distorts the high energy cutoff. The scattered neutron may subsequently interact with a hydrogen atom, and, because of its reduced energy, produces recoil protons also of reduced energy, thereby shifting the spectrum to lower energies.

The use of ^{4}He as a proportional gas in neutron spectrometers was suggested many decades ago, perhaps initially by Baldinger et al. [1938]. The use of ^{4}He gas is attractive because the range of an energetic ^{4}He ion is significantly lower to that of a proton of equal energy. The effect is enhanced because a ^{4}He recoil ion can carry at most only 64% of the initial fast neutron energy, and the proportional gas (^{4}He) has a higher stopping power than H_2 gas. From Eq. (18.4), the maximum scatter energy of a ^{4}He recoil ion from a 2 MeV neutron is found to be 1.28 MeV, and the range of this recoil ion in 2 atm of He is 17.5 ± 0.37 mm, over 9 times less than in 2 atm of $^1H_2$ gas. Further, the total microscopic elastic scatter cross section for ^{4}He surpasses that of ^{1}H at approximately 800 keV. Hence, the interaction efficiency is higher in a ^{4}He proportional counter than in a $^1H_2$ counter with an equal atomic density. For neutron energies up to 15 MeV, it is necessary to increase the stopping power of recoil protons by adding another noble gas. Because Xe and Kr are more susceptible to gas impurities, and there is a natural radioactive isotope ^{85}Kr that can add to the background, a common choice is to use a large percentage of Ar. Birch [1988] reports on a 40% Ar/60% ^{4}He mixture for the measurement of 15 MeV neutrons.

Unlike ^{1}H, the differential cross section for ^{4}He is not uniform at all center-of-mass scattering angles.[7] Consequently, the pulse height spectrum becomes somewhat complicated. The lab system and center-of-mass system differential cross sections for ^{4}He are shown in Figs. 18.15 and 18.16, respectively. The results of using the data of Fig. 18.16 combined with Eqs. (18.4) and (18.28) are shown in Figs. 18.17 and 18.18, which show the idealized features expected from ^{4}He proportional gas detector. The pulse height spectral distortions imposed by variations in charge carrier collections times, wall effect, and detector dimensions have been modeled by various research groups [for example Atwater 1972; McDaniel and Hungerford 1979; Weyrauch et al. 1998]. Atwater [1972] provides a model that includes the wall effect, gas pressure, and Gaussian smearing to produce a more realistic recoil spectrum for a ^{4}He detector and is shown in Figs. 18.19 and 18.20. The similarity of the results of Figs. 18.17 and 18.18 to those of Figs. 18.19 and 18.20 are apparent.

[7] In fact, ^{1}H is the only nuclide that possesses this property in the MeV energy range.

Birch [1988] reports that the proton background from (n,p) reactions in the steel wall of the chamber become considerable for neutron energies above 10 MeV. To mitigate this problem a 0.5-mm-thick lead liner is inserted into the gas-chamber. Weyrauch et al. [1998] further develop a model for commercial ^{4}He proportional counters and give a variety of comparisons of theoretical to measured results. It is interesting to note that, although ^{4}He gas-filled recoil detectors work adequately as neutron spectrometers, the problems with charge collection are greatly mitigated if the device is instead used as a gas scintillation detector [Jebali et al. 2015].

18.3.2 Unfolding the Recoil Energy Spectrum

If a fast neutron detector is to be used for neutron spectroscopy to determine the energy dependent flux $\phi(E)$ of the neutrons incident on the device, the signals recorded by the instrument must be processed to obtain an estimate of $\phi(E)$. None of the fast neutron detectors described in this chapter directly give $\phi(E)$ and some unfolding of the measured data must be made to obtain the energy information. Briefly mentioned

here is how unfolding a measured recoil energy spectrum can be approached. The measured recoil energy T is related to the incident neutron flux $\phi(E)$ by a Fredholm integral equation

$$T = \int_0^{E_{\max}} R(T,E)\phi(E)\,dE, \qquad 0 \le T \le T_{\max}, \tag{18.30}$$

where $E_{\max}$ is the maximum neutron energy, $T_{\max} = (1-\alpha)E_{\max}$ is the maximum recoil energy, and $R(T,E)$ is the spectrometer response function which gives the probability of observing a recoil energy T per unit intensity of an incident monoenergetic (E) neutron beam. The response function, as a first approximation, is given by Eq. (18.28). But an accurate determination of $R(T,E)$ requires Monte Carlo simulations to account for multiple scatters, wall and end effects, statistical fluctuations, non-linearities in the scintillators, and non-ideal behavior of the electronics.

To obtain $\phi(E)$ from Eq. (18.30), the integral equation (like that for a Bonner sphere) is first converted to a set of linear algebraic equations. This conversion can be performed by several methods. The simplest method is to form a contiguous energy grid $E_1 = 0, E_2, \ldots E_i, E_{i+1}, \ldots, E_{I+1} = E_{\max}$ with $\Delta_i \equiv E_{i+1} - E_i$. Similarly, the recoil energy range $(0, T_{\max})$ is split into J contiguous energy intervals Δ_j. Typically, the Δ_j are equi-width and are the interval widths of the MCA channels used to record the recoil energies.

Equation (18.30) can be written as

$$T = \sum_{i=1}^{I} \int_{E_i}^{E_{i+1}} R(E,T)\phi(E)\,dE. \tag{18.31}$$

Integration over the jth recoil energy interval gives

$$\int_{T_j}^{T_{j+1}} T\,dT \equiv T_j = \sum_{i=1}^{I} \int_{E_i}^{E_{i+1}} dE \int_{T_j}^{T_{j+1}} dT R(E,T)\phi(E) \qquad j = 1, \ldots, J\,, \tag{18.32}$$

where T_j is the measured count rate in channel j of the MCA spectrum of the recoil energy spectrum. If the flux $\phi(E) \simeq \phi_i$ is constant in each neutron energy interval Δ_i, then Eq. (18.32) becomes

$$T_j = \sum_{i=1}^{I} R_{ji}\phi_i, \qquad j = 1, \ldots, J\,, \tag{18.33}$$

where the elements of the response matrix are

$$R_{ji} = \int_{E_i}^{E_{i+1}} dE \int_{T_j}^{T_{j+1}} dT R(E,T). \tag{18.34}$$

Hence, J linear algebraic equations for the I unknowns of the ϕ_i are obtained. If the recoil atoms and incident neutrons use the same energy grid, then $I = J$ and the solution to Eq. (18.34) can be obtained by standard means. Birch [1988] describes two unfolding methods to determine the incident neutron spectrum from the ^{4}He recoil spectrum, namely matrix inversion and iterative unfolding. He reports better resolution for the iterative unfolding method, especially after differentiating the pulse height spectrum and the response functions.

18.3.3 Scintillators Used in Recoil Neutron Scattering

The basic physics regarding scintillation detectors are described in Chapters 12 and 13 and are not repeated here, except perhaps for some clarification. Both inorganic and organic scintillators are used for fast neutron

detectors. The inorganic scintillators can be used as adjacent devices to a recoil medium, such as a hydrogenous material, and which fluoresces from the interactions of recoil ions. Organic scintillators are usually deployed as a combined recoil-fluorescence detector, in which proton (or carbon) recoils from fast neutrons in the organic compound subsequently fluoresce the scintillator. Already discussed in Chapter 13, organic compounds suffer non-linear light yield as the differential energy deposition increases. A few of the detectors and configurations that primarily use recoil reactions as the detection mechanism are briefly described in the following sections.

Response of Organic Scintillators

Organic scintillators, discussed in Section 13.3, are compositions of hydrogen, carbon, and some with other elements such as nitrogen. Proton recoil scattering is nearly isotropic in the center-of-mass system, and the resulting pulse height spectrum for monoenergetic incident neutrons resembles closely a simple step function that extends from zero energy up to the incident neutron energy E. Further, from Eq. (18.4), a fast neutron may impart all of its energy to a proton recoil in a single scatter, but at most only 28% of its energy to a carbon atom with a single scatter. Consequently, the response function from an organic scintillator deviates from the ideal step function. In fact, there are multiple factors that transform the observed pulse height spectrum, including the characteristic non-linear response of organic scintillators, statistical fluctuations, multiple scattering, edge effects, and directional asymmetry [Swartz and Owen 1960].

The Ideal Case There are numerous organic scintillators that contain only hydrogen and carbon atoms, such as the crystalline organics anthracene and stilbene, numerous plastics, and many liquids. Notably, many popular organic fluors contain nitrogen. However, for simplicity, the discussion is limited here to organic scintillators that contain only H and C.

With the definition used by Swartz and Owen [1960], efficiency is the ratio of the number of recoil protons to incident neutrons. The molecular density N_{hc} of the organic scintillator is

$$N_{hc} = \frac{\rho N_a}{A}, \tag{18.35}$$

where ρ is the mass density, and N_a and A have the usual designations of Avogadro's number and the substance's molecular weight. The atomic densities of hydrogen and carbon can be expressed, respectively, as

$$N_H = f_H N_{hc} = m_H \frac{\rho N_a}{A^2} \qquad \text{and} \qquad N_H = f_C N_{hc} = 12 m_C \frac{\rho N_a}{A^2}, \tag{18.36}$$

where f_H and f_C are, respectively, the mass fractions of hydrogen and carbon per molecule. Here m_H and m_C are, respectively, the masses of hydrogen and carbon per molecule, which, to a good approximation, are the number of hydrogen and carbon atoms per molecule. Multiplication by the microscopic scattering cross section gives the macroscopic scattering cross sections,

$$\Sigma_H = \sigma_H N_H \qquad \text{and} \qquad \Sigma_C = \sigma_C N_C. \tag{18.37}$$

The expected efficiency for proton recoil interactions involving a single scatter is,

$$\epsilon_{1h} = \frac{N_1(E_0, \ell)}{N_0} = \frac{\Sigma_H}{(\Sigma_H + \Sigma_C)} \left[1 - \exp\left[-(\Sigma_H + \Sigma_C)\ell\right]\right], \tag{18.38}$$

where $N_1(E_0, \ell)$ is the number of recoil protons produced by a single scatter of a neutron with initial energy E_0 in a scintillator of length ℓ and N_0 is the fluence of neutrons impinging on the scintillator. Equation (18.38) indicates that, provided that the crystal is of adequate length, a sufficiently high efficiency can be expected. In practice, large volumes of organic detector are impractical, mainly because the absorption efficiencies

of gamma rays and charged particles also increase and ultimately interfere with the recoil signal. The use of various discrimination methods can reduce background interference. These methods include pulse height analysis, pulse shape analysis, coincidence (or anticoincidence) counting, capture gating with loaded scintillators, and the selection of clever scintillator physical dimensions to reduce energy deposition from energetic electrons. The ideal pulse height spectrum can be defined by a step function,

$$N(T_p) = \begin{cases} N_1(E_0, \ell)/E_0 & T_p \leq E_0 \\ 0 & T_p > E_0 \end{cases} . \tag{18.39}$$

Unlike gas detectors which measure the energy distribution of the recoil atoms directly, scintillators produce a light yield distribution from the energy deposited by the recoil atoms. It is much more difficult to extract the energy distribution of the incident neutrons from the pulse height spectrum of the light output than from the pulse height distribution of the energy from recoil atoms as produced by a gas detector. Further, there are various distortion effects that alter the ideal differential pulse height spectrum of light. Some of these effects include non-proportional light yield, statistical fluctuations, carbon scattering, multiple proton scatters, recoil protons escaping the detector, and in some cases direction asymmetry in light yield. The combined effects cause the distortion from the ideal case Fig. 18.21(a) to that shown in Fig. 18.21(f). A brief discussion of these effects follows.

Scintillator Non-linearity The non-linearity of the light output L of an organic scintillator is given by Eq. (13.36), which with slight changes in notation, can be written as[8]

$$\frac{dL}{dx} = \frac{\widehat{A}\, dT/dx}{1 + k\widehat{B}\, dT/dx}, \tag{18.40}$$

where k is the probability that an exciton is lost to a non-radiative transition, $k\widehat{B}$ is the quenching parameter, $\widehat{A}$ is a proportionality constant, and L is the luminous output.

The variable P (same energy units as L) for pulse height is introduced as $P = L/\widehat{A}$, such that Eq. (18.40) becomes

$$\frac{dP}{dT} = \frac{1}{1 + k\widehat{B}\, dT/dx}. \tag{18.41}$$

If $k\widehat{B}$ is known, then numerical integration of Eq. (18.41) yields values of P. In the ideal case, $k\widehat{B}$ is zero and $P = T$; hence P would also be a rectangular step function for proton recoils. Also, for energetic electrons, dT/dx is small and $P = T$ once again. However, for recoil protons, scintillation quenching can have a significant impact on the luminescent yield and the quenching parameter cannot be ignored. The number of recoil protons with energy between T_p and $T_p + dT_p$ is defined as $N(T_p)dT_p$, where T_p is the initial energy of the recoil proton. The pulse height spectrum of the light output is written as $N(P)dP$ so that

$$N(P) = N(T_p)\frac{dT_p}{dP}. \tag{18.42}$$

Typically a solution to Eq. (18.42) is obtained through numerical methods and unfolding algorithms [Slaughter and Strout 1982]. However, in some cases, empirical formulas fit to measured data can simplify the evaluation of Eq. (18.42). For instance, the light yield L or P can be modeled as a power function of the

[8] Here the empirical constants are denoted by $\widehat{A}$ and $\widehat{B}$ to avoid confusion with the symbols without the accent. Also the charged particle energy is denoted by T instead of E to avoid confusion with the neutron energy.

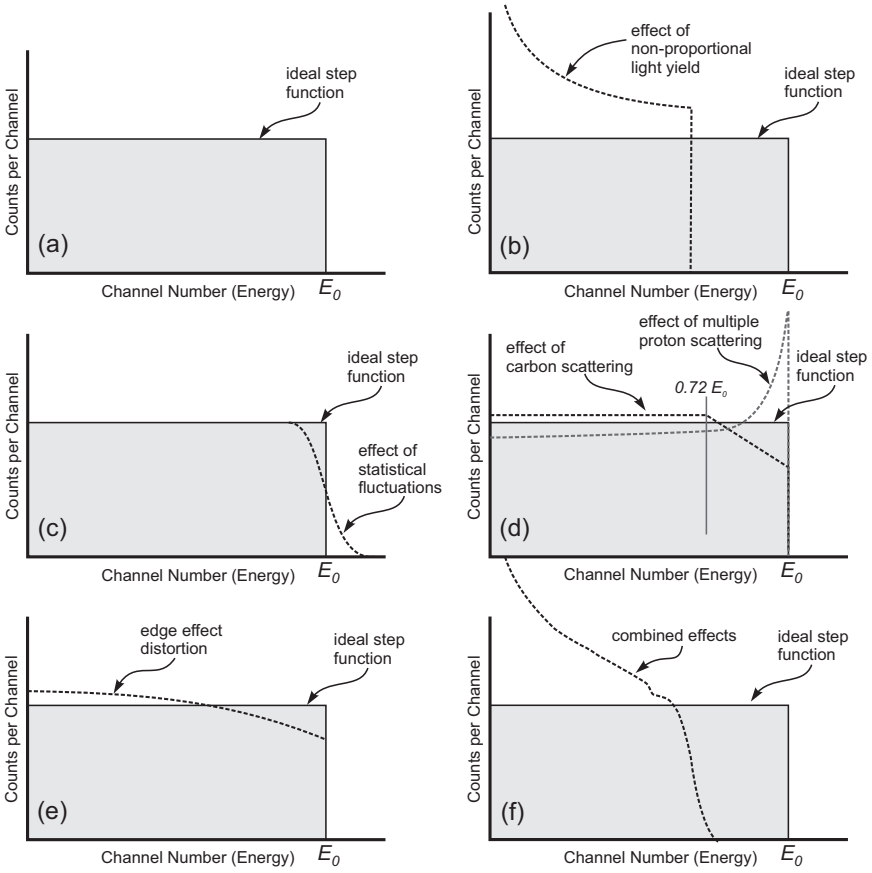

Figure 18.21. Representative pulse-height distortions from neutron scattering in an organic scintillator. (a) The ideal case with no distortions; (b) non-linear light yield; (c) statistical fluctuations; (d) carbon scattering and multiple proton scattering; (e) edge effects; and (f) the resulting spectrum from the combined effects.

recoil energy, usually a form of $T_p^{1.5}$. Based on the data given by Craun and Smith [1970] for stilbene, this approach yields

$$P(T_p) = \left[0.0204 + \frac{5.397}{T_p^{1.5}}\right]^{-1} \simeq \frac{T_p^{1.5}}{5.397}, \tag{18.43}$$

where the approximation ignores the small offset of 0.0204, and P and T_p are both in units of MeV. Given a value of $k\widehat{B} \approx 0.01$ mg cm^{-2} MeV^{-1} and the data of Craun and Smith [1970], the values of dT_p/dP for stilbene are approximated by,

$$\frac{dT_p}{dP} \approx \frac{-1.781 + 64.237\sqrt{T_p} + 6.77T_p}{1 - 5.239\sqrt{T_p} + 26.157E_p - 1.72T_p^{1.5}}, \quad 0.005 < T_p < 15 \text{ MeV}. \tag{18.44}$$

The distortion in the pulse height spectrum from the idealized proton recoil spectrum, which is normalized to unit height, is shown in Fig. 18.22. It is notable that the general shape of the pulse height spectrum due solely to scintillator non-linearity is determined analytically with the use of empirical fits. The normalized

luminous output, from Eq. (18.43), is described by

$$P(T_p) \approx c_1 T_p^{1.5}, \tag{18.45}$$

where c_1 is a constant of proportionality. Then from Eq. (18.42)

$$N(P) = \frac{N(T_p)}{dP/dT_p}. \tag{18.46}$$

Because $N(T_p)$ is constant for $T_p < E_0$

$$N(P) = \frac{c_2}{1.5\sqrt{T_p}}. \tag{18.47}$$

From Eq. (18.45) it is seen that $\sqrt{T_p}$ is proportional to $P^{1/3}$ and substitution of this result into Eq. (18.47) yields the expected shape of the pulse height distribution, namely

$$N(P) = \frac{c_3}{P^{1/3}}, \tag{18.48}$$

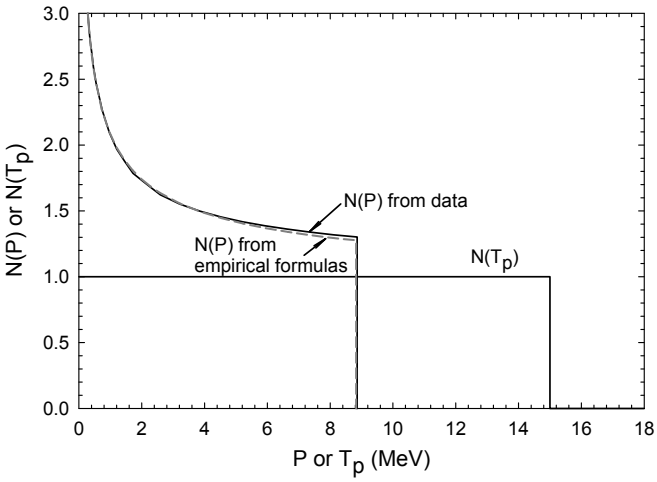

Figure 18.22. Distortion of the ideal pulse height spectrum for stilbene due to non-linear light yield. Shown is the expected pulse height spectrum from 15-MeV neutrons.

where c_3 is a constant of proportionality. This dependence of $N(P)$ on P is clearly seen in Fig. 18.22.

Statistical Fluctuations The effect of statistical fluctuations on detector energy resolution was covered in prior chapters, mainly in Sections 6.9 and 6.10 on counting statistics and error propagation and in Section 10.5.4 for proportional counters. In general, the energy resolution of a detector is limited by the fluctuation in charge carriers. For a scintillator, there are multiple sources of fluctuations, such as fluctuations in the number of excited free electrons and excitons produced, the fraction of charges that decay by fluorescence, the number of photons arriving at the light detection device, the charge carriers produced at the light detector (photoelectrons, for instance), and the gain. These fluctuations produce a variation in the light output near $T = E_0$ such that $dN(P)/dP$ assumes a Gaussian shape with mean $\langle P \rangle \simeq E_0$ and a variance σ_P^2. This effect softens the high energy edge by producing a sigmoid transition instead of the step function change, as shown in Fig. 18.21(c).

Multiple Scattering Protons entering the detector may undergo scattering with carbon atoms. From Eq. (18.4), at most only 28% of the initial proton energy can be transferred to a carbon atom with a single scatter so that the scattered neutron has a residual energy ranging from $0.72E_0$ to E_0. The recoil carbon atom also has kinetic energy, but the luminescence is low and these events are considered to add negligible fluorescence [Swartz and Owen 1960], and hence do not contribute (appreciably) to the pulse height spectrum.

The efficiency of neutrons scattering once by carbon can be expressed by,

$$\epsilon_{1c} = \frac{N_C(E_0, \ell)}{N_0} = \frac{\Sigma_C}{(\Sigma_H + \Sigma_C)} \left[1 - \exp\left[-(\Sigma_H + \Sigma_C)\ell\right]\right]. \tag{18.49}$$

Suppose that the energy of the carbon scattered neutrons can be defined by an average neutron energy $\overline{E}_1$ and that these neutrons must pass through some average amount of material $\overline{\ell}_1$ of scintillator. If the organic scintillator is sufficiently thick to allow at least two neutron scatters, the efficiency of proton scattering first from carbon followed by scattering from hydrogen is

$$\epsilon_{2(ch)} = \frac{N_2(E_0, \ell, \overline{\ell}_1)}{N_0} = \frac{N_C(E_0, \ell)}{N_0} \frac{\Sigma_H(\overline{E}_1)}{[\Sigma_H(\overline{E}_1) + \Sigma_C(\overline{E}_1)]} \left[1 - \exp\left\{-[\Sigma_H(\overline{E}_1) + \Sigma_C(\overline{E}_1)][\overline{\ell}_1]\right\}\right]. \tag{18.50}$$

The total proton scattering efficiency becomes

$$\epsilon_t = \epsilon_{1h} + \epsilon_{2(ch)}. \tag{18.51}$$

Swartz and Owen [1960] note that the result of Eq. (18.51) is often nearly the same as if no carbon scattering occurred, i.e., $\Sigma_C = 0$. The effect on the pulse height spectrum is shown in Fig. 18.21(d). Although some carbon scattered neutrons may exit the detector, this problem can be greatly mitigated by using detectors that are relatively wide. Hence, carbon scattering tends to reduce the energy of some neutrons, but not necessarily the number of proton recoils. Instead, the spectrum is shifted such that the number of counts is slightly increased in the lower energy region, while the number of counts is slightly decreased in the energy range between $0.72E_0$ to E_0. Overall the total number of counts recorded in the pulse height spectrum would change little.

There is also the possibility of multiple proton scatters, in which two proton recoils from a single neutron occur rapidly in succession and are recorded as a single event. Such double (n,p) scattering emphasizes the higher energy region of the pulse height spectrum [Segel et al. 1954], an opposite effect to that of carbon scattering. A depiction of this effect on the spectrum is shown in Fig. 18.21(d). Note that if the detector were sufficiently thick, the total neutron energy would be deposited in the detector for each event. Because of non-linear light yield, there would be a variance about the average luminescence per neutron, even from a monoenergetic neutron source. Overall, these two different scattering effects tend to partially offset each other in small detectors. In either case, the knowledge of the differential scattering cross section combined with the knowledge of the scintillator specific light yield can be used to model the pulse height spectrum with Monte-Carlo methods.

Edge Effects Edge effects occur as a consequence of losing recoil protons from the detector periphery. This effect is enhanced for detectors with dimensions less than the average range of the recoil protons. A count is still recorded for the recoil proton, but the pulse height is diminished by the amount of energy not deposited in the detector. Intuitively, one can understand that energy loss from protons escaping the detector increases counts in the lower energy channels while reducing events in the higher channels, as depicted in Fig. 18.21(e).

Threshold Reactions At sufficiently high neutron energies, there are threshold reactions that can be of concern [Mösner at al. 1966; Grin et al. 1969], mainly the $^{12}\mathrm{C}(n,\alpha)^9\mathrm{Be}$ and the $^{12}\mathrm{C}(n,n)3\alpha$ reactions with Q-values of 5.70 MeV and 7.27 MeV, respectively. Both of these reactions release energetic heavy ions, and consequently add to the total neutron detection efficiency [Hermsdrof et al. 1973]. However, because of non-proportional light yield, especially for ions heavier than protons (see Chapter 13), the added luminescence further distorts the differential pulse height spectrum. From the result of Problem 18.11, the threshold energy for these reactions are 6.176 MeV and 7.881 MeV, respectively, as shown in Fig. 18.23.

Directional Asymmetry Thus far, it has been assumed that the light yield is relatively constant for all proton trajectories. However, both anthracene and stilbene show directional dependence on light emission, reportedly as much as 15% variation [Swartz and Owen 1960]. However, directional asymmetry is generally not a problem with plastic and liquid scintillators. In the case of varied light yield with proton direction, the overall result is an increased variance in the pulse height spectrum, further smearing and distorting the idealized spectrum and is shown in Fig. 18.21(f).

Dependence on the Lower Level Discriminator (LLD) From Fig. 18.21(a), it becomes evident that the pulse height spectrum ranges from channel 0 (no energy transfer) up to the total fast neutron energy E_0. If the LLD is set to zero, then electronic noise and background radiation contaminate the spectrum.[9] Hence, it is traditional to set the LLD to discriminate neutron events from other events such as gamma ray

[9] The condition with LLD = 0 is at times referred to as the zero bias condition, an unfortunate choice, mainly because this condition is also used more accurately to describe radiation detectors that operate with no voltage applied.

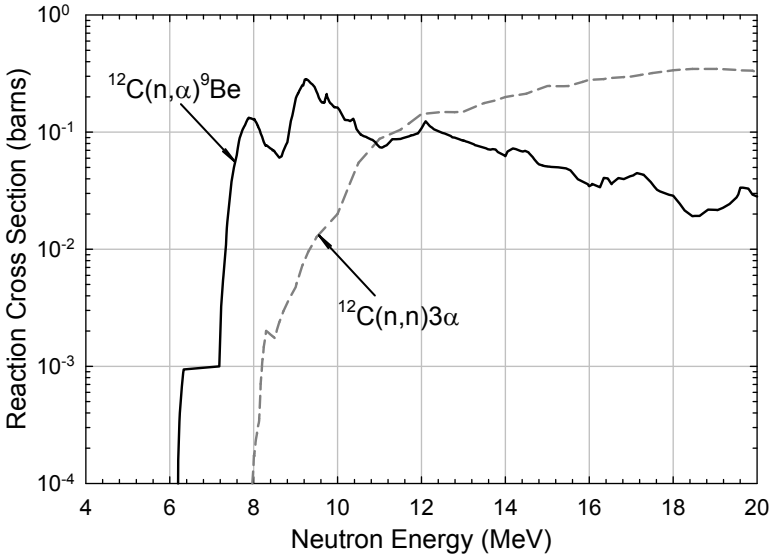

Figure 18.23. Fast neutron reaction cross sections for ^{12}C. Data are from [ENDF VIII 2018].

interactions; however, such discrimination artificially reduces the overall detection efficiency by eliminating low energy (n,p) recoil events. This reduction in efficiency is non-linear, being zero for proton recoils below the LLD, and also decreases as the fast neutron energy E_0 is increased.

Suppose the LLD is set at 500 keV. Under such a condition, only a few select events with $\theta_c \simeq 180°$ allow 500 keV neutrons to be detected. The number of possible detectable scatter angles increases as E_0 increases and produces higher efficiency for neutron energies greater than E_0, in this example, 500 keV. The overall scatter cross section for ^{1}H decreases with energy (see Fig. 18.14), which decreases the detection efficiency even though the detectable scatter angle θ_c increases. Combined, these effects produce a maximum in the efficiency curve as a function of neutron energy and LLD setting, as depicted in Fig. 18.24.

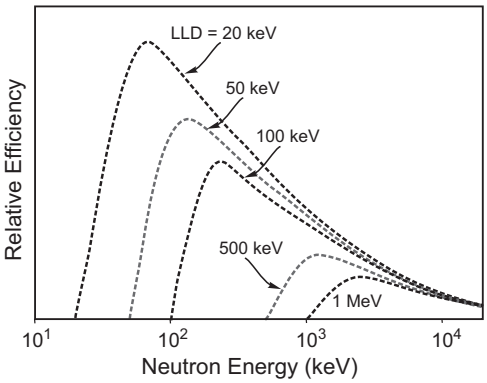

Figure 18.24. Efficiency is a function of the LLD setting, neutron energy, and elastic scattering cross section.

Multiple Neutron Energies For multienergetic neutron sources, the varied emission energies will work to further smear the features in the output spectrum. For instance, the varied energies from a PuBe source range from hundreds of keV up to 11.5 MeV (see Fig. 5.5), with all energies being susceptible to the response deviations described in the previous sections on ion recoils. Hence, the spectral features for proton recoils from a multienergetic source will be a convolution of the various energies, their emission probabilities, and combined distortion effects for each of these emission energies.

Pulse Shape Discrimination Detectors

Pulse shape discrimination (PSD) is used as a method to distinguish between different ionizing events in a scintillation detector, already outlined in Sec. 13.3.1 under organic scintillators. The basic method takes advantage of the different pulse output pulse shapes produced by a scintillator from heavy ions, electrons, and

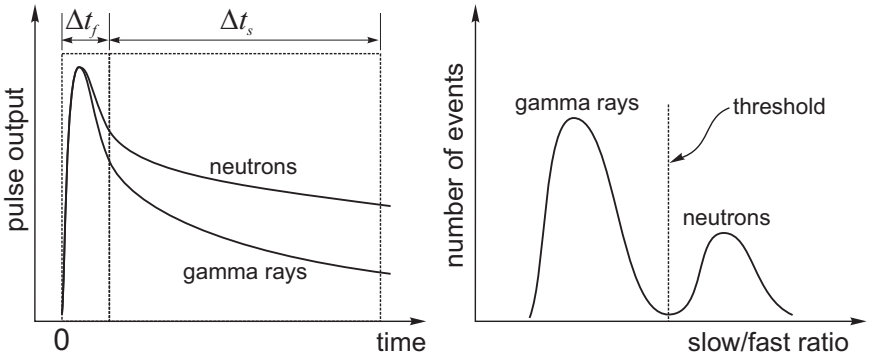

Figure 18.25. Depiction of two different pulse shapes for a scintillator. Divided into two regions, the ratios of the integrated output produce a PSD spectrum that distinguishes between gamma-ray and heavy ion events.

gamma-rays. Gamma-ray pulses tend to be shorter with a faster decay time than those observed for heavy ion events. Consequently, by time gating the pulse shape into two separate regions a distinct separation between heavy ion and gamma-ray events becomes apparent. Plastic scintillators with high hydrogen-to-carbon ratios can be used as fast neutron detectors from proton recoil events. For many scintillators, both organic and inorganic, the pulse shapes for fast protons are much different than those for gamma-ray reactions.

Consider the depiction of scintillator output pulse shapes in Fig. 18.25(left). A time window width Δt_f is set for the fast decay component while a second time window width Δt_s is set for the slow decay component. The integrated output over Δt_s divided by the integrated output over Δt_f yields unique signatures characteristic of gamma-rays or neutrons. The number of these pulse height ratios as a function of the ratio value often reveals a clear distinction between gamma-ray and neutron induced pulses, as depicted in Fig. 18.25(right). Several examples of pulse shape discrimination spectra from organic scintillators are shown in Chapter 13.3.

Although many organic scintillators can distinguish between neutron and gamma-ray events with PSD, there are a select few that perform better than most and are so identified in Sec. 13.3.2. Also, some inorganic scintillators show discrimination between pulse heights for various forms of ionizing radiation. Because most inorganic materials are more efficient at absorbing gamma rays than the organic scintillators, they are generally not used for such purposes. However, there are some exceptions such as the use of ZnS:Ag adjacent to a plastic waveguide.

Shown in Figs. 18.26 and 18.27 are proton recoil spectra from a ^{252}Cf source and an AmBe source taken with a plastic scintillator. The *pulse shapes* were separated into gamma-ray and neutron events with the pulse shape analysis technique, and then plotted as a function of *pulse height* digitally sorted into a sequence of channels. Both ^{252}Cf and AmBe neutron sources emit a broad spectrum of energies as described in Section 5.4. Consequently, the pulse height spectra in Figs. 18.26 and 18.27 also show continua, blurred by the multiple effects described in Fig. 18.21, a similar result to that reported by Cester et al. [2014].

Proton Recoil Telescope

The various problems with the degradation of the energy resolution in a plastic scintillator can be reduced if the energies of recoil protons are accurately measured. Further, if the scatter angle of the recoil proton is known accurately, the initial neutron energy can be determined from Eq. (18.4) with $A = 1$. A device to accomplish such measurements was introduced during the 1940s and is described by Johnson [1960]. The basic device, named a *proton recoil telescope*, consists of a thin hydrogenous material acting as a proton radiator with high resolution detectors positioned, in some manner, behind the radiator. This configuration

mostly mitigates the multiple problems encountered with organic scintillator spectrometers as described in the previous sections. The purpose of the proton recoil telescope is to accurately measure the energy of impinging fast neutrons. However, this goal also requires that the radiator be relatively thin in order to diminish energy self-absorption and to preserve the energy of the recoiling proton. Consequently the efficiency of the device is quite low, often below 10^{-4}.

There are several designs proposed for proton recoil telescopes, each intended for a specific use. In some cases, the proton recoil telescope is used as a neutron spectrometer and the proton energy and the scatter angle must be known accurately. Collimators can be used to ensure that only specific proton angular trajectories are allowed to reach the particle detector [Johnson 1960]. Collimators may also be used to define the fast neutron direction with respect to the radiator and the proton detectors located at known angles to the radiator. For instance, Hawke et al. [2002] report on two such configurations, depicted in Fig. 18.28, to operate as proton recoil spectrometers. The collimator is used to align the neutrons to the radiator and the detector is offset from the neutron beam at a known angle. This out-of-line configuration reduces direct neutron interactions in the proton detector. The annular configuration (Fig. 18.28(b)) has the added advantage of a larger source solid angle, thereby increasing the overall detection efficiency.

To remove background interference, a thin ΔE detector can be placed in front of the proton detector and operated in coincidence [Ryves 1976; Cazzaniga et al. 2015; Marini et al. 2017]. The thin ΔT detector samples a small portion of energy from the proton while the main detector absorbs the remaining energy T'. For detectors responding linearly to energy deposition, the initial neutron energy E is obtained from Eq. (18.4) as

$$E = (\Delta T + T') \cos^2 \theta_r. \tag{18.52}$$

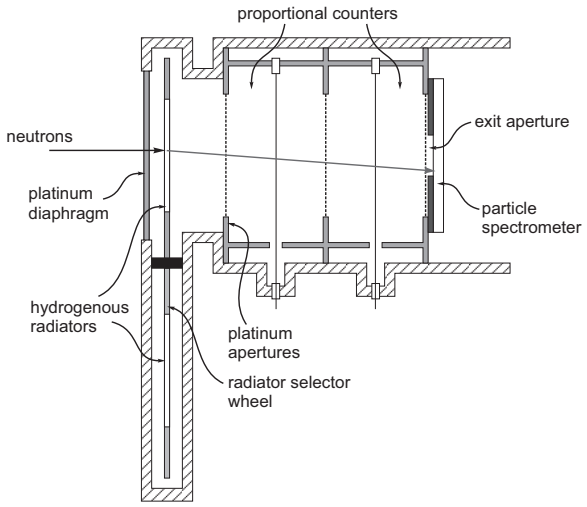

Figure 18.29. A proton recoil telescope. The radiator and the exit aperture define the acceptance solid angle of the proton recoils. Based on Bame et al. [1957].

The product of $(\Delta T)(T')$ gives a measure of the particle mass [Parkinson and Bodandsky 1965; Chaminade et al. 1967; Homeyer 1967], and can be used to assure that the impinging particle is a proton and not another charged particle type. Donzella et al. [2010] describe a proton recoil telescope with a multilayer segmented radiator, two position sensitive ΔT Si detectors, followed by a CsI:Tl detector, all operated in coincidence. The segmented radiator doubles as a position sensitive organic scintillator, giving the originating location of the (n,p) reaction. The reported energy resolution of the fast neutrons ranged from 20% FWHM at "a few" MeV to 2% FWHM at approximately 160 MeV, and the device had an average efficiency of about 3×10^{-5}. An advanced version, with multiple position sensitive ΔT CMOS detectors aligned with a silicon surface barrier detector is reported by Combe et al. [2018]. This device has an in-line configuration, and the proton recoil angles are tracked between the three CMOS pixel detectors before capturing the residual energy in the silicon surface barrier detector.

For monoenergetic neutron sources, the efficiency of the spectrometer may be the most important factor, especially for measurements of cross sections. Early designs, still in use, have a dual chamber proportional counter arranged between the proton radiator and a spectroscopic detector [Johnson and Trail 1956; Bame et al. 1957; Ryves 1976; Lövestam 2006], as shown in Fig. 18.29. The geometry of these devices is an in-line configuration. These proton recoil telescopes have several different radiators on a selector wheel that allows the user to easily change the targets, each radiator target usually having different mass thicknesses of the same substance. The reason for these different targets is to account for changes in (n, p) cross section as the fast neutron energy changes [Bame et al. 1957]. The particle spectrometer can be a scintillator [Johnson and Trail 1956; Bame et al. 1957] or semiconductor detector [Ryves 1976; Lövestam 2006]. The proportional counters and the neutron spectrometer are operated in triple coincidence to reduce background.

Capture Gated Neutron Spectrometer

The capture gated concept is implemented with a loaded scintillator [Drake e al. 1986], most commonly an organic scintillator loaded with ^{10}B, or with loaded scintillator immersed in an organic scintillator [Czirr and Jensen 1989]. From the previous section describing the pulse height spectrum from elastic scattering in an organic scintillator, fast neutrons produce a continuous spectrum of energies with distortions arising from many effects. The interaction time for elastic scattering, including multiple scatters, is relatively short, typically tens to hundreds of nanoseconds. If the neutron loses nearly all of its kinetic energy from elastic scattering in the scintillator, the thermalized neutron continues to diffuse until it is absorbed by either a

hydrogen atom (332 mb) or (less probable) with a carbon atom (3.53 mb). The $^{1}H(n,\gamma)^{2}H$ reaction releases a 2.22 MeV gamma ray, but this gamma ray usually escapes the organic scintillator and goes undetected. Should the neutron react with carbon, there are three possible gamma-ray emissions (1.26 MeV, 3.68 MeV, 4.95 MeV) also of high energy and most likely to escape the scintillator. If instead a small fraction of ^{10}B atoms are distributed within the organic scintillator, for instance 1% loading, the chance of absorption in the boron is over 100 times greater than in the hydrogen. Upon absorption in the boron, the $^{10}B(n,\alpha)^{7}Li$ reaction releases reaction product energy of either 2.31 MeV (94%) or 2.79 MeV (6%). In either case, these reaction products also produce scintillation light from the detector.

Capture gated neutron spectroscopy is possible because the time required to thermalize the neutron is much less than the time it takes for the thermalized neutron to diffuse to a ^{10}B location. Hence, there are two releases of scintillation photons, first from the elastic scattering and second from the $^{10}B(n,\alpha)^{7}Li$ reaction, separated by some time period Δt, usually between 10 and 20 μs. Because it is unlikely that an epithermal or fast neutron interacts in the ^{10}B, these paired scintillations occur predominantly when the initial fast neutron has lost all of its kinetic energy. Hence, the magnitude of the first scintillation release is indicative of the initial neutron energy and the second scintillation release indicates that the neutron did indeed lose all (or most) of its kinetic energy. Because the Q-value of the $^{10}B(n,\alpha)^{7}Li$ reaction is recognizable, it is a simple matter of calibrating the detection system to recognize within a given Δt the two separate pulses, that the latter emission pulse has the distinctive energy signature from the ^{10}B reaction. Hence, the energy of the second pulse can also be discriminated with an energy window to ensure that it is truly from a $^{10}B(n,\alpha)^{7}Li$ reaction. If the second pulse does not appear within some set coincidence time Δt, or if the relative energy indicates that it is not from the ^{10}B reaction, the former pulse is rejected. The method reduces the overall fast neutron counting efficiency of the scintillation detector, although the quality of the energy spectrum is improved.

Ideally, the scintillation light produced by fast neutrons that have been thermalized in an organic scintillator would be indicative of the total energy deposited, regardless of the number of scatters required for thermalization. In reality, there is an average number of scatters needed to thermalize a neutron and also a variance about that average. For mono-energetic neutrons, this physical result means that the scatter angles and recoil proton energies of the scattering events are different, although the total energy loss for fully absorbed neutrons must still be the same for all incident neutrons. As discussed in Sec. 13.3.1, organic scintillators respond non-linearly to heavy charged particles, especially as the specific energy loss dT/dx increases. The light yield per scatter is a function of the recoil proton energy and also the energy loss per unit distance dE/dx, thereby adding to the variance in light yield. Consequently, the energy resolution of the neutron spectrum is much broader than predicted by simple Gaussian statistics based on charge carrier production (see Fig. 18.30). Attempts to mitigate the problem of non-linear light yield have been tried by using segmented detectors to compartmentalize the light emission, thereby allowing light yield corrections to the energy deposited [Abdurashitov et al. 2002; Bowden et al. 2009].

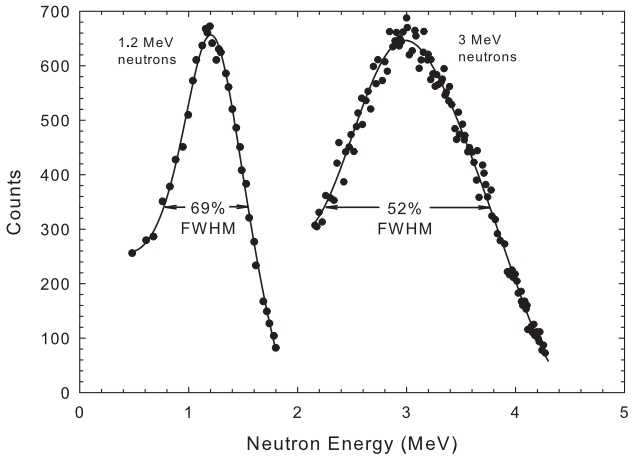

Figure 18.30. Capture gated spectra from monoenergetic fast neutrons. The system consisted of a plastic scintillator annulus around a ^{3}He gas-filled detector. Data are from Drake et al. [1986].

Although boron-loaded plastics are a popular choice for capture-gated neutron spectroscopy [Drake et al. 1986; Feldmann et al. 1991; Kamykowski 1992; Holm et al. 2014], many other configurations have been reported with good results. Boron-loaded liquid scintillators have been reported with the added function of pulse shape discrimination to eliminate gamma-ray background [Jastaniah and Sellin 2004; Flaska and Pozzi 2009]. One of the earliest implementations of capture-gated neutron spectroscopy used a plastic scintillator annulus around a ^{3}He gas-filled detector [Drake et al. 1986]. Lithium can also be added to plastic or liquid scintillators [Czirr et al. 2002; Fisher et al. 2011 ; Wilhelm et al. 2017], the advantage is a higher Q value (4.73 MeV), a single decay branch, and no gamma-ray emissions from an excited state. A disadvantage of using LiF is the lower neutron absorption cross section (microscopic and macroscopic) [McGregor et al. 2003]. Pulse shape discrimination methods have also been used with a Li-glass/plastic scintillator layered structured, also operated as a capture gated detector [Czirr and Jensen 1994]. Nattress et al. [2016] describe the use of Li-loaded glass rods arrayed in a matrix inside a plastic scintillator.

Hornyak Buttons

ZnS:Ag has a unique property of having relatively low light yield for electron interactions while being reasonably bright for heavy ion interactions. This particular property was put to use by Hornyak in 1952 (see discussion on Zinc Sulfide in Section 13.2.2). The original *Hornyak buttons* were fabricated by mixing a fine powder of ZnS:Ag with PMMA[10] molding powder and curing the samples in shapes as small plugs [Hornyak 1952]. That fact that PMMA is a non-scintillating organic helps to reduce background light from gamma-ray events. However, in high radiation fields of mixed neutrons and gamma rays, the production of Čerenkov emissions from the PMMA are possible ($n = 1.49$) and, thus, increase the background. Regardless, Hornyak [1952] reported good efficiency for fast neutrons while still being relatively insensitive to gamma-ray background.

At mass thicknesses of 25 mg cm^{-2} or greater, ZnS:Ag becomes opaque to its own light emissions. This mass thickness is equivalent to 61 microns of pure ZnS:Ag (4.09 g cm^{-3}). However, ZnS:Ag is usually deployed as a powder mixed with a binder, which reduces the volume density of ZnS:Ag, but the opaqueness problem remains. Because of self-absorption light losses, modern Hornyak button designs deviate from the original design. Instead of mixing the ZnS:Ag into the PMMA, modern Hornyak buttons are usually arranged in a bullseye pattern, with concentric alternating rings of PMMA and ZnS:Ag. Protons scatter from the PMMA rings into the ZnS:Ag and produce light. The light subsequently emerges from the ZnS:Ag back into the PMMA and is guided to a light sensor, usually a PMT.

Gamma-ray interactions in PMMA can produce Čerenkov radiation emissions. In low radiation environments, simple pulse height discrimination is sufficient to effectively distinguish between neutron and gamma-ray events. However, in mixed-field high-radiation environments, the production of significant Čerenkov radiation can require that the lower level discriminator be set at much higher channels, a setting that consequently also removes neutron events and lowers neutron detection efficiency. It has been demonstrated that PSD can improve the detection efficiency of Hornyak-style devices [Johnson et al. 2016], more than doubling the efficiency than with pulse height discrimination alone.

PRESCILA Detector

The PRESCILA (Proton REcoil SCIntillator – Los Alamos) detector is another recoil detector based primarily on proton recoils entering a ZnS:Ag scintillator layer (see Fig. 18.31). The PRESCILA detector was developed at Los Alamos National Laboratory with the goal of producing a new REM meter of much lighter weight than conventional polyethylene REM balls [Olsher and Seagraves 2003; Olsher et al. 2004]. The basic device has a large central cube of Lucite that serves both as a light guide and also as a moderator to thermalize neutrons. The device has concentric ring style Hornyak buttons on four sides (EJ-410P in Fig. 18.32),

[10] Polymethyl methacrylate with brand names such as Lucite, Plexiglas, and Acrylite.

each recessed into borated polyethylene plates, used for fast neutron counts. On top, the detector has a thermal-neutron detector made from a combination of ^{6}LiF and ZnS:Ag. The Lucite block is attached to a PMT, and the PRESCILA wand output can be connected to a handheld survey meter (Fig. 18.31).

The response of the PRESCILA detector is reasonably flat over a wide range of energies. The relative response per unit dose equivalent to both $H^*(10)$ and NCRP-38, in which a uniform result of 1.0 for all energies is the desired outcome, are shown in Figs. 18.33 and 18.34. The response to neutrons is overestimated for energies below 100 keV while the response to fast neutrons is underestimated between the energies of 100 keV and 2 MeV [Olsher et al. 2004]. The overall response was designed to provide a relatively uniform dose equivalent. Comparatively, the response from the Hankins rem ball and the Andersson-Braun cylinder seem to be flatter over these same energy regions. At energies between 2 MeV to 20 MeV, the response from the PRESCILA becomes relatively flat, while the responses from the Hankins rem ball and the Andersson-Braun cylinder both, almost identically, decrease as energy is increased above 7 MeV. Finally, the PRESCILA detector is considerably smaller and weighs only 4.5 lbs (2 kg), which is much less than the rem ball or cylinder. For handheld field instruments, size and weight are important considerations.

Gas-Filled Scintillation Detectors

Recall from Sec. 13.4 that several gases were discovered to scintillate, often in the UV region.[11] Of these gases, He is the best candidate for use in a gas recoil scintillation detector, mainly because of its lower atomic number compared to those of the other noble gases so that more energy is transferred to a recoil atom from a neutron scattering event. For ^{3}He gas, there is also the possibility of producing energetic ions from the (n,p) reaction that can also cause the gas to fluoresce. The use of ^{4}He gas as a recoil scintillator, rather than as a proportional counter, mitigates problems associated with charge collection and avalanche production [Chandra et al. 2012]. Further, the response speed is faster than in a proportional counter and the scintillation mechanism allows the use of pulse shape discrimination methods. The kinematics of (n,α) scattering are the same as described for proportional counters; hence the maximum energy transfer per neutron scatter is only 64%. The recoil ^{4}He ions fluoresce the gas, and photomultiplier tubes (PMT) [Jebali et al. 2015] or compact silicon photomultipliers (SiPM) can be used to measure the light yield [Arktis 2017]. A pressurized tube filled with ^{4}He gas is attached to a light collection device, and because charge carrier collection is not required and charge mobility is not an issue, these chambers can be pressurized, in some cases up to 150 atm [Kelley et al. 2015]. The high pressure reduces the recoil ^{4}He ion range and, consequently, also the wall effect so that the overall efficiency for the neutron interactions is increased.

18.4 Semiconductor Fast Neutron Detectors

The use of a hydrogenous radiator, such a polyethylene, attached to a semiconductor diode has been explored as a compact fast neutron detector and as a beam port monitor [Klann and McGregor 2000, 2002; Klann et al. 2001, 2002; De Lurgio et al. 2003]. These detectors rely on the recoil proton entering a Schottky or *pn* junction diode. The energy recorded is the proton recoil energy minus the energy self-absorption losses as the proton traverses the radiator. The maximum range of the proton limits the useful radiator thickness and, consequently, also determines the efficiency as a function of neutron energy. The maximum range of 14-MeV

[11] The only noble gas that appears not to effectively scintillate is neon [Northrop and Gursky 1958], although liquid neon does have use as a scintillator [Nikkel et al. 2008].

protons in high density polyethylene is approximately 2.2 mm, with lower energies having smaller ranges. The neutron interaction efficiency is combined with the recoil energy and solid angle, the escape probability of the recoil proton, and the LLD setting to determine the efficiency as a function of energy [Klann and McGregor 2000]. Models indicate that 0.11% detection efficiency is possible for 14-MeV neutrons with a 2.2 mm HDPE attached to a semiconductor diode. In general, the fast neutron detection efficiency is relatively low for these detectors, but their compactness and low power requirement are advantageous under special conditions [De Lurgio et al. 2003].

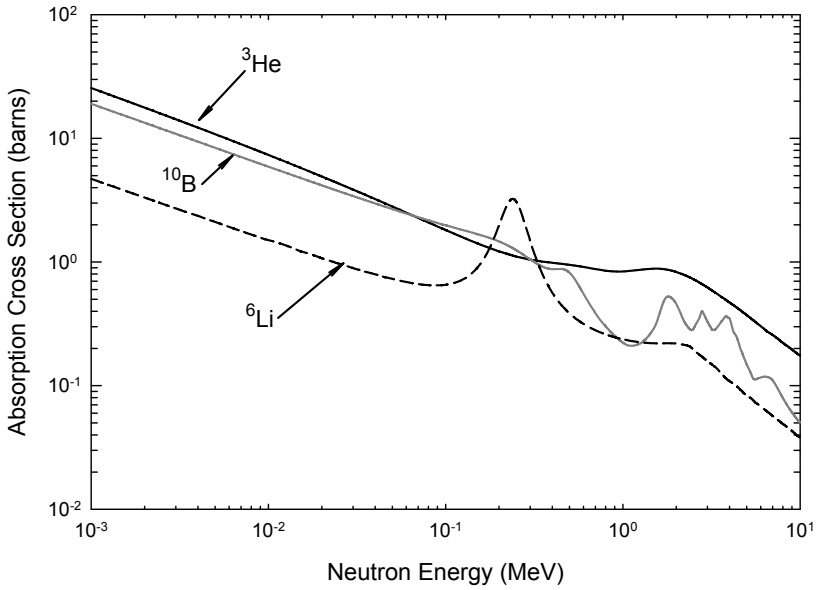

Figure 18.35. Absorption cross sections for ^{3}He, ^{6}Li, and ^{10}B in the fast neutron region. Data are from [ENDFPLOT 2017].

There are several direct interactions that can also induce pulses from the semiconductor detector. For instance, Si is a frequent choice for a particle detector, mainly because of its relatively low absorption coefficient for gamma rays. However, fast neutrons can interact in Si and release ionizing particles. For instance, the (n,p) and (n,α) reactions can produce energetic particles directly in the semiconductor, ions which do not suffer self-absorption. Although produced by neutrons, these events are considered part of the background as are possible gamma-ray interactions [Dearnaley and Northrop 1966]. One method used to reduce background is a compensated diode in which one section of the diode is covered with a hydrogenous radiator while the remaining area, of equal size, remains bare. The hydrogenous side records both proton recoils and background, while the bare side records background, and, thus, can be subtracted.

18.5 Detectors Based on Absorption Reactions

As described in Chapter 17, there are many thermal-neutron detectors based on absorption reactions. However, there are only a few isotopes with high thermal-neutron absorption cross sections that produce spontaneous ionizing reaction products. These same materials can be used for epithermal and fast neutron detection, although the absorption cross sections are reduced. The two most popular absorption reactions for fast neutron detection are the ^{3}He(n,p)^{3}H and the ^{6}Li(n,t)^{4}He reactions, whose cross section is shown in Fig. 18.35.

18.5.1 ^{3}He Detectors

^{3}He proportional counters are a popular choice for thermal-neutron detection; however, they are also used for fast-neutron detection with combined effects from recoil scattering, fast-neutron absorption, and thermal-neutron absorption. A few possible event trajectories are depicted in Fig. 18.36. As with thermal-neutron detection, the fast neutrons, with energy E, may become moderated outside of the detector, and then absorbed in the detector with negligible kinetic energy transferred to the reac-

tion products. Such a trajectory, depicted in track 4, results in the deposition of the ^{3}He(n,p)^{3}H Q-value of 0.764 MeV in the gas. Alternatively, the neutron may be fully moderated in the detector (unlikely) and then be absorbed in the gas, as depicted in track 1, so that a total energy of $E + 0.764$ MeV is absorbed in the gas. Although the absorption cross section for ^{3}He is small for fast neutrons, there is also a small possibility that the neutron becomes fully absorbed with the reaction products producing an energy deposition of $E_n + 0.764$. Such an event is depicted as track 2 in Fig. 18.12. Finally, a recoil scatter may occur and the scattered neutron leaves the system, as shown by track 3, so that a continuous distribution of energies up to $0.75E$ is deposited, the maximum recoil energy as given by Eq. (18.4) (see Example 18.3). The idealized shape of this continuum component is given by Eq. (18.28). When all of these possible outcomes are combined, the resulting pulse height spectrum of the energy deposited in the gas has fast effects superimposed onto the traditional thermal-neutron response as shown in Fig. 18.37.

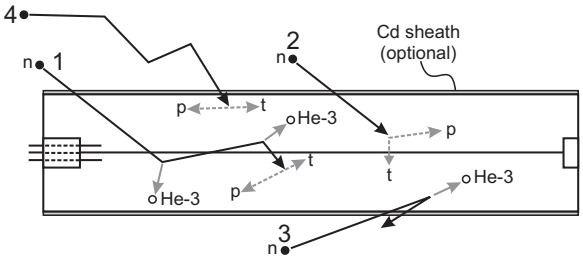

Figure 18.36. Neutron interaction possibilities for a ^{3}He gas detector.

Example 18.3: Determine the energies of the spectral features produced by monoenergetic 6 MeV neutrons interacting in a ^{3}He detector.

Solution:

1. There is a thermal-neutron peak at 0.764 MeV from slow neutrons interacting directly with the ^{3}He by the ^{3}He(n,p)^{3}H reaction.
2. The elastic scatter reaction results in an endpoint energy, given by Eq. (18.4), of

$$T = \frac{4A}{(A+1)^2}E = \frac{(4)(3)}{4^2}(6)\ \text{MeV} = 0.75(6\ \text{MeV}) = 4.5\ \text{MeV}.$$

3. The full energy peak is at an energy equal to the total kinetic energy added to the Q value, namely, 6.764 MeV.

Typically ^{3}He gas-filled neutron detectors are designed as cylindrical proportional counters [Shalev and Cuttler 1973], mainly because of the many advantages already described in Chapter 10. Recall that the electronic pulse is formed primarily from ion motion, and that after the Townsend avalanche has progressed, over 50% of the signal is generated as the ion cloud travels a distance of only a few microns from the anode wire. Consequently, a spectrum can be formed, albeit a relatively low resolution one. To improve the energy absorption efficiency of the recoil He ions, aimed at decreasing the wall effect, a heavy gas with greater stopping power can be added. Candidates include Ar, Kr, and Xe, each having a lower ionization potential than He. However, all of these gases also have lower electron and ion mobilities than He. The use of long shaping times several microseconds long are encouraged for best results [Shalev and Cuttler 1973]. The addition of CO_2 or CH_4 can help increase the average charge carrier velocities [Shalev and Cuttler 1973; Owen et al. 1981]. Regardless, the pulse height spectrum becomes more complicated from recoils with these added fill gases. There have been reports on the rejection of elastic scatter events through pulse height discrimination [Sayres and Coppola 1964].

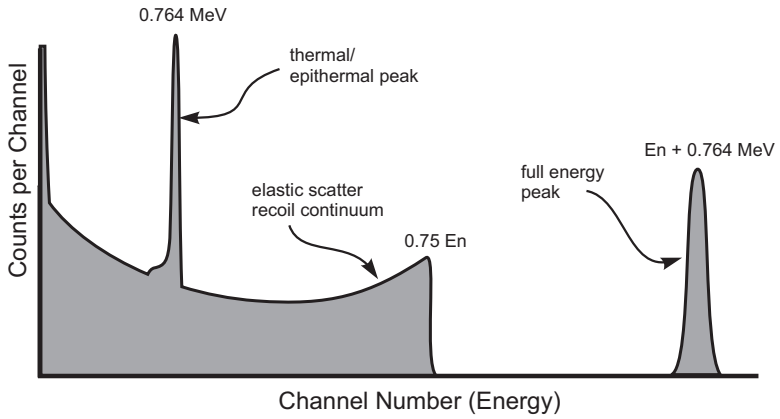

Figure 18.37. The main spectral features resulting from fast neutrons interacting in a ^{3}He detector.

Other designs include the gridded ion chamber, configured as a cylindrical design with a concentric grid[12] surrounding the central anode wire [Franz et al. 1977; Sailor and Prussin 1980; Owen et al. 1981]. Recall from Sec. 9.5.5 that gridded ion chambers rely almost entirely on electron motion and can have better energy resolution than proportional counters. The lower electric fields used to operate gridded ion chambers reduce the electron velocities, and, consequently, increases dead time. The counting gas is commonly a mixture of different gases, including ^{3}He, Ar, and CH_4 [Owen et al. 1981). The results of Franz et al. [1977] and Owen et al. [1981] demonstrate the relatively good energy resolution that is achievable. An example neutron spectrum from a gridded ion chamber is shown in Fig. 18.38.

Although the recoil spectrum is complicated by the addition of other gases than ^{3}He, Owen et al. [1981] discuss unfolding methods that can be used to produce a neutron energy pulse height spectrum. Franz et al. [1977] list many difficulties encountered with these detectors, including distortions from the wall effect, proton recoil contributions (from the CH_4 in the gas mixture), interaction location dependent rise times, gamma-ray background, and microphonics. The thermal-neutron signal can be suppressed by inserting the ^{3}He detector into filter composed of cadmium and boron [Franz et al. 1977]. Such methods diminish the elastic scatter and thermal-neutron portion of the spectrum while preserving the full energy peak of the fast neutrons $(Q + E)$. With the techniques outlined in Franz et al. [1977], reasonably high energy resolution of complex fast neutron spectra can be achieved.

18.5.2 ^{6}LiI:Eu Scintillators

Scintillators can also be used as direct conversion detectors if at least one element in the scintillator compound produces spontaneous reaction products upon the absorption of a fast neutron. A drawback is that the most commonly used neutron absorption solid state materials, ^{6}Li and ^{10}B, have very reduced interaction cross sections in the fast neutron region.

Discussed in Chapters 13 and 17, and also previously in this chapter for moderated devices, the scintillator ^{6}LiI:Eu has also been applied directly for fast neutron measurements. The concept is similar to the use of ^{3}He as a fast neutron detector. Fast neutrons that directly interact ^{6}Li(n,t)^{4}He yield reaction products with a total Q-value of 4.78 MeV. The kinetic energy of the reaction is added to Q-value to produce a full energy

[12] The reference Shalev and Cuttler [1973] is the often quoted source of the cylindrical gridded ^{3}He chamber design. However, there is no mention of a grid in this paper, Frisch is not referenced, and the authors clearly refer to the device as a proportional counter and not a gridded ion chamber.

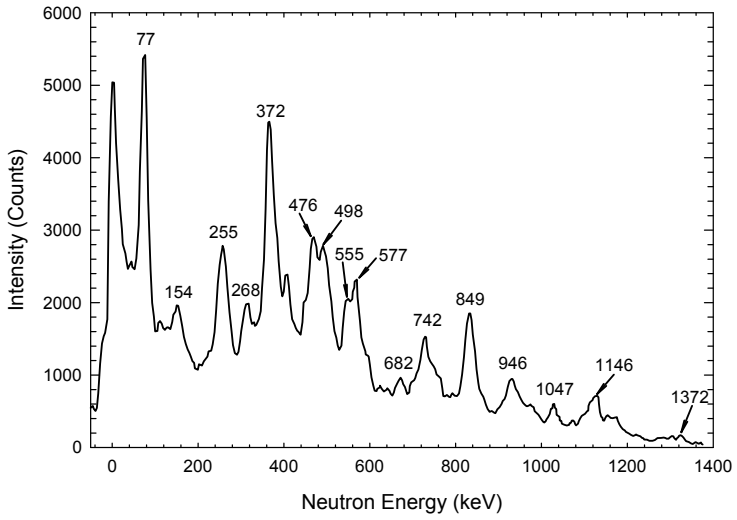

Figure 18.38. Delayed neutron spectrum from ^{137}I measured with a ^{3}He gas-filled gridded ion chamber. Data are extracted from [Franz et al. 1977].

of the reaction at $E+Q$. Murray [1958] and Johnson et al. [1969] describe competing fast neutron reactions that can complicate the spectrum. The spectrum is further confused by the intrinsic non-linear response of ^{6}LiI:Eu to fast neutrons at room temperature. Consequently, the energy resolution for fast neutrons in ^{6}LiI:Eu is relatively poor. Murray [1958] and Johnson et al. [1969] found that cooling the ^{6}LiI:Eu crystal to cryogenic temperatures, near that of liquid nitrogen, greatly improved both the linearity and resolution of the detector. Example pulse height spectra of fast neutrons (5.3 MeV) at different temperatures are shown in Fig. 18.39.

18.5.3 ^{6}Li Sandwich

Thermal-neutron detection with ^{6}Li foils or ^{6}LiF layers between detection media has been described thoroughly in Sec. 17.3.2. This "sandwich" structure, possibly first explored by Love and Murray [1961] is depicted in Fig. 18.40. It can also be used for fast neutron detection, although there are some notable differences in performance. Analysis of the detection efficiency for thermal neutrons is simplified by assuming that the reaction particle trajectories are emitted in opposite directions. However, for neutron energies above thermal (0.0259 eV), their kinetic energy must be added to the Q-value of the ^{6}Li(n,t)^{4}He reaction (see Problem 13). For slow neutrons, this added energy has little effect on the reaction product trajectories, so that the simplifying approximation that the reaction products are generally emitted in opposite directions can still be used. However, for epithermal and fast neutrons the emission angle between reaction products is less than 180°. The emission angle decreases as E increases and the reaction products are emitted increasingly in the general direction of the original incident neutron.

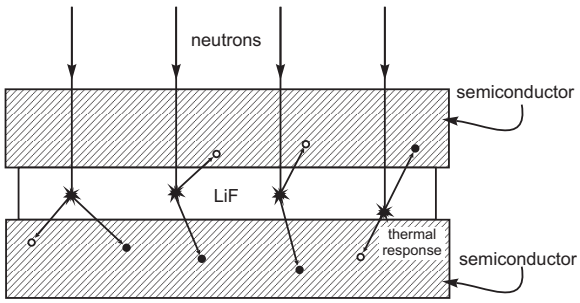

Figure 18.40. The LiF sandwich depicting possible reaction product trajectories for fast neutron interactions.

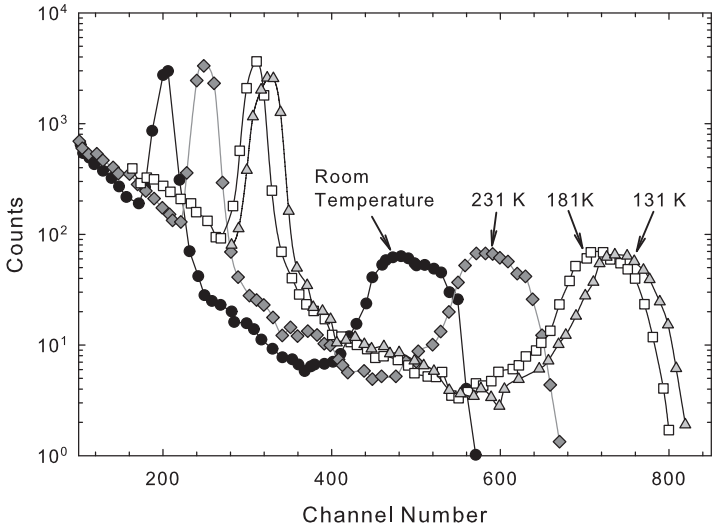

Figure 18.39. ^{6}LiI:Eu scintillator pulse height spectra at different temperatures for 5.3 MeV neutrons. The energy resolution of the full energy peak improves as the temperature is lowered, with FWHM of 18% (RT), 15% (231 K), 12% (181 K), and 10% (131 K). Data are extracted from [Murray 1958].

Background can be significantly discriminated from thermal-neutron detection by operating the two detectors in coincidence, but this operation comes at the expense of detection efficiency [McGregor et al. 2003]. Unfortunately, it can be an inefficient detection method for fast neutrons, mainly because the chance of coincidence decreases as the neutron energy increases. Because of energy self-absorption as the reaction products pass through the LiF foil, the total energy deposited in the detector has a broad spectrum instead of a single energy peak. This energy loss effect can be reduced by using LiF foils that are much thinner than the combined reaction product ranges, although this approach also reduces the efficiency [Dearnaley and Northrop 1966], which is further diminished by the reduced absorption cross section at high neutron energies. Detailed responses and efficiencies for a ^{6}Li sandwich structure are described by Rydin [1968].

Bishop [1968] and Silk [1968] report on results from a ^{6}LiF sandwich. Most of the calibrations were conducted with thermal neutrons, although both works report results from fast neutrons. In both cases, a thin LiF radiator produced higher resolution results, and produced rough neutron spectra from nuclear reactors. Rickard [1973] describes methods to improve the fast neutron energy resolution, using either a summing technique or isolating and measuring only the triton emission. Unfolding methods have also been employed to improve resolution [Seghour and Sens 1999]. The drawback to this particular use of semiconductors in a reactor environment is the rapid destruction of the semiconductor detector [Gersch et al. 2002].

Although gamma-ray interactions in low Z semiconductors (Si, SiC) are generally small, neutron events may not be easily discriminated from other possible radiations and interactions. Sources of background can also arise from direct interactions in the semiconductor. For instance, direct (n,p) reactions in Si produce energetic reaction products. Because these protons are released directly in the semiconductor, they do not suffer self-absorption effects. Consequently, the protons can produce pulses similar in magnitude to those produced by the ^{6}Li(n,t)^{3}H reaction [Rydin 1968]. This damage effect in silicon has been proposed as a possible fast-neutron dosimeter [Kramer 1966].

18.5.4 The Grey Detector

Closely related to the Hankins rem meter (or Bonner spheres) is the so-called "grey" detector [Pönitz 1968]. Recall that the Hankins rem meter is operated by moderating fast neutrons in a hydrogenous ball of material that, upon thermalization, could migrate to an internal thermal-neutron detector. The grey detector operates in a similar fashion, except that the neutron detector is removed. Instead, the thermalized neutron may be absorbed in the hydrogenous material, promptly emitting a 2.2-MeV gamma ray. A NaI:Tl detector placed adjacent to the moderator is used to detect these gamma rays, thereby yielding a measure of the neutron interactions. Pönitz [1968] assumes that (1) the moderating ball is of adequate size to moderate and absorb the neutrons with negligible leakage and (2) gamma rays escape the moderating material with no absorption. These two assumptions are valid for neutron energies ranging from thermal to 2 MeV for a moderator sphere (water or paraffin) between 20 and 25 cm diameter [Pönitz 1968]. The efficiency response for neutrons with energies from thermal to 2 MeV neutrons is relatively flat. However, for neutrons with higher energies, knowledge of the neutron leakage becomes increasingly important in order to determine the detector efficiency [Poenitz 1969].

18.5.5 Cryogenic Detectors

A low temperature solution to neutron spectroscopy was investigated by de Marcillac et al. [1993] and Richardson et al. [1998]. These devices are called both *bolometers* or *microcalorimeters* interchangeably, although there is a difference in function between the two (see Chapter 19). The difference between the two devices is that a bolometer measures the amount of radiation incident upon the device (similar to a current mode device), whereas a calorimeter measures the energy of individual interactions in the device (similar to a pulse mode spectrometer) [Kraus 1996]. In a bolometer the radiation absorber is attached to a thermally sensitive electronic component, typically a thermistor.[13] Both of these cryogenic detectors measure the thermal energy deposited in a low temperature (milli-Kelvin or mK) radiation absorber. The increase in heat in the absorber is converted into an electronic pulse, yielding a measure of the heat change and, thus, the energy deposited.

Bolometers for radiation detection are cryogenically cooled through a heat sink that returns the absorber and thermistor to the pre-irradiation equilibrium condition. A voltage is applied to the thermistor to produce a steady-state current. When radiation deposits energy in the absorber, the thermistor temperature increases, causing a change in current flow. This change can be measured as a current or voltage pulse, either being indicative of energy absorbed.

A microcalorimeter can be fashioned by attaching an absorber to a superconducting film. Below a specific transition temperature, the resistance of the superconductor is zero. If the temperature is set slightly below that temperature, then heat added to the system moves the superconductor above the transition temperature so it no longer has zero resistance. Consequently, current flow through the superconductor material now produces a voltage, which gives a measure of the energy deposited in the absorber. This type of calorimeter is called a transition edge superconducting (TES) spectrometer.

Bolometers and microcalorimeters have been demonstrated as functional neutron spectrometers [de Marcillac et al. 1993; Silver et al. 2002]. These devices work, usually, by attaching a material that incorporates either ^{6}Li or ^{10}B to a thermally sensitive electronic device. For either coating, the neutron reaction results in energy deposition of the Q-value plus the neutron kinetic energy. The work of de Marcillac et al. [1993] describes the use of a 2-g sample of ^{6}LiF operated below 100 mK and describes the difference in response for different ionizing particles. Measured results indicated that the (n,α) reaction produced counts in a lower energy channel than anticipated from calibrations with monoenergetic alpha particles.

[13] A type of resistor in which the resistance is a function of the temperature.

Neutron sensitive bolometers or microcalorimeters use energetic neutron reactions to deposit energy in the absorber, most commonly the ^{6}Li(n,t)^{4}He and the ^{10}B(n,α)^{7}Li reactions. While the work by de Marcillac et al. [1993] focused on the use of LiF as the absorber, Richardson et al. [1998] investigated the use ^{6}LiPb as an absorber for a neutron bolometer. In both studies, thermal neutrons were the radiation of interest. Energy resolution as low as 16 keV FWHM was observed for a 2-g sample of LiF operated at 10 K [de Marcillac et al. 1993; Silver et al. 2002] also report on an optimization study with enriched ^{6}LiF as a thermal-neutron detector, the largest sample being 1 cm^3. The best results were obtained from the smaller sample, $4 \times 4 \times 2$ mm^3 and produced an energy resolution of 39 keV FWHM with pulses having a 80 μs rise time and 3.1 ms decay time.

Niedermayr et al. [2004] investigated the ^{10}B(n,α)^{7}Li reaction with a TiB_2 calorimeter, and also the ^{6}Li(n,t)^{4}He reaction with ^{6}LiF bolometers [Niedermayr et al. 2007; Hau et al. 2006]. Although the purpose of exploring TiB_2 as a TES microcalorimeter was to produce a fast neutron spectrometer, Niedermayr et al. [2004] describe results only for thermal-neutron reactions and report 10.5 keV FWHM for the excited state (2.31 MeV) and 5.5 keV FWHM for the ground state (2.792 MeV).

Fast neutron spectroscopy was explored by Hau et al. [2006] with ^{6}LiF samples, in which fast neutrons of energy E deposit total energy of $E_{total} = E + Q$ in the absorber. Energy resolution of 55 keV FWHM was reported for thermal neutrons. Spectra were also reported for a ^{252}Cf source. There was a clear spectral separation between neutron absorption events and the other events resulting from either elastic scattering or gamma-ray interactions. A single elastic recoil from ^{6}Li can, at most, deposit only $0.49E$. The residual energy can be recovered if the scattered neutron is subsequently absorbed. Otherwise, a substantial gap appears between the elastic scatter spectrum and the absorption spectrum. A similar situation occurs for gamma-rays, mainly because they most likely interact in the LiF crystal through Compton scattering, thereby also depositing only a fraction of their energy. Also, Hau et al. [2006] note that certain features in the absorption pulse height spectrum reflect the energy dependence of the ^{6}Li(n,t)^{4}He energy-dependent microscopic absorption cross section. Niedermayr et al. [2007] expand on the ^{6}Li fast neutron detection by describing a simple unfolding method to recover the actual energy distribution from the neutron source, which can be quite different from the elastic scattering or absorption spectrum.

Merlo et al. [2015] describe a TES microcalorimeter made of a Nb strip coated with 450 nm of natural boron. The difficulty with this structure is similar to that of a thin neutron absorbing detector [McGregor and Shultis 2004], namely, the absorber is too thin to (efficiently) absorb the total Q-value energy of the (n,α) reaction or that of a fast neutron. Consequently, the device may operate as a neutron counter, but not as a neutron spectrometer. Shishido et al. [2017] expand on this same concept by applying ^{10}B to a serpentine Nb superconducting electrode. Instead of using the TES method, Shishido et al. [2017] use another superconducting phenomenon, in which energy deposited in the superconductor causes a change in the magnetic inductance by a decrease in the Cooper pair density.[14] This device, called a microwave kinetic inductance detector (MKID), allows the position of interacting neutrons to be determined in one dimension along the serpentine pattern, reportedly with 1.3 mm spatial resolution.

18.5.6 Foil Activation Methods

One of the earliest methods for determining the energy dependence of the neutron field was the placement of different foils in the neutron field, and from the activity produced in the irradiated foils, the energy spectrum of the neutrons could be inferred. One of the earliest publications on the subject [McElroy et al. 1967] used a hand analysis to analyze the foil data. Because each foil material has cross sections with different energy dependence, the activation of each foil changes as the neutron spectrum changes. In Sec. 17.8 a detailed description of how a gold foil, bare and cadmium covered, can be used to determine characteristics of a

[14] Cooper pairs are the fundamental conduction mechanism in superconductors. See Cooper [1956] and also Ogg [1946].

typical neutron spectrum from a thermal reactor. In this section it is seen that the use of multiple foils can be used to determine a neutron energy spectrum in a way that is very similar to that used by the Bonner spheres. In fact, unfolding Bonner sphere measurements is exactly the same as unfolding foil activities and the same unfolding algorithms have been used for both.

The term foil as used here can be in various forms: powder, wires, or actual metallic foils although they are "small" to reduce self-absorption effects and to give good spatial resolution. For fluxes that have high energy neutrons, materials that have threshold cross sections are attractive. Typically ten or so different foils are used and activities are measured when the foils are irradiated, both when bare and when covered by some slow neutron filter material (typically, cadmium or gold). There appears to be no best set of foils to use in all situations. Some widely used foil reactions are listed in Table 18.2.

18.5.7 The Foil Inversion Problem

With the method discussed in Sec. 17.8.2, the saturation activity can be determined by counting the radiation emitted by a particular radioisotope produced by the neutron irradiation of a foil. Usually a gamma ray of a well-defined energy is counted, although beta-particle counting is also sometimes used. Division by the number of activation target atoms that are in the foil gives the specific saturated activity A_i per target atom at infinite dilution (so the burnup of the activation product can be ignored) for the ith activation reaction. Further, this specific activity is corrected for self-shielding and flux depression. This activity is given by the Fredholm integral equation

$$A_i = \int_0^\infty R_i(E)\phi(E)\,dE \qquad i = 1, \ldots, N. \tag{18.53}$$

Here $\phi(E)$ is the energy dependent flux at the point of interest and the response function is

$$R_i(E) = \sigma_i(E)\exp[-N_c x_c \sigma_c(E)], \tag{18.54}$$

where $\sigma_i(E)$ is the microscopic activation cross section for the ith reaction. The exponential term accounts for a cover material, such as cadmium, placed around the foil to suppress activation by thermal or epithermal neutrons. The cover has an atom density of N_c, thickness x_c, and absorption cross section $\sigma_c(E)$. For a bare foil $x_c = 0$ and the exponential term in Eq. (18.54) is absent.

Estimation of the Energy-Dependent Flux

In principle, any method used to solve the Bonner sphere problem of Eqs. (18.9) can be used to invert the foil activation problem. A general overview is provided by Cross and Ing [1987]. Here the basis of the SAND-II code [McElroy et al. 1969] is reviewed because it was the first code upon which many subsequent codes with minor algorithmic changes and additional features, such as enhanced error analysis, are based. To convert Eqs. (18.53) a contiguous energy grid E_j, $j = 1, \ldots, M$ is defined such that $\phi(E) = 0$ if $E < E_1$ or $E > E_M$. The grid spacing is $\Delta_j = E_{j+1} - E_j$. In SAND-II, 620 energy intervals are used covering the range 10^{-10} to 18 MeV (45 intervals per decade up to 1 MeV and 170 intervals between 1 and 18 MeV).

Equations (18.53) can be written as

$$A_i = \sum_{j=1}^{M} \int_{E_j}^{E_{j+1}} R_i(E)\phi(E)\,dE \equiv \sum_{j=1}^{M} A_{ij} \qquad i = 1, \ldots, N. \tag{18.55}$$

The solution procedure begins by assuming an initial flux guess ϕ_j^0, $E_j \le E_{j+1}$ and then this flux is refined iteratively ϕ_j^k, $k = 1, 2, \ldots, K$ by making the *calculated* partial activities A_{ij}^k, which depend on ϕ_j^k, to agree with the *measured* activities A_i to within some specified tolerance. To calculate the activity, it is first assumed

Table 18.2. Some activation foils used for thermal- and fast-neutron measurements. Most foils are irradiated with Cd, Au, or ^{10}B covers to suppress contributions from thermal and epithermal neutrons.

Element	Reaction	Nat. abundance	Threshold energy (MeV)	γ-rays (MeV) [yield %]	Half-Life

	^{46}Ti(n,p)^{46}Sc	8.25	1.619	0.8896 [99.98] 1.211 [99.98]	83.81 d
	^{48}Ti(n,p)^{48}Sc	73.72	3.274	0.9835 [100.0] 1.0375 [97.5] 1.3121 [100.0]	43.7 h
U	^{238}U(n,f)^{140}La	99.27	–	1.5962 [95.5]	1.678 d
	^{238}U(n,f)^{140}Ba	99.27	0	0.5373 [23.5]	12.75 d
Zr	^{90}Zr(n,2n)^{89}Zr	51.45	12.102	0.9091 [99.04]	3.27 d

the cross sections are constant over an energy interval, i.e.,

$$\overline{\sigma}_{ij} \simeq \frac{1}{\Delta_j} \int_{E_j}^{E_{j+1}} \sigma_i(E)\, dE. \tag{18.56}$$

Likewise the cover cross section is a constant $\overline{\sigma}_c$ over each energy interval. Thus for the k iteration

$$A_{ij}^k = \overline{\sigma}_{ij} \exp[-N_c x_c \overline{\sigma}_{cj}] \phi_j^k \Delta_j = \overline{R}_{ij} \phi_j^k \Delta_j, \tag{18.57}$$

from which the calculated activity A_i for the ith reaction is found from Eq. (18.55).

To update the flux profile, two parameters are used: an activity weighting term $W_{ij} = A_{ij}^k / A_j^k$ and a so-called activity-weighted correction term

$$C_j^k = \frac{\sum_{i=1}^N W_{ij}^k \ln(A_i / A_i^k)}{\sum_{i=1}^N W_{ij}^k}. \tag{18.58}$$

The next estimate of the flux is then computed as

$$\phi_j^{k+1} = \phi_j^k \exp(C_j^k). \tag{18.59}$$

This iterative procedure is continued until the standard deviations of the ratios of measured to calculated activities is less than some specified value. There is also a foil discard test such that if the measured activity of a particular reaction deviates more than some specified number of standard deviations from the calculated value that foil is removed and another solution without that foil is obtained.

The background and methodology of the SAND-II code has been extensively studied (see references cited by McElroy et al. [1969]). There are many other unfolding methods and codes available, some of which are reviewed by Moghari [1979].

18.6 Summary

In this chapter many different types of fast neutron detectors have been briefly described. The detection of fast neutrons is accomplished by using one of the following three techniques. (1) The fast neutrons are first moderated to lower energies and those that become thermalized are detected using thermal neutron detectors. Bonner spheres and rem balls are examples of fast neutron detectors based on the moderation principle. (2) Charged recoil atoms produced by fast neutron scattering can be measured in charged particle detectors. This technique is the basis for many types of recoil spectrometers. (3) Finally, fast neutrons can often produce nuclear reactions not possible with thermal neutrons and products of these fast neutron interactions can often be measured and the fast neutron flux can be inferred. Foil activation methods typify the use of this method to distinguish neutrons with a wide range of energies.

In almost all of these detectors indirect information about the energy dependence of the neutron field is obtained and, hence, they can also be used as neutron energy spectrometers and not just detectors. However, their use as energy spectrometers is not as straightforward as, say, with gamma-ray spectrometers where full energy peaks in the output pulse height spectrum immediately give the energies of incident monoenergetic gamma rays. The output spectrum from neutron spectrometers, by contrast, is not easy to interpret for two main reasons. First, most neutron fields have a continuum of neutron energies without any superimposed monoenergetic peaks. Second, the output pulse height spectrum from a fast neutron spectrometer often bears little resemblance to the neutron spectrum. Consequently, the output must be post-processed or unfolded to recover energy information about the incident neutrons. In fact, the output from any radiation spectrometer needs to be unfolded to recover *all* details of the energy dependence of the incident radiation. Although a

few brief discussions are given in this chapter about the unfolding or deconvolution of the output from fast neutron devices, the general topic of unfolding is worthy of several chapters, or even a book, to be treated thoroughly.

PROBLEMS

1. For $A = 1$, show that Eq. (18.2) implies that $\theta_c = 2\theta_s$.

2. Determine the thermal neutron absorption length for a ^{3}He gas-filled detector pressurized to 4 atm. If the detector is 1 inch in diameter (2.54 cm), what is the maximum attenuation for a beam of neutrons intersecting perpendicularly the tube cross section?

3. You have a $^{10}BF_3$ detector built from a 25 mm diameter (I.D.) Al tube, backfilled with 0.2 atm of $^{10}BF_3$ and 2 atm of Ar gas. If a 0.5 cm diameter thermal neutron (2200 m s^{-1}) beam intersects through the detector mid-section, what is the expected intrinsic thermal neutron detection efficiency?

4. Given a a thermal neutron beam (0.025 eV) intersecting a 10-mm-thick

5. sample of CLYC:Ce, determine the intrinsic thermal neutron detection efficiency of the CLYC:Ce sample. If the natural Li is replaced with 96% enriched ^{6}Li, what is the new thermal-neutron detection efficiency?

6. Plot ω_c versus the corresponding ω_s for $A = 1$, 2, 4, 10, 50, 100, and 200. What does this graph reveal about the center of mass and laboratory coordinate systems as A becomes large?

7. The speed of the K-shell electrons in ^{4}He, as given by the Bohr model [Shultis and Faw 2016] as $v_K = e^2/(\epsilon_o h)$. Compare this speed to that of a 4-MeV recoil ^{4}He atom. At this recoil speed, the shake-off effect has removed almost all of the electrons from the helium, so that a 4-MeV ^{4}He beam in gas has about an average charge of $+1.99e$ per atom [Evans 1955].

8. Derive Eq. (18.24) from Eq. (18.23).

9. Derive Eq. (18.27).

10. Consider a general binary nuclear reaction X(x,y)Y and use the conservation of energy and momentum constraints, as used in Chapter 4, to show

$$\sqrt{E_y} = \sqrt{\frac{m_x m_y E_x}{(m_y + m_Y)^2}}\,\omega_y \pm \sqrt{\frac{m_x m_y E_x}{(m_y + m_Y)^2}\omega_y^2 + \left[\frac{m_Y - m_x}{(m_y + m_Y)}E_x + \frac{m_Y Q}{(m_y + m_Y)}\right]},$$

where the Q-value is

$$Q = (m_x + m_X - m_y - m_Y)c^2.$$

11. From the previous problem for exoergic reactions $Q < 0$, show the kinematic threshold for this reaction is

$$E_x^{th} = -\frac{m_y + m_Y}{m_y + m_Y - m_x}Q \simeq \left(1 + \frac{m_x}{m_X}\right)Q.$$

12. Find the Q-values and threshold energies for the reactions (a) $^{12}C(n,\alpha)^9Be$ and (b) $^{12}C(n,n)3\alpha$. The threshold energies can be calculated from Eq. (4.46) and from the formula developed in the previous problem.

13. From the result of Problem 18-9 show that for exoergic reactions ($Q > 0$) as $E_x \to 0$

$$E_y = \frac{m_Y}{m_y + m_Y} Q \qquad \text{and} \qquad E_Y = \frac{m_y}{m_y + m_Y} Q,$$

so that

$$Q = E_y + E_Y.$$

14. The energetics of the ^{6}Li(n,t)^{4}He reaction are given in Sec. 17.2.3 for a thermal neutron. If the same reaction is caused by a 1-MeV neutron, what are the kinetic energies of the reaction products? As the energy of the neutron increases, how does the angle between the reaction products change?

Chapter 19

Luminescent, Film, and Cryogenic Detectors

The crystals were swallowed by the patients, recovered one or two days later, and the accumulated dosage in roentgens was measured by matching the thermoluminescence intensity with that produced in the crystals by a known roentgen dosage.

Farrington Daniels

19.1 Luminescent Dosimeters

A luminescent dosimeter is a type of phosphorescent detector that can store energy information for extended periods of time. This passive readout detector has the property of storing electronic charges in deep traps that are later depopulated with an intentional and controlled sampling method. Hence, a luminescent detector is a type of integrating dosimeter. Typically, the device can be reused after the reading of the accumulated dose is complete. Luminescent dosimeters are popular for radiation dosimetry because of their wide sensitivity range, compact size, linear response to radiation, relative energy independence, and their reusability. However, because a readout system is required to obtain doses from these dosimeters, they cannot provide immediate dose information. Further, once read, the accumulated dose is effectively erased and, consequently, there is no permanent record.

19.1.1 Thermoluminescent Dosimeters

Thermoluminescence (TL), as the name implies, is the release of photons from a substance when heat is applied. The time when thermoluminescence was discovered is unknown, although the phenomenon was recorded in alchemist texts dating back at least to 1602 [Arnold 1991]. The first scientific report on thermoluminescence was presented by Robert Boyle in 1663 to the Royal Society of London [Becker 1973], where he described glimmering light from diamond samples when heated. TL was first used as early as 1895 by Weidemann and Schmidt to detect ionizing radiation. Hence, the thermoluminescent phenomenon has been known for quite a while.

The physical aspects of thermoluminescence were studied by many researchers after the pioneering work of Weidemann and Schmidt, and include, for example, work by Randall and Wilkins [1945], Boyd [1949], and numerous references provided in Becker [1973] and Horowitz [1984a]. However, it was not until 1954 that Farrington Daniels, after studying the radiation effects of thermoluminescent minerals [Daniels et al. 1949; 1953; Daniels and Saunders 1950; see also Boyd 1949; Saunders et al. 1953], suggested the use of thermoluminescent materials, particularly LiF, as dosimeters [Morehead and Daniels 1957; Cameron 1991]. Several additional thermoluminescent materials have since been studied as dosimeters as well, including CaF_2, $CaSO_4$, and $Li_2B_4O_7$ [Kossel et al. 1954; Ginther and Kirk 1957; Hecklesberg and Daniels 1957; Schulman et al. 1967].

General Operation

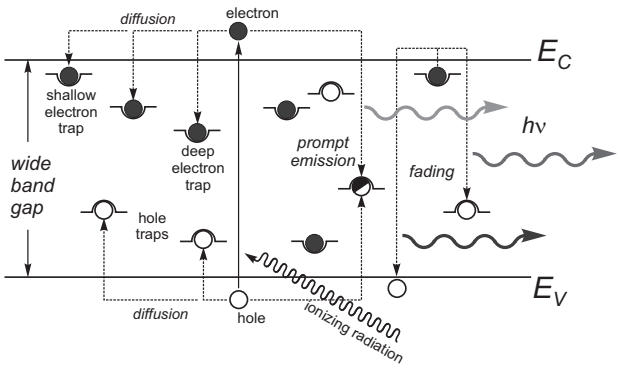

Figure 19.1. Band diagram depicting electronic trapping and emission during the irradiation and storage time.

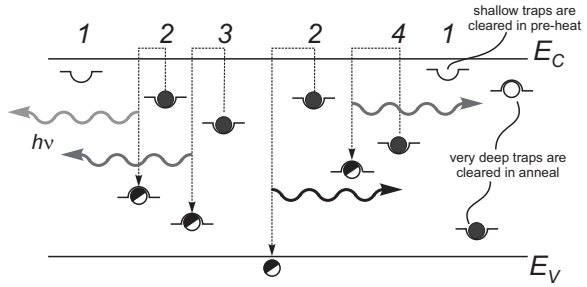

Figure 19.2. Band diagram depicting detrapping and emission during the heating time. The shallow traps (1) are emptied during the preheat phase. After preheat, the PMT counter is activated and the total photon yield is integrated as the traps release charges in order of trap energy (2, 3, and 4). These deeper traps are used to provide a reading of the accumulated dose. After the read time, the counter is deactivated and the TLD temperature is increased to release charges from the deepest traps.

Thermoluminecesnce involves two main processes: (1) radiation absorption with subsequent electron trapping, and (2) electron and hole recombination with light emission. During the absorption process, TL materials absorb energy from ionizing radiation and excite electron-hole pairs. These electrons and holes diffuse through the crystal, much as they do in a scintillator, and during their migration they can recombine or fall into electronic traps located in the band gap (see Fig. 19.1). However, unlike scintillators that rapidly release photons via *fluorescence*, thermoluminescent materials undergo a delayed release of photons and should more correctly be referred to as *phosphorescence*. The phosphorescence emission time is a function of the trap energy. Shallow traps tend to release charge carriers in a relatively short period of time while deep traps can retain charge carriers for long periods of time, in some cases for many decades. These storage traps can be designed into the material by adding select amounts of specific impurities.

If the trap is unstable, or shallow, recombination may occur at room temperature, an effect often termed as "fading". However, the stable deeper traps retain charge carriers provided that they do not absorb enough energy to excite the electrons or holes back into the conduction or valence bands, respectively. When energy is deposited in a TL material, trapped electrons and holes may acquire sufficient energy to be dislodged and allow them to return to the conduction or valence bands, respectively, and then rapidly recombine at a luminescent center. As these electrons and holes recombine, the excess energy is released as UV or visible light as shown in Fig. 19.2. By recording the number of photons released with a light sensor (such as a photomultiplier tube), the number of trapped charges can be measured. Ultimately, the total number of photons detected gives a measure of the sample radiation dose.

The governing differential equations that predict the dynamic behavior of a TLD are generally coupled and non-linear. Only for simple models, and even then with restrictive assumptions, are analytic solutions possible. Nevertheless, much can be learned from these simple models. Below a few simple TLD dynamic models are summarized.

Modeling the Thermoluminescence Intensity

Randall and Wilkins [1945] proposed a model for luminescent output from a thermoluminescent dosimeter (TLD).[1] In their model all of the electron traps are at a single energy E_t below the conduction band. The

[1] See also Garlick and Wilkins [1945].

probability per unit time of releasing an electron from a trap back to the conduction band is

$$p = \overline{\omega} \exp\left[\frac{-E_t}{kT}\right], \qquad E_V < E_t < E_C, \tag{19.1}$$

where $\overline{\omega}$ is a *frequency factor* associated with the trap, and k and T have their usual meanings. Randall and Wilkins [1945] explain that the trapped electron is like a particle in a potential box and that the frequency factor $\overline{\omega}$ is the product of the frequency with which the electron strikes the sides of the box times the Mott and Gurney [1948] reflection coefficient. Alternatively, $\overline{\omega}$ can be thought of as the frequency with which a trapped electron interacts with the lattice phonons times a transition probability. The frequency factor $\overline{\omega}$ can never be greater than the lattice vibrational frequency and is usually several orders of magnitude less than this limiting frequency, i.e., $\overline{\omega} \ll 10^{13}$ s^{-1} [Mott and Gurney 1948; Randall and Wilkins 1945].

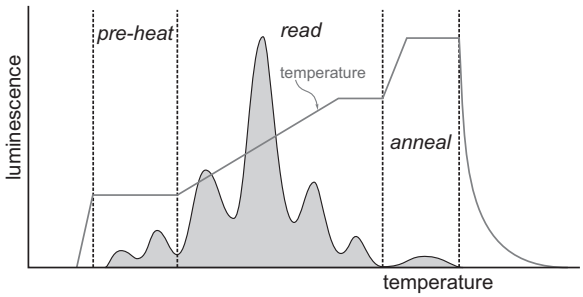

Figure 19.3. Depiction of a temperature-dependent glow curve from a TLD with multiple trap energies, showing the three regions of operation for the TLD reader.

If $N_{te}(t)$ is the density of electrons located in traps at time t, then the average number of trap releases per unit time per unit volume is $N_{te}(t)p$ or

$$-\frac{dN_{te}(t)}{dt} = N_{te}(t)\overline{\omega} \exp\left[\frac{-E_t}{kT}\right]. \tag{19.2}$$

If the emitted electrons are not retrapped, then the intensity of the thermoluminescent glow is proportional to the electron release rate, i.e.,

$$I(t) = -C\frac{dN_{te}(t)}{dt} = CN_{te}(t)\overline{\omega} \exp\left[\frac{-E_t}{kT}\right], \tag{19.3}$$

where C is a constant describing the luminescent efficiency and volume of the TLD. If the TLD is heated at a uniform rate

$$R_T = \frac{dT}{dt}, \tag{19.4}$$

the independent variable t can be replaced by T through $dt = (1/R_T)\,dT$ so that Eq. (19.3) can be written as

$$\frac{dN_{te}(T)}{N_{te}(T)} = -\frac{\overline{\omega}}{R_T} \exp\left[\frac{-E_t}{kT}\right] dT. \tag{19.5}$$

If $N_{te}(T_0)$ is the density of electrons in traps at time t_0 and temperature T_0, then Eq. (19.5) can be integrated to find

$$\ln\left[\frac{N_{te}(T)}{N_{te}(T_0)}\right] = -\frac{\overline{\omega}}{R_T}\int_{T_0}^{T} \exp\left[\frac{-E_t}{kT'}\right] dT'. \tag{19.6}$$

Substitution of the result of Eq. (19.6) into Eq. (19.3) yields

$$\begin{aligned} I(T) &= -C\frac{dN_{te}(t)}{dt} = -C\frac{dN_{te}(T)}{dT}\frac{dT}{dt} = -C\frac{dN_{te}(T)}{dT}R_T \\ &= N_{te}(T_0)C\,\overline{\omega} \exp\left[\frac{-E_t}{kT}\right] \exp\left[-\frac{\overline{\omega}}{R_T}\int_{T_0}^{T} \exp\left[\frac{-E_t}{kT'}\right] dT'\right]. \end{aligned} \tag{19.7}$$

Equation (19.7) describes the emission of a temperature-dependent *glow curve* of a TLD. Figure 19.3 shows a typical glow curve for a TLD with multiple trap energies and Fig. 19.4 shows results for the above model of a

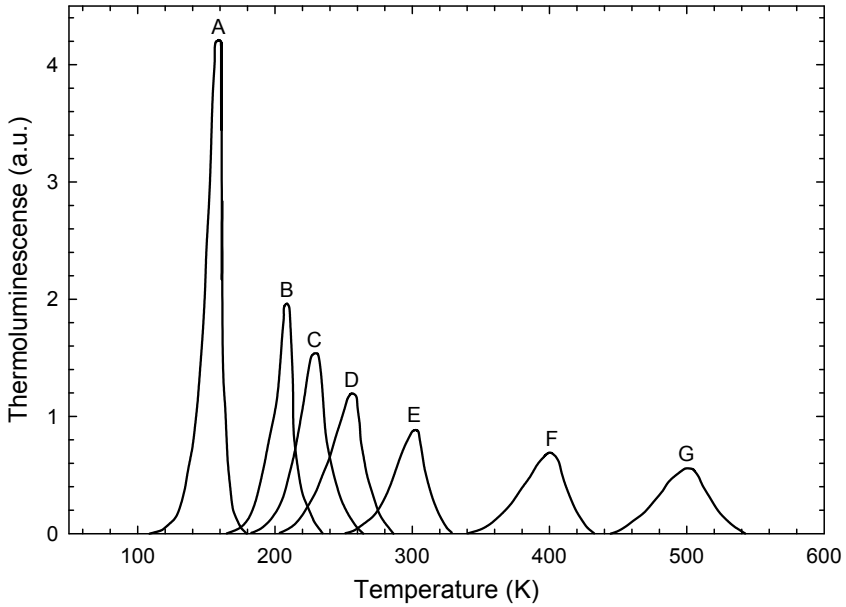

Figure 19.4. Theoretical glow curves versus temperature for phosphors with a single trap level, assuming no retrapping of electrons, after irradiation at $T = 90$ K with $R_T = 2.5$ °C/sec. Parameters for the various cases are:

(A) $E_t = 0.3$ eV, $\overline{\omega} = 10^9$ s^{-1}; (B) $E_t = 0.4$ eV, $\overline{\omega} = 10^9$ s^{-1}
(C) $E_t = 0.4$ eV, $\overline{\omega} = 10^8$ s^{-1}; (D) $E_t = 0.4$ eV, $\overline{\omega} = 10^7$ s^{-1}
(E) $E_t = 0.6$ eV, $\overline{\omega} = 10^9$ s^{-1}; (F) $E_t = 0.8$ eV, $\overline{\omega} = 10^9$ s^{-1}
(G) $E_t = 0.4$ eV, $\overline{\omega} = 10^6$ s^{-1}

After Garlick and Gibson [1948].

TLD with a single trap energy. The maximum intensity $I_{\max}$ for a glow peak can be found by differentiation of Eq. (19.7) with respect to T and setting the result to zero. In this manner, the temperature T_m at peak luminosity is found from the relationship

$$\frac{E_t}{kT_m^2} = \frac{\overline{\omega}}{R_T} \exp\left[\frac{-E_t}{kT_m}\right]. \tag{19.8}$$

There are several properties that can be gleaned from Eq. (19.7) and Eq. (19.8) [Garlick 1949]. First, the temperature of the glow peak maximum increases with E_t for constant values of $\overline{\omega}$ and R_T. Second, as the heating rate R_T is increased or the value of $\overline{\omega}$ is decreased, the glow peak shifts to higher temperatures for constant values of E_t. For any constant value of filled trap states $N_{te}(T_0)$, the total luminosity, the area of the glow curve, should remain constant, although the shape changes with $\overline{\omega}$, E_{te}, and R_T. Finally, at low temperatures ($T \ll T_m$), the initial portion of the glow curve should follow the prediction of Eq. (19.3).

Schayes and Brooke [1963] derived an expression for the maximum luminosity that includes the effects of total dose and heating rate,

$$I_m \simeq \frac{k}{E_t} R_T N_{te}(t_0) \left[\frac{e^{-1+2u^*-6(u^*)^2}}{(u^*)^2}\right], \tag{19.9}$$

where the dimensionless temperature at the glow curve maximum is $u^* = (kT_m)/E_t$. From Eq. (19.9), it would seem that the maximum output intensity would remain constant provided that the radiation exposure

is adjusted to be proportional to $1/R_T$. In other words, if N_{te} is linearly adjusted to exactly counter the effect of R_T, the glow peak maximum output is constant. These predictions were tested with experiments performed by Gorbics et al. [1969], in which glow curves were measured for CaF_2:Mn, natural fluorite, LiF (TLD-100), $CaSO_4$:Mn, $Li_2B_4O_7$:Mn, and lithium aluminosilicate (LAS) glass. The glow curves were obtained at different heating rates for different gamma-ray exposures. The important results indicate that thermal quenching occurs for rapid heating rates, consequently reducing the total light yield and maximum light intensity. Shown in Fig. 19.5 and Fig. 19.6 are temperature and time dependent glow curves, respectively, for CaF_2:Mn (TLD-400) at several different heating rates. The TLDs were exposed to gamma rays from ^{60}Co for a time proportional to $1/R_T$. The results should yield identical peak maxima but, as can be seen from the results of Fig. 19.5 and Fig. 19.6, do not. The deviation from Eq. (19.9) is a consequence of TLD *thermal quenching* [Gorbics et al. 1969].

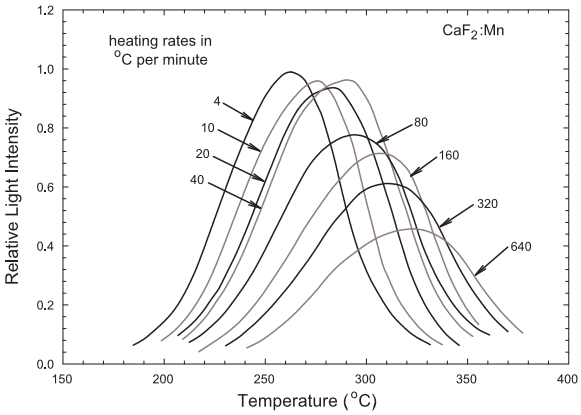

Figure 19.5. Glow curves versus temperature for CaF_2:Mn for eight different heating rates. For each case the gamma-ray exposure was adjusted to be proportional to $1/R_T$, an adjustment which should lead to a nearly constant glow curve maximum given by Eq. (19.8). Data are from Gorbics et al. [1969].

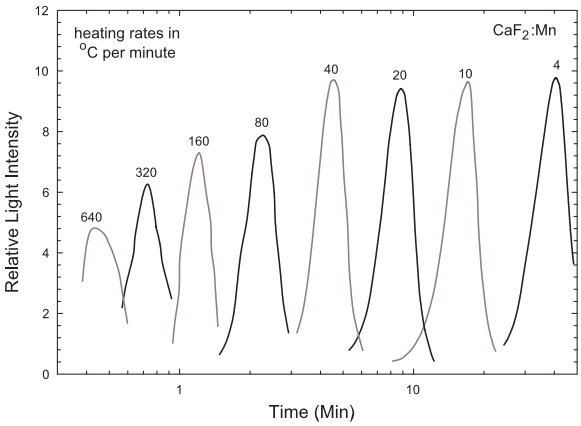

Figure 19.6. Glow curves versus time for CaF_2:Mn for eight different heating rates. For each case the gamma-ray exposure was proportional to $1/R_T$. Data are from Gorbics et al. [1969].

Attix [1986] points out a few other properties that can be seen from the results of Fig. 19.5 and Fig. 19.6. First, the length of time required to reach the glow peak maximum is nearly inversely proportional to the heating rate. Second, for heating rates below 40°C per min, the glow curve areas, as a function of temperature, are nearly identical. Yet, the dose for these glow curves was decreased by a factor of 10 as the heating rate was increased from 4°C per min to 40°C per min. At heating rates greater than 40°C per min, the glow curve area is observed to decrease. Third, the glow curve area as a function of time is observed to be nearly proportional to the dose for heating rates less than 40°C per min. Fourth, the glow curve peak temperature increases with heating rate. Finally, for CaF_2:Mn, the temperature for the onset of thermal quenching was approximately 290°C. Overall, for dosimetry purposes, it was concluded by Attix that the total light emission over time is a superior dose metric, compared to the light emission maximum, because there is a smaller error associated with fluctuations in the heating rate.

For most TLDs there are numerous levels of electron and hole traps that are mostly designed into the TLD by purposely adding dopants that act as traps and luminescent centers. The photons emitted from the multiple traps can be added to produce the total luminescent glow. Hence, the glow curve is described by [Leverenz 1950],

$$I(T) = \sum_{i=1}^{M} N_{te}^i \overline{\omega}^i C^i \exp\left[-\frac{E_t^i}{kT}\right] \exp\left[-\frac{\overline{\omega}^i}{R_T}\int_{T_0}^{T} \exp\left[-\frac{E_t^i}{kT'}\right] dT'\right], \tag{19.10}$$

where the superscript i identifies the trap and properties and M is the number of different trap levels. Luminescent centers that are close in energy may not be resolved and, thus, cause the appearance of asymmetric and wider glow peaks.

For the derivation of Eq. (19.7), Randall and Wilkins [1945] assumed that no electron retrapping occurred once excited from traps. Garlick [1949] considered a simplistic case for retrapping, for which detrapped electrons have equal probability of falling into either luminescent centers or empty trapping centers. For simplicity, assume that the material has one type of trapping center distributed uniformly with density N_t. Further, it is assumed that there are no empty luminescent centers[2] in the unexcited phosphor. The density of filled trapping centers is N_{te} and the density of empty trapping centers is N_{t0}; hence

$$N_{t0} = N_t - N_{te}. \tag{19.11}$$

If the material is an insulator, and most TLD materials are, the density of electrons in the conduction band should be considerably less than the density of trapped electrons N_{te}. Heating causes centers to depopulate so they become a source of electrons for the traps. Hence, the density of trapped electrons becomes the same as the density of empty luminescent centers ($N_{te} = N_{\ell 0}$).[3]

For a density of electron-filled traps of N_{te}, the probability that a detrapped electron falls into a luminescent center, which has a density of $N_{\ell t}$, is

$$p = \frac{N_{te}}{N_{t0} + N_{\ell 0}} = \frac{N_{te}}{(N_t - N_{te}) + N_{te}} = \frac{N_{te}}{N_t}. \tag{19.12}$$

Equation (19.12) indicates that when few traps are populated, then there is a low probability that detrapped electrons recombine at luminescent centers. Further, if the traps are completely populated, i.e., $N_{te} = N_t$, a detrapped electron has no option but to recombine at a luminescent center. From this interpretation, Eq. (19.2) is modified to

$$-\frac{dN_{te}(t)}{dt} = \frac{N_{te}(t)^2}{N_t}\overline{\omega}\exp\left[\frac{-E_t}{kT(t)}\right]. \tag{19.13}$$

Note that it is assumed in Eq. (19.12) and Eq. (19.13) that the capture probabilities of the trap and luminous centers are equal, but this is an assumption that may not be true.

To solve the above separable differential equation, first change the independent variable to T with the use of Eq. (19.4). The solution is

$$N_{te}(T) = \left\{\frac{1}{N_{te}(T_0)} + \frac{1}{N_t}\int_{T_0}^{T}\frac{\overline{\omega}}{R_T}\exp\left[-\frac{E_t}{kT'}\right]\,dT'\right\}^{-1}. \tag{19.14}$$

From this result the thermoluminescent intensity I as a function of temperature, which is increased at a uniform rate [Garlick and Gibson 1948], is

$$I(T) = -C\frac{dN_{te}}{dt} = -C\frac{dN_{te}}{dT}\frac{dT}{dt} = \frac{C\dfrac{N_{te}(T_0)^2}{N_t}\overline{\omega}\exp\left[\dfrac{-E_t}{kT}\right]}{\left[1 + \dfrac{N_{te}(T_0)}{N_t}\displaystyle\int_{T_0}^{T}\frac{\overline{\omega}}{R_T}\exp\left[\frac{-E_t}{kT'}\right]\,dT'\right]^2}. \tag{19.15}$$

[2] An imperfection in the crystal responsible for luminescent emissions. In the present case, these imperfections are hole traps. When occupied by an electron, they are not capable of producing light from recombination. If the electron is excited from the center, then it is effectively occupied by a hole. An electron recombining with a hole at the luminescent center releases a photon.

[3] Garlick and Gibson [1948] appear to use the condition that the only significant source of trapped electrons is from depopulated luminescent centers.

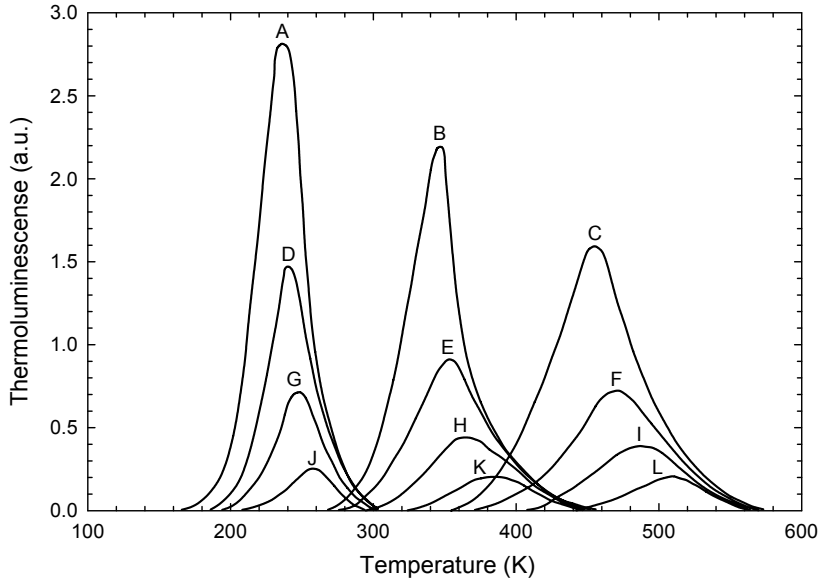

Figure 19.7. Theoretical glow curves versus temperature for phosphors with a single trap level, including the effects of electron retrapping, after irradiation at $T = 90$ K with $R_T = 2.5$ °C/sec and $\overline{\omega} = 10^9$ s^{-1}. Parameters for the various curves are as follows:

(A) $E_t = 0.4$ eV, $N_{te}(0) = N_T$ (B) $E_t = 0.6$ eV, $N_{te}(0) = N_T$
(C) $E_t = 0.8$ eV, $N_{te}(0) = N_T$ (D) $E_t = 0.4$ eV, $N_{te}(0) = 0.5N_T$
(E) $E_t = 0.6$ eV, $N_{te}(0) = 0.5N_T$ (F) $E_t = 0.8$ eV, $N_{te}(0) = 0.5N_T$
(G) $E_t = 0.4$ eV, $N_{te}(0) = 0.25N_T$ (H) $E_t = 0.6$ eV, $N_{te}(0) = 0.25N_T$
(I) $E_t = 0.8$ eV, $N_{te}(0) = 0.25N_T$ (J) $E_t = 0.4$ eV, $N_{te}(0) = 0.1N_T$
(K) $E_t = 0.6$ eV, $N_{te}(0) = 0.1N_T$ (L) $E_t = 0.8$ eV, $N_{te}(0) = 0.1N_T$

After Garlick and Gibson [1948].

Example results of Eq. (19.15) are shown in Fig. 19.7 and a few characteristics are observed. First, for constant values of $N_{te}(T_0)$, $\overline{\omega}$, and R_T, the temperature of the luminescent peak maximum increases nearly proportional with the trap energy. Second, for constant values of $N_{te}(T_0)$ and N_t, the temperature of the luminescent peak maximum increases with R_T or decreases with $\overline{\omega}$. Third, the area under each curve is proportional to the number of initial trapped electrons, or $N_{te}(T_0)/N_T$. Further, the shape of the glow curve and position of the maximum is also a function of $N_{te}(T_0)/N_T$. Finally, at low temperatures, the integral in the denominator portion of Eq. (19.15) is much smaller than unity, and the beginning of the glow curve should follow

$$I(T) \simeq C\left[N_{te}(T_0)\right]^2 \frac{\overline{\omega}}{N_t} \exp\left[\frac{-E_t}{kT}\right], \tag{19.16}$$

a prediction that differs slightly from the result of Eq. (19.3).

A much more rigorous treatment on retrapping is offered by Halperin and Braner [1960], which leads to [Horowitz 1984a],

$$I(T) \simeq C\left[N_{te}(T_0)\right]^2 \frac{\overline{\omega} A_m}{N_t A_n} \exp\left[\frac{-E_t}{kT}\right], \tag{19.17}$$

where A_n is the probability of falling, into a trap while A_m is the probability of recombining at a luminescent center. Note that Eq. (19.17) is the same result as Eq. (19.16) for $A_m = A_n$, as originally assumed in the model of Garlick and Gibson [1948].

These models, as earlier stated, serve to provide a basic understanding of the thermoluminescent process. Yet, as pointed out by Bos [2001], the actual thermoluminescent process can be complex, meaning that the absorption and decay processes can deviate from these ideal cases. For instance, the luminescent centers may be complex defect structures that are difficult to identify or characterize. In some cases, the defects may not be stable when heated. Overall, to help mitigate the impact of these physical issues, Bos [2001] recommends that the steps taken to measure the radiation dose be carefully controlled, including the irradiation process, read-out, and annealing.

TLD Systems A TLD response is measured with a TLD reader. There are many different models, but all have a few features in common (see Fig. 19.8). A TLD reader has a drawer unit that may have a small filament pan that a TLD chip may be placed upon, or it may have a cradle that the inner part of a TLD badge may be inserted. The drawer is shut in a light-tight enclosure with a backfill gas flowing into the chamber, usually N_2 or Ar.

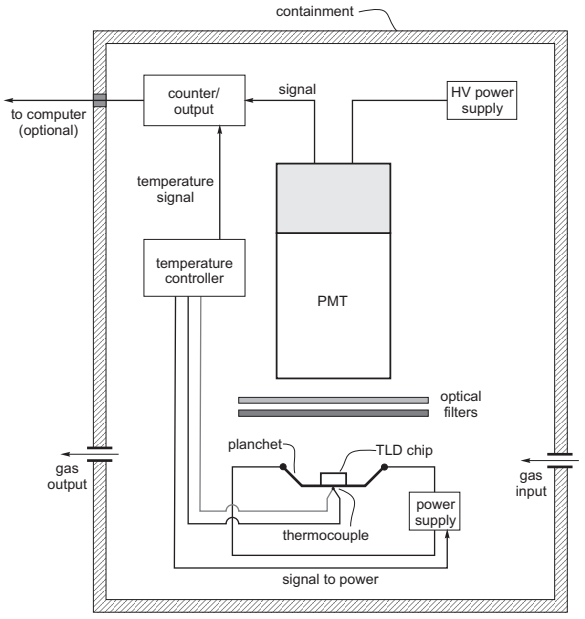

Figure 19.8. The basic components of a TLD reader.

The backfill gas is necessary to prevent background luminescent from TLD surface contamination, such a oxidation, during the heating process. After the chamber is purged of air, usually about a minute, the TLD reader is activated to operate in the regions depicted in Fig. 19.3. The TLD is heated, usually by a current flowing through the resistive filament pan or through radiant heating of the pan. A thermocouple is used to measure the pan temperature and provide feedback in order to control the filament temperature during the heating process. A photomultiplier tube (PMT) is used to record the light output from the TLD. Optical filters are placed between the TLD and the PMT to reduce contamination from spurious light emissions during the readout process. The current from the PMT is a measure of the light emission and, thus, is also a relative measure of the dose received by the TLD. This current is recorded and displayed as a glow curve on a monitor. The TLD reader itself may have a built-in display or, more frequently, is connected to a computer with a display monitor. The system is programmable with a variable stage input so that the user can select the temperature range, temperature ramp rate, temperature hold times, and temperatures between which the electronic output is measured.

Low energy traps are unreliable for dosimetry because they release electrons at room temperature, an effect referred to as *trap leakage*. Consequently, the light emission from shallow traps is a strong function of TLD storage time after the TLD irradiation. To avoid measuring the emissions from these shallow traps, current from the PMT is not recorded until a preset threshold temperature is reached that is sufficient to empty these traps. The TLD reader increases the temperature of the sample up to the lower threshold temperature and then begins recording the current, or accumulated charge, from the PMT output. This initial heating phase is called the preheat step. A typical lower threshold temperature is approximately 150°C, but varies with the TLD material selected. Above the low temperature threshold, the current

and total charge from the PMT is recorded and, in some systems, the glow curve is displayed. Because the PMT is an amplification device, the total charge measured is an amplification of the total number of initial electrons producing thermoluminescence. Under constant operating conditions, it is expected that the measured charge is proportional to the actual TLD dose so the dose can be determined by multiplication of the measured charge by a scaling constant. At a high temperature threshold or limit, the TLD reader stops recording the output but continues to heat the TLD in order to clear the deep traps. A typical higher threshold temperature is approximately 300°C, enough to clear the important dosimetry traps for most TLD materials, although this limit may be set higher for certain TLDs that have important glow curvs features above 300°C. Although deeper traps could be useful because of their long-term electron storage properties, spurious infrared emissions from the heated TLD and surroundings can leak into the PMT and produce an exaggerated dose. For reliability reasons, deep traps are usually not included in the dose measurement. After the anneal step, the heating is terminated and the TLD is allowed to cool. It is important that the fill gas continues to flow as the TLD is cooled to avoid oxidation and possible TLD damage. A typical operating temperature range may go up to 400°C to clear the deep traps. Properties of some of the most widely used TLDs are given in Table 19.1.

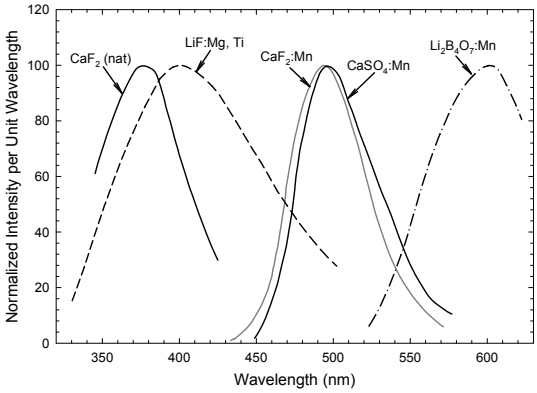

Figure 19.9. Emission spectra from several TLD phosphors normalized to a peak intensity of 100 per unit wavelength. Data from Fowler and Attix [1966] and Gorbics [1966].

From the results of Gorbics et al. [1969], it is clear that precise control of the heating rate is important for reliable and repeatable TLD dosimetry results. An established calibration method should be used to ensure that the measured charge corresponds to a known dose standard. Further, the temperature measurement of the pan must be rapid and accurate so that the reader measures current during the proper temperature limits. Although this precaution may seem insignificant, the pan temperature may differ from the actual TLD temperature (an insulator) or that of the thermocouple. This precaution is especially important for rapid heating rates. It was seen in Sec. 14.1.6 that the voltage has a strong influence on the gain of a PMT, so the TLD output should be compared periodically with a calibrated TLD phosphor to ensure that gain is constant and with insignificant variance. The TLD reader enclosure is sealed when the pan drawer is closed, and should be kept in such manner when not in operation to avoid contamination of the optical surfaces in the system. Further, to avoid possible reader damage, the system gas should be used to purge the enclosure of air before operating the heater.

Emission Spectra As with scintillators, it is preferable to use TLD phosphors with emission spectra that match well with the response functions of widely available photo-multiplier tubes. Shown in Fig. 19.9 are the emission spectra for some common TLD phosphors. It is notable that LiF:Mg,Ti (TLD-100) matches well to common bi-alkali PMTs. CaF_2:Mn, $CaSO_4$:Mn, and $Li_2B_4O_7$ on the other hand do not match well to common PMTs. However, their peak wavelengths near 500 nm and 600 nm present interesting possibilities for TLD readout systems based on Si diode technology, including silicon photomultipliers (SiPMs). The drawback is that long wavelength readout systems also have increased sensitivity to long wavelength photons from infrared emissions, a source of background from the heating process.

Sensitivity Sensitivity is determined by the amount of light released per unit energy absorbed in the TLD. The lower limit of detectable light emission is a function of the TLD reader and, thus, also determines the lower limit of detectable ionizing dose. The photoelectric process dominates at low energy, especially with

Table 19.1. Common thermoluminescent materials used for radiation dosimetry.

*Sensitivity at 30-keV photons relative to sensitivity at 1-MeV photons (^{60}Co).

**Affected by water content.

†Depends on preparation method.

TLDs made of relatively high Z materials. Shown in Fig. 19.10 are calculated sensitivity responses to photon energy for several different TLD materials. Note that TLDs manufactured from relatively high Z materials, in particular CaF_2, $CaSO_4$, $CaCO_3$, SiO_2, and Al_2O_3, have a much higher response to photons below 100 keV.

Stability and Fading Low energy traps are unreliable for dosimetry because they release electrons at room temperature, an effect known as *trap leakage* or *fading* with minor distinction. Trap leakage is short-term electron loss to recombination from relatively shallow traps and usually occurs in hours to days after irradiation. Fading refers to a longer term loss of electrons from deep traps over an extended period of time. Both cases are primarily due to thermal vibration of the crystal lattice from the ambient temperature causing the ejection and recombination of electrons. Consequently, the TLD reader is usually programmed to clear shallow traps before the system begins recording the electronic signal from the PMT.

Recall the probability of electron emission from a trap, described by Eq. (19.1), has a strong temperature dependence. The half-life of the trap is defined as the time for the filled population to emit half of the electrons

$$t_{1/2} = \frac{\ln(2)}{p} = \frac{\ln(2)}{\overline{\omega}} \exp\left[\frac{E_t}{kT}\right], \tag{19.18}$$

where p is the emission probability and $\overline{\omega}$ is the frequency factor. Energy levels shallower than approximately 1 eV fade rapidly, while energy levels exceeding 1.5 eV are generally long lived, even with large frequency factors [Shani 1991].

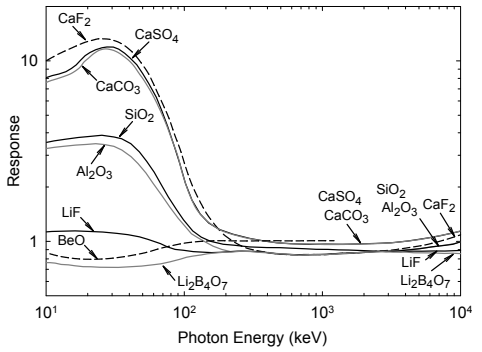

Figure 19.10. Theoretical sensitivity of TL phosphors as a function of photon energy, calculated as a function of ratio of the energy deposited in the phosphor to the energy deposited in tissue. Data combined from Cluchet and Joffre [1965] and Scarpa [1970].

Methods to reduce the effect of fading include a pre-irradiation anneal to clear the traps and reduce their relative contribution to the glow curve. After irradiation, a pre-heat step is routinely performed to empty these traps before the PMT is used to record the thermoluminescence. For most TLDs, the pre-heat step is performed for temperatures below 150°C, although this temperature threshold may vary with the TLD material. Storage of the TLDs in darkness at cool temperature can reduce fading. However, because shallow traps are still unreliable as a dosimetry record, mainly due to fading during the exposure period, the pre-heat step is still recommended.

Superlinearity and Sensitization At low radiation doses, the response of TLD phosphors is nearly linear. However, at high doses the response of a TLD deviates from linearity and becomes supralinear as shown in Fig. 19.11. The threshold for supralinear behavior is a function of the phosphor types, occurring at approximately 10 röntgens (R) for $Li_2B_4O_7$:Mn and as high as 10^4 R for CaF_2:Mn. At excessive doses the thermoluminescence decreases with dose.

If one simply regards the retrapping model of Garlick and Gibson [1948], the luminescence would be expected to increase as $N_{te}(T_0) \rightarrow N_t$, because the electrons are more likely to fall into luminescent centers than traps that are already filled with electrons, a prediction that can be observed from Fig. 19.7. Hence, the luminescent efficiency should increase with dose. At some degree of irradiation, the traps become saturated and no additional electrons can be stored in the traps. Consequently, the TLD material reaches a luminosity limit. Additional irradiation can cause damage to the material, thereby introducing more defect centers that act as traps that compete with the luminescent centers and consequently reduce the luminosity. The supralinear effect for several TLD materials is shown in Fig. 19.12.

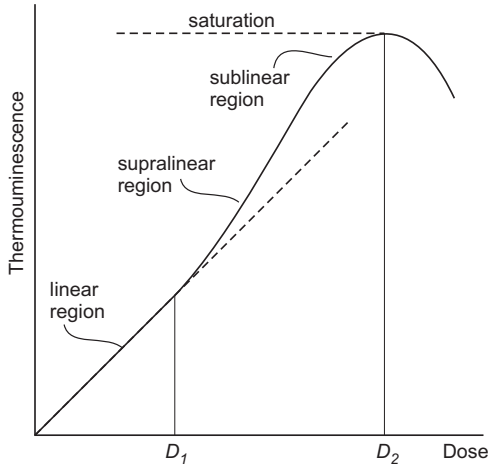

Figure 19.11. Representation of thermoluminescent growth curve depicting the linear, supralinear, sublinear, and saturation regions.

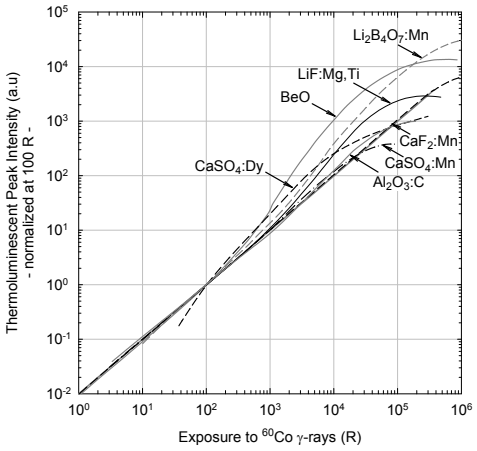

Figure 19.12. Thermoluminescent growth curves for several common TLD materials. The graphs were all normalized at 100 R. Data are from Attix [1986]; Lakshmanan et al. [1981]; Marrone and Attix [1964]; Portal et al. [1980]; Sunta et al. [1971]; Tochilin et al. [1969]; and Wilson and Cameron [1968].

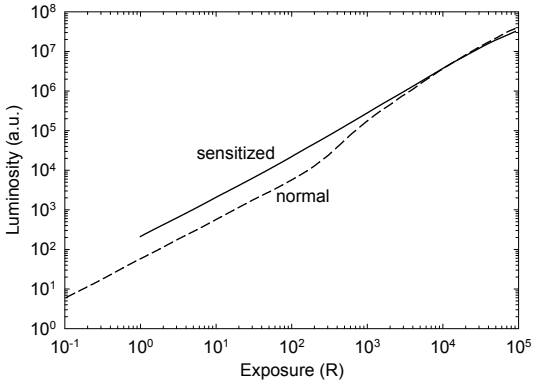

Figure 19.13. TL as a function of exposure for $Li_2B_4O_7$:Mn before and after radiation-induced sensitization from exposure to ^{60}Co gamma rays. Data are from West [1967].

Sensitization is the process whereby a TLD becomes more sensitive to radiation (S/S_o) after exposure to a large radiation fluence. Here S is the sensitivity after the process and S_o is the response for unsensitized samples. The production of additional traps from radiation damage makes a TLD produce more light as a function of radiation exposure, as shown for $Li_2B_4O_7$:Mn in Fig. 19.13. S/S_o values of 5 can be achieved with TLD-100 [Horowitz 1984b]. The sensitization process is different for each type of TLD material. For instance, Cameron et al. [1968] describe a process in which LiF is irradiated to about 10^5 R and subsequently annealed at 300°C for an hour. Sensitization can lead to increased linearity over a wider range than that observed with an unsensitized sample, and TLDs may be purposely sensitized to take advantage of this property. However, the deep traps produced during the process may become a source of low background phosphorescence, a nuisance for low-level dosimetry measurements [Horowitz 1984b]. Mayhugh and Fullerton [1975] describe a method to reduce interference effects of deep levels on low exposure measurements, in which TLD-100 samples are illuminated with UV radiation while being annealed at 300°C. Such samples retain high sensitivity while remaining useful in the mR range.

Radiation Damage The response of TLDs declines at higher radiation exposures than used for sensitization, usually greater than 10^5 R [Cameron et al. 1968; Shani 1991]. Multiple models have been proposed for the high radiation behavior observed for TLDs that involve the formation of competing trap centers in the materials [Horowitz 1984b]. If a significant density of shallow traps are created from radiation damage,

they effectively accumulate electrons that might otherwise lodge in the useful phosphorescent centers. These shallow traps are neglected during the measurement process, and consequently the overall signal decreases below the predicted linear output. If deep traps are introduced by radiation damage, they also do not contribute to the glow curve signal because they require higher temperatures to depopulate. In either case, the competing traps emit electrons at temperatures outside of the read region depicted in Fig. 19.3. This radiation damage may be permanent and cannot be removed by annealing. Further, at high doses, electrons filling the usual phosphorescent centers can cause a saturation effect, in which the probability of filling these useful centers diminishes as fewer become available. At high radiation doses, TLDs become discolored, an indicator of significant radiation damage. With increasing radiation exposure, TLDs change in appearance from translucent white, to yellow, brown, dark brown, and eventually to black. The formation of these color centers causes re-absorption of luminescent photons, resulting in a decrease in light output. Overall, the useful linear range of most TLDs is from tens of mR up to approximately 10^3 R, and the useful sensitized range is from hundreds of mR up to approximately 10^5 R. The thermoluminescent intensity as a function of dose for several TLD materials are compared in Fig. 19.12.

Calibration Calibration procedures are based on comparisons between known TLD radiation exposures and the response of unknown TLD exposures. The procedure requires a number of stringent controls, including sample size and mass, calibration standard location with respect to the radiation source, and temperature and time control of the glow curves. Further, it is important that the actual TLD reader be maintained by periodically verifying the correct response to a known TLD exposure (dose).

Calibration generally consists of irradiating a TLD with a known dose and calibrating the TLD reader to correlate the glow curve output with that known dose. Suppose that the sample dosimeter is deployed and irradiated in a known environment with a known dose of D_k and produces a glow curve response of R_k. Then a simple calibration factor becomes

$$f_D = \frac{D_k}{R_k}. \tag{19.19}$$

Given an unknown exposure of ionizing radiation to a dosimeter under the same conditions, the unknown dose D_u is a function of the glow curve response R_u, and is determined from

$$D_u = f_D R_u. \tag{19.20}$$

If the same TLD chip is used for the calibration and then, shortly after being cleared, is used for dosimetry measurements, then the correlation seems straightforward. However, complexities arise from the non-linear response of TLDs to gamma-ray energies as shown in Fig. 19.10. The identified dose may be incorrect unless the same radiation type and energy are used for both the calibration and the measurement. Further, because TLDs are often used to determine dose, a correction must be made to relate the TLD response to that which would occur within tissue (or bone). The outcome becomes even more complicated because the response of a TLD changes with accumulated dose, storage time, thermal history, and even the environment. Consequently the value of f_D must be measured periodically.

If the individual TLDs are also calibrated, this process may account for variances in the TLD output. However, complications can arise if a general average response for a type of TLD is used for calibration to characterize additional TLDs of supposedly the same type. Clearly such an assumption can promote error, mainly because of variances in the responses between individual TLD chips.

To correct the response for different radiations and energies, the TLD can be exposed to various sources and the independent values of f_D can be recorded. However, this cumbersome method is usually replaced by calibrating the TLD with a single reference source. For instance, the source in the calibration table of Fig. 19.14 is ^{137}Cs, while another common source is ^{60}Co. This reference source can be used to determine a reference dose D_r and the resulting reference TLD reader response R_r. This result can be directly compared

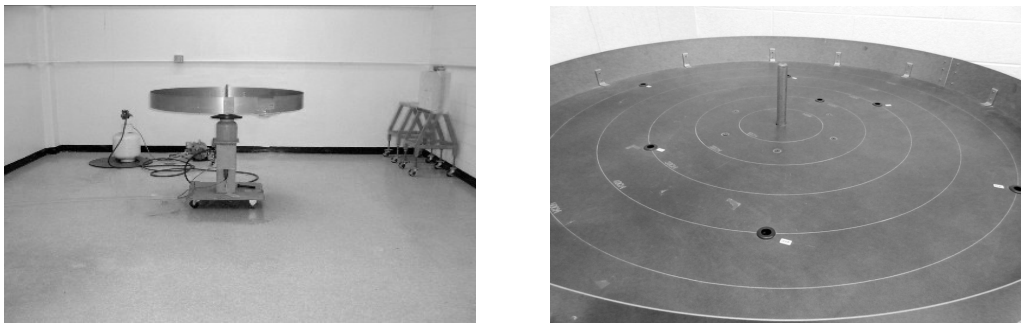

Figure 19.14. A dosimetry calibration table in a low scatter environment. (left) A ^{137}Cs source is stored in the shield below the table. (right) The source is raised through the port stem when in use. Concentric rings increasing by 10 cm radial increments mark placement locations.

to the known dose at the working location, where the badge is deployed, to find a relative scaling factor η_r. The calibration factor for the reference source is

$$f_r = D_r/R_r. \tag{19.21}$$

The relative response is defined as

$$\eta_r = f_D/f_r, \tag{19.22}$$

which gives the user a method to calibrate TLDs from the reference source. For high energy electrons and gamma rays, above 300 keV, the response is almost constant for most TLD materials, hence η_r is also essentially constant. For lower energies, this simply is not true. Further, at high doses, the TLD may become sensitized, thereby also changing the response. Consequently, the reference source can be used only for a limited energy range and dose.

A calibration system typically consists of a table, preferably made from low Z material such as plastic or wood to minimize photon scattering, that contains a port for a gamma-ray source. The gamma-ray source is stored in a radiation shield below the table, and is mechanically raised up through the port to expose the calibration TLDs placed at various distances from the port. Although ^{60}Co is a source frequently used for calibration, ^{137}Cs and ^{226}Ra are also widely used. Source strengths of a few mCi are often used to reduce statistical uncertainty and exposure time. The table is usually circular with concentric distance markings surrounding the source port. These tables typically are between 2 to 4 meters in diameter. If the source-to-TLD distance is greater than 2 m, air scattered photons may become significant and can skew the calibration from the ideal, point-source, uncollided flux model usually assumed in the calibration process. Likewise placement of the TLDs too close to the source may introduce complexities arising from the finite source size and uncertainties in the solid angle of irradiation. Hence, TLDs are usually placed a distance of 10 cm to 2 m away from the source port. In Fig. 19.14 an example of a TLD calibration table is shown.

The calibration system is placed in an empty room of such size that the detectors are always much closer to the source than the floor, ceiling or walls. This precaution minimizes the TLD absorption of scattered gamma rays. The TLDs should be placed at known locations from the source, horizontally and vertically, usually on premarked lines on the table as shown in Fig. 19.14(right). The gamma-ray exposure for each TLD can then be calculated from the known source activity based on an uncollided photon flux model to produce a calibration curve.

The TLD reader can also suffer from slight changes in light sensitivity, also causing error in the dose measurement. Lindskoug and Lundberg [1984] recommend testing the TLD reader as often as each day (presumably for daily usage of the instrument) with a constant light source. They also suggest the use of

a TLD dosimeter as that light source, irradiated at a constant known dose beforehand, used each day and stored in a refrigerator between uses. This new calibration factor f_L is multiplied by Eq. (19.20) to correct for TLD reader response changes. Overall, the measured dose can be determined with

$$D_u = \eta_r f_L f_r R_u. \tag{19.23}$$

Some TLDs, such as LiF, have a density close to that of tissue, which explains, in part, the popularity of LiF. In other words, the light yield from the glow curve must be calibrated to the dose in tissue. A simple correction method is to assume that the dose of the TLD is related to tissue dose by ratio of the mass collisional stopping powers. Energy deposition is also a function of radiation type. Shani [1991] presents several formulations describing the relation between dose and TLD response for different radiations, including electrons, heavy charged particles, gamma rays, and neutrons. Many are sensitive to both neutrons and gamma rays, while others have almost no sensitivity to neutrons; hence, by strategically pairing different TLDs, separate gamma-ray and neutron doses can be determined.

TLD Forms

Thermoluminescent materials are available in many physical forms such as powder, compressed ribbon, dispersed in Teflon, pellets, plates, and single crystals. Many TLD materials are initially grown as an ingot with the activator dopant included. Unfortunately, the impurity concentration is distributed through the crystal according to its migration coefficient and, consequently, the activator concentration varies throughout the crystal. If TLDs are sliced directly from such an ingot, they usually have a wide variation in radiation response. To avoid this variability, the ingot is often ground into powder, usually with an average grain size of about 200 microns, and the powder is then thoroughly mixed to produce a uniform activator concentration [Mayhugh 2000]. This thermoluminescent powder can be deployed in a gelatin capsule, a glass capillary, or plastic tubing. For plastic tubing or gelatin capsules, the irradiated TLD powder is poured into a planchet pan and read. Powder encapsulated in potassium-free glass capillaries can be read in the capsule. The more convenient and commercial TLD forms have the powder hot-pressed into solid ribbons, rods, or sliced into small chips and disks. These forms are easy to handle and can be placed directly on the heater planchet for readout.

Often the sensitivity or stability of some TLD materials is improved when embedded in an inert material such as Teflon. The TLD powder is mixed with the inert material and then compressed into pellets or chips with thicknesses of about 100 to 300 microns. These chips can be inserted into containers that are inserted directly into the TLD reader. Finally, under special conditions, single crystal TLDs cut directly from a single crystal ingot are sometimes used. However, because of the wide variance in doping distribution in the bulk crystal, and variance in response among different chips, this form is unpopular for generally dosimetry.

Summary of Advantages and Disadvantages

The advantages of thermoluminescent dosimeters as a dose detector are many. TLDs are relatively inexpensive and can be acquired in many different forms. By properly using established annealing methods, they can be reused multiple times. Further, with periodic calibration, the variance in dose measurement can be kept small. Most TLDs are made from relatively low Z materials and have a low mass density; hence, they can be modeled as nearly tissue equivalent dosimeters. Their small size is convenient for dosimetry because they can be modeled as point detectors. The dose measurement range is large with some TLDs being capable of measuring radiation doses below a millirem while also being able to measure doses above 10^4 rem. Finally, modern TLD readers can be connected to personal computers to provide straightforward readout and data interpretation.

However, TLDs also have some disadvantages. First, once a TLD is read, the dosimetry information is erased from the dosimeter and, thus, is quite different from photographic dosimetry methods. All TLDs

fade with time, some more rapidly than others. Consequently, the luminescence is a function of storage time and storage environment. Further, the luminescence for many TLDs is a function of the irradiation rate as well as the total dose, and some TLDs show strong supralinearity. The output luminescence and glow peak maxima for many TLDs are functions of the heating rate. TLDs are sensitive to UV light and proper storage and annealing before deployment is necessary. The emission spectrum for some TLDs is mismatched to the response function of many photomultiplier tubes and thus decreases the measured luminosity. TLDs can have different sensitivities, even when made from similar materials. Thus each individual TLD must be calibrated. Finally, TLD sensitivity can change after receiving large radiation doses, an effect termed as sensitization.

Common Materials for Thermoluminescent Dosimetry

Numerous materials have been investigated as thermoluminescent materials, including many common minerals. In fact, there are so many that it is impractical to discuss all of them here, and authors of books devoted to this topic seldom wander down that path. Instead, discussed here are a few common materials successfully used as TLDs, many of which are commercially available and widely used.

Lithium Fluoride

Lithium fluoride (LiF) is the most studied of the TLD materials and also is the most popular TLD in use today. The relatively low density of LiF is closer to tissue than most other TLD materials, an important property for dosimeters. LiF is stable at low temperatures and is mostly chemically inert. Manufacturers of LiF optics warn that the material is attacked by atmospheric moisture at temperatures above 400°C.[4]

LiF TLDs are available with many different ^{7}Li enrichments and activators, the most popular being the TLD-100, formed from natural LiF doped with Mg and Ti. Enriched and highly sensitive LiF TLDs are also available for special applications. Those most used are listed in Table 19.1.

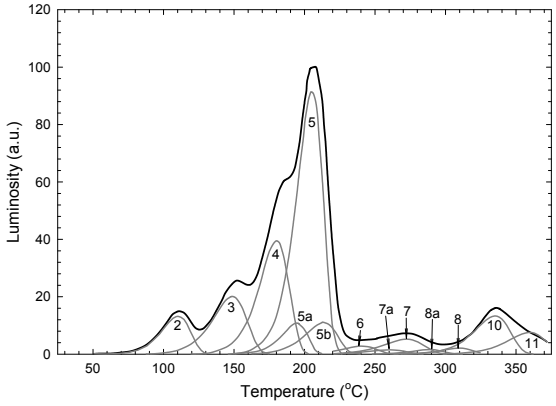

Figure 19.15. The normalized glow curve and its various composite components for LiF TLD-100 exposed to 1 Gy gamma irradiation. The luminosity is in arbitrary or relative units (a.u.). Composite data acquired and adjusted from Livingstone et al. [2009] and Horowitz and Moscovitch [2013].

Although LiF can be grown as a single crystal, this form is generally not used for TLDs. Instead, dopants are added to the purified LiF starting material and single crystals are grown from a melt process, typically with Czochralski or Stockbarger methods. The unfavorable segregation coefficient of Mg causes it to migrate during growth (as with other activators during zone melt purification) and, consequently, a non-uniform doping distribution is produced. As mentioned above, this non-uniform activator distribution can be ameliorated by pulverizing the crystal, mixing the resulting powder, and hot pressing or sintering the mixed powder into rods and ribbons. The end product is a translucent material with a relatively uniform distribution of the activator dopants. A normalized composite representation of a LiF:Mg,Ti glow curve with the separate trap luminosity components is shown in Fig. 19.15. The emissions denoted 2 and 3 in this figure are usually excluded from a measurement, typically set to begin when the temperature ramp reaches 150°C and extends up to approximately 225°C. Hence, the main luminescent contributions

[4] Apparently, LiF in the presence of water moisture at elevated temperatures hydrolizes and forms HF, which consequently attacks glass.

come from peaks 4, 5, 5a, and 5b. The sensitivity is linear in the range between 1 mR and 1 kR, and is supralinear between 1 and 50 kR.

To clear the deeper traps, some care is required for proper annealing of TLD-100 dosimeters to maintain reliable reuse. The annealing is usually performed at 400°C for 1 hour, followed by a slow cooling step and a longer term ($\sim$ 24 hours) anneal at 80°C. However, to prevent damage to LiF material embedded in a temperature sensitive binder, these TLDs can also be annealed at lower temperatures ranging between 280° to 300°C [Becker 1973].

The higher temperature annealing is important to empty traps 6 through 11, thereby reducing background phosphorescence. The IR contamination of the spectrum from the heater is the reason these higher temperature traps are not used in the dose measurement. Although fading is relatively slow, different low fade rates arising from different annealing procedures have been reported. When the annealing method is rigorously controlled, the fading can be limited to approximately 5 to 10% per year [McKeever 1985].

TLD-100 dosimeters are sensitive to charged particles, gamma rays, and neutrons. Gamma rays excite primary electrons in the material through the photoelectric effect, Compton scattering, or pair production. These energetic electrons excite secondary electrons in the material through Coulombic scattering. It is unlikely that energetic electrons deposit all of their energy in a small TLD chip before reaching the detector boundaries; hence, usually only a fraction of the incident energy is measured. The same is true for energetic beta particles. However, dosimetry is based on the amount of ionization produced in the body, primarily body tissue, and *cavity theory* attempts to correct for these energy losses.[5]

Heavy charged particles produce electron-hole pairs directly through Coulombic scattering. Because natural Li has a natural abundance of approximately 7.6% ^{6}Li, neutrons are also detected through the ^{6}Li(n,t)^{4}He reaction, in which the triton and helium reaction products directly ionize the material. The ranges of alpha particles and heavy ions are relatively short in LiF, usually only tens of microns, and most of the energy of the reaction products can be absorbed in the dosimeter. The glow curve from electrons and heavy ions is significantly different because a glow curve peak appears at 275°C from alpha particles [McKeever 1985]. Hence, the glow curve peak 7 (Fig. 19.15) is enhanced by high *linear energy transfer* (LET) radiation [Budd et al. 1979]. In some cases, the enhanced response of peak 7 has been used to extend the sensitivity of TLD-100 dosimeters out to 10^7 R [Jones and Martin 1968].

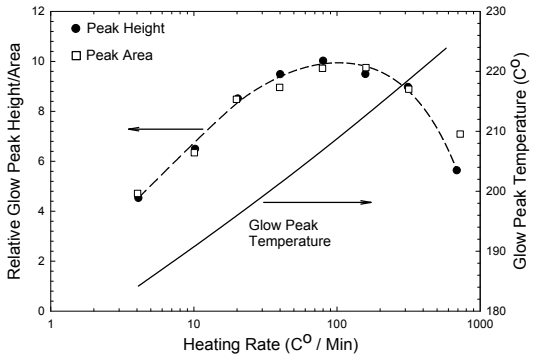

Figure 19.16. Comparative results for LiF TLD-100 dosimeters, showing deviation in peak height and area as a function of heating rate. The gamma-ray exposure was adjusted to be proportional to $1/R_T$ for the peak height, while the exposure was normalized for the peak area data. Also shown is the change in peak temperature with heating rate. Data are from Gorbics et al. [1969].

The glow peak properties of LiF:Mn,Ti changes with heating rate, and thus, this TLD requires a calibrated and constant measurement procedure. Both the glow curve peak height (peak 5) and the glow curve area have an output maxima near a heating rate of 80°C per minute (see Fig. 19.16). Further, the thermal location of the glow peak increases with heating rate, changing from 185°C at a rate of 4°C per minute up to 225°C at a rate of 700°C per minute. If operated at the luminosity maximum, the glow peak appears near 205°C.

The neutron response of LiF can be enhanced by replacing the natural Li with approximately 95.6% enriched ^{6}Li, and TLDs of this type are labeled TLD-600. The emission of heavy charged particles with high

[5] Part of cavity theory is the assumption that an electron leaving the dosimeter is replaced by an electron leaving the surrounding environment and into the dosimeter. This condition is known as *charged particle equilibrium.*

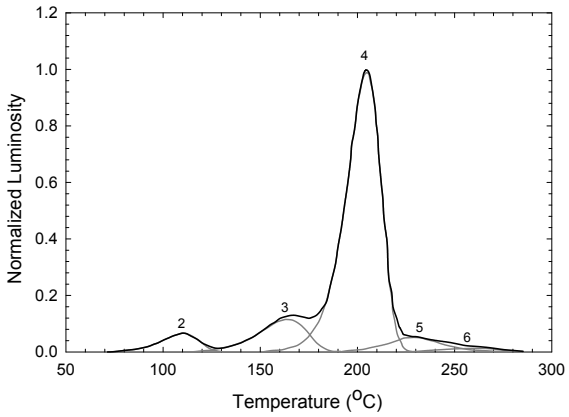

Figure 19.17. The normalized glow curve with its various components for LiF TLD-100H exposed to 5 Gy gamma irradiation. Data were acquired and adjusted from those of Triolo et al. [2006].

LET produces a glow curve with a significant increase in peak 7 with respect to peak 5 for neutron reactions. With proper calibration, the ratio of peak 7 to peak 5 can give a measure of the neutron dose [McKeever 1985]. LiF depleted of ^{6}Li, having 99.99% ^{7}Li, are relatively insensitive to neutrons and are labeled TLD-700. Often TLD-600 dosimeters are paired with TLD-700 dosimeters in a single dosimeter badge. By comparing the signals from TLD-600 and TLD-700 pairs, a separate measure of the neutron and gamma-ray dose can be determined.

The sensitivity of LiF is enhanced by changing the activation phosphors from a combination of Mg and Ti to a combination of Mg, Cu, and P, and natural LiF with this activator combination are labeled TLD-100H (also, GR-200). The glow curve is different than observed with TLD-100 with the main peak appearing near 200°C [Triolo et al. 2006], as shown in Fig. 19.17. Overall, these dosimeters can usefully measure lower doses than TLD-100, ranging from 10^{-5} R to about 10^3 R. However, they do not have the extended upper range observed with TLD-100. Further, the maximum thermal range is limited to no more than 240°C or the TLD is permanently damaged. Unfortunately, this restriction also means that TLD-100H dosimeters cannot be annealed to clear the deep traps. Eventually, after many exposures, the background emissions from these deep traps can begin to interfere with low dose measurements.

A relatively new LiF TLD with Mg, Cu, Si activators is under investigation [Kim at al. 2010; Horowitz and Moscovich 2013]. The main peak appears near 250°C, higher than TLD-100, but still low enough to minimize IR contamination. These LiF TLDs have similar sensitivity as the TLD-100H, but the deep traps can be annealed without damaging the dosimeter. Kim at al. [2010] report that after a multi-step anneal process, the residual deep trap signal is reduced to only 0.05%.

Calcium Fluoride

Calcium fluoride (CaF_2), or fluorite, is a mineral with attractive properties for thermoluminescent dosimetry. There are four prevalent CaF_2 TLD types, namely natural fluorite, Dy-doped (TLD-200), Tm-doped (TLD-300), and Mn-doped (TLD-400). A characteristic shared by all CaF_2 TLDs is the elevated gamma-ray energy absorption at energies below 100 keV (see Fig. 19.10), a consequence of the generally higher mass density of CaF_2. To reduce the effect, filters can be employed to flatten the gamma-response at these lower energies. Reviews of important CaF_2 TLD properties can be found in the literature [Becker 1973; Harvey et al. 2010; Bidyasar 2014].

CaF_2:MBLE Natural CaF_2, sometimes called MBLE CaF_2, was studied extensively and was a commercial TLD product for many years.[6] However, CaF_2:natural is far from an ideal TLD material because material obtained from different sources can have significantly different glow curves as shown in Fig. 19.18. Peaks in the glow curves, labeled in Roman numerals by Schayes et al. [1967], appear between the temperatures of 70°C and 600°C. The useful glow peaks for dosimetry are identified as III and III′, and appear with different luminosity for the samples of Fig. 19.18. Cameron et al. [1968] report that the integrated light yield from peaks III and III′ comprise approximately 75% of the total light yield. Although there are some smaller glow

[6] Studied and developed by Manufacture Belge des Lampes Électriques (or MBLE) in Belgium, these TLDs are no longer manufactured.

peaks at higher temperatures, they are generally not used for dosimetry because temperatures above 450°C can permanently damage CaF_2 TLDs.

The linearity of CaF_2 is quite good, and these TLDs show good linearity for gamma-ray exposures up to 10^4 R and exhibit only slight supralinearity up to 10^5 R. CaF_2 becomes sensitized at high gamma-ray exposures between 10^4 and 4×10^4 R, with a maximum gain in sensitivity ranging between 1.6 to 4 if annealed at 450°C for 30 minutes [Cameron et al. 1968; Sunta and Kathuria 1971]. From Fig. 19.19, the main glow peak does shift in temperature with increasing heating rate; however, the total peak area and the total peak height remain remarkably constant for a wide range of heating rates.

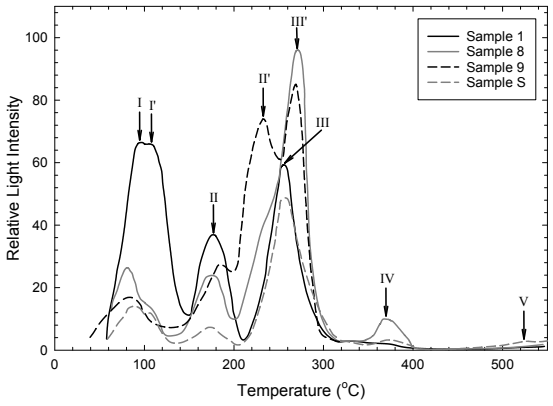

Figure 19.18. Glow curves from several samples of natural CaF_2. Data were adopted and adjusted from those of Schayes et al. [1967].

Natural CaF_2 is strongly sensitive to UV light, which primarily affects the output of glow peak III′. It is believed that UV irradiation assists with the movement of electrons from deep traps to shallow traps, producing additional luminescence in glow peak III. Brooke and Schayes [1967] describe a method of UV sensitization, or thermoluminescent build-up, that allows rereading of TLDs numerous times from a single radiation exposure, provided that the initial exposure exceeds approximately 5 R. Overall, the overexposure of CaF_2:natural causes a *bleaching* of the TLD and the signal changes from that of competing processes, including thermoluminescent build-up, charge transfer, and fading. TLDs unexposed to ionizing radiation tend to increase in luminescence, while the radiation induced signals tend to decrease with UV exposure [Becker 1973].

CaF_2:Dy (TLD-200) Developed by Harshaw for commercial use,[7] TLD-200 is a synthetic Dy-doped form of CaF_2. It is highly sensitive, much more so than TLD-100, and thus can be used for low-dose measurements. The glow curve is relatively complicated, as shown in Fig. 19.20, with two salient composite peaks, one glow peak appearing between 80°C and 210°C and another high-temperature composite glow peak appearing between 250°C and 450°C [Yazici et al. 2002; Bidyasagar et al. 2014]. Each of these composite glow peaks is formed from several trap levels, and their intensity changes with radiation type, dose, and preheat method.

TLD-200 is not as linear as CaF_2:MBLE or CaF_2:Mn, and begins showing peak height supralinearity near a dose of 5×10^3 rad, extending up to approximately 5×10^4 rad before becoming sublinear [Hasan and Charalambous 1983]. The integrated luminescence (all peaks between 50°C and 370°C) shows supralinearity starting as low as 800 rad. Saturation occurs between an exposure of 10^5 R and 10^6 R [Becker 1973]. Becker [1973] reports that linearity can be improved by pre-irradiation and annealing TLD-200 at 600°C for two hours.

Fading can be significant, reportedly up to 25% in a month if post-irradiation treatments are not applied [Binder and Cameron 1969]. If illuminated during storage, for instance in a diffuse room light, fading can increase up to 30% in a single day. The main cause of fading is from the low temperature glow peak components. If eliminated by post-irradiation annealing, nominally 80°C for 10 minutes, the fading can be reduced to 13% per month [Binder and Cameron 1969], but at the expense of 20%-30% reduction in sensitivity.

CaF_2:Tm (TLD-300) Thulium-doped CaF_2 was introduced as a dosimeter material in 1977 [Lucas and Kapsar 1977] and put into commercial use as TLD-300 by Harshaw. The glow curve of TLD-300 (see Fig. 19.21) displays two main composite peaks in the spectrum, centered near 175°C and 260°C, generally

[7] Now produced by Thermo-Fisher Scientific. See Thermo-Fisher [2016].

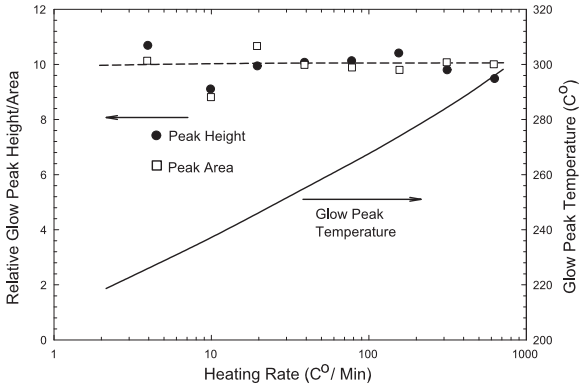

Figure 19.19. Comparative results for natural CaF_2, showing deviation in peak height and area as a function of heating rate. The gamma-ray exposure was adjusted to be proportional to $1/R_T$ for the peak height, while the exposure was normalized for the peak area data. Also shown is the change in peak temperature with heating rate. Data are from Gorbics et al. [1969].

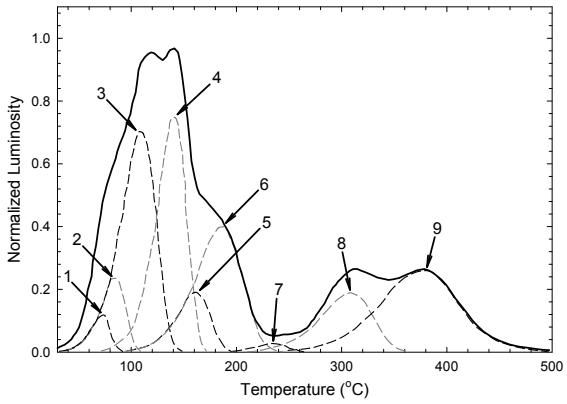

Figure 19.20. Normalized glow curves for typical TLD-200 exposure measurements after gamma-ray irradiation. Data adopted and adjusted from those of Yazici et al. [2002] and Massillon-JL et al. [2008].

labeled as peak 3 and peak 5, although the observed peak 5 is really a combination of peaks 5 and 6 [Massilon-JL et al. 2008]. A third glow peak is present if readout occurs within 24 hours of exposure and is centered near 100°C; however, this glow peak usually fades after 24 hours and usually does not appear in the glow curve. The output characteristics of TLD-300 are relatively stable and appear not to be affected by the heating rate [Kafadar et al. 2013].

The luminosity of the two main peaks is strongly dependent on the linear energy transfer and the ratio of peak 3 to peak 5 decreases with increasing LET. This feature can be used in dose interpretation in mixed radiation fields. Furretta and Tuyn [1985] show that the ratio of peak 3 to peak 5 increases from 1.22 for ^{3}H beta-particle emissions up to 3.15 for ^{90}Sr beta-particle emissions. Because the ratio also shows a strong dependence with heavy ions, Massilon-JL et al. [2008] suggest its use as an indicator of ion beam quality.

The recommended anneal process for TLD-300 is one hour at 400°C followed by a rapid quench cooling in air to room temperature at a rate of 75°C per minute [Massillon-JL et al. 2008]. Fading is reduced to approximately 5% over a 4-week period for both peak 3 and peak 5, while the contribution from peak 6 appears unaffected [Kafadar et al. 2013].

CaF_2:Mn (TLD-400) Mn-doped CaF_2 was developed for thermoluminescent dosimetry at the Naval Research Laboratory in the late 1950s and early 1960s [Ginther and Kirk 1957, Schulman et al. 1960]. The general method of producing TLD-400 material is by first chemically precipitating CaF_2 and MnF_2 into solution, following by filtering and drying the residue in an inert atmosphere. The sintered material is then ground to particle sizes of about 100 microns and thoroughly mixed. Afterwards, the material is formed into various shapes and sizes and sintered.

TLD-400 has a simple glow curve consisting of just one main glow peak appearing between 260 to 320 °C, depending on the heating rate as shown in Fig. 19.22. The relatively higher glow peak temperature indicates emission from a deep trap, yet CaF_2:Mn has high fading rate of up to 10% per month. TLD-400 has a higher intrinsic sensitivity than TLD-100, and can be used to measure radiation exposures below 1 mR. The response of TLD-400 is linear over a wide range, up to 3×10^5 R before sublinearity is observed (See Fig. 19.12). Further, there appears to be no dependence on the type of ionizing radiation or LET as observed with LiF-based TLDs. The dose rate dependence is relatively constant up to a heating rate of

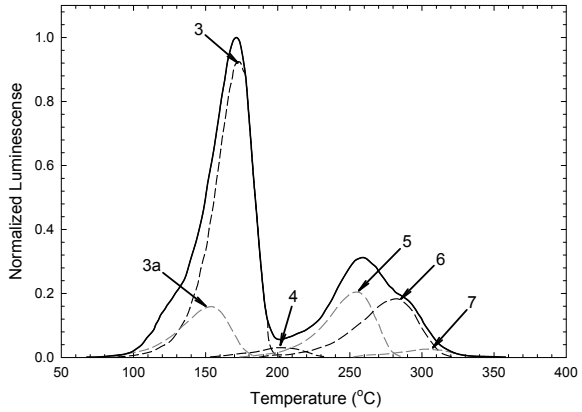

Figure 19.21. Normalized glow curves for typical TLD-300 exposure measurements after gamma-ray irradiation. Data adopted and adjusted from those of Yazici et al. [2002] and Massillon-JL et al. [2008].

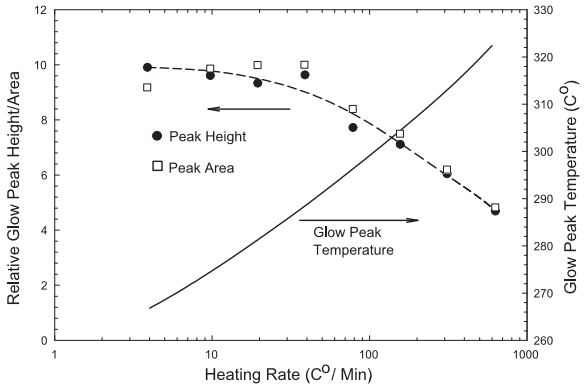

Figure 19.22. Comparative results for CaF_2:Mn dosimeters, showing deviation in peak height and area as a function of heating rate. Also shown is the change in peak temperature with heating rate. Data are from Gorbics et al. [1969].

approximately 30°C per minute before both the relative glow curve peak height and integrated area begin to decline. As with all CaF_2 TLDs, TLD-400 is overly sensitive to gamma-ray energies below 100 keV. Although filters can be used to soften the response to lower energy gamma rays and x rays, the same filters can also over-attenuate soft x rays, thereby producing a lower measured dose.

Calcium Sulphate

Calcium sulphate ($CaSO_4$) is a relatively high Z material that has been studied for use as a thermoluminescent dosimeter. Mn-doped $CaSO_4$ has a low temperature glow curve peak (see Fig. 19.23), which fades rapidly at room temperature. Fading is reportedly to be as high as 40% within one day, and up to 85% after three days [Fowler and Attix 1966]. Consequently, $CaSO_4$:Mn is not useful as a dosimeter except, perhaps, for short-term laboratory experiments in which the TLD is read soon after irradiation. Regardless of this drawback, $CaSO_4$:Mn is very sensitive to ionizing radiation and capable of measuring exposures in the μR range [Fowler and Attix 1966]. The main reason for this perceived higher sensitivity is actually a fortuitous benefit of the low-temperature glow curve, in which the background IR emissions from the heater and TLD are small by comparison to the thermoluminescence. Hence, the signal-to-noise ratio is high so that measurement of low doses is possible. The emission spectrum from $CaSO_4$:Mn peaks near 500 nm, which is somewhat long in wavelength to be a good match to most bi-alkali PMTs. All forms of $CaSO_4$ are overly sensitive to gamma rays below 100 keV, much like CaF_2. Although the glow peak maximum shifts from approximately 80°C to over 120°C for heating rates between 10 C°/min up to 500 C°/min, the peak height and peak area remain remarkably constant for heating rates below 150 C°/min (see Fig. 19.24).

Because of the high fading, other phosphors for $CaSO_4$ were studied. For instance, Sm was tested as an activator with encouraging results [Cameron et al. 1968], but the main glow peaks appear at 100°C and 400°C, with an emission spectrum centered at 600 nm, too high for efficient coupling to conventional PMTs. Of the activators explored, both Dy-doped and Tm-doped have proven to be relatively successful. The main glow peak for both $CaSO_4$:Dy (also called TLD-900) and $CaSO_4$:Tm appears at approximately 225°C. Although the glow peak appears simple, Souza et al. [1993] report at least ten peaks in the TLD-900 glow curve, although only seven actually comprise the main glow peak. Of these deconvolved peaks Harvey et al. [2010] note that only two or three are important for doses below 10 R.

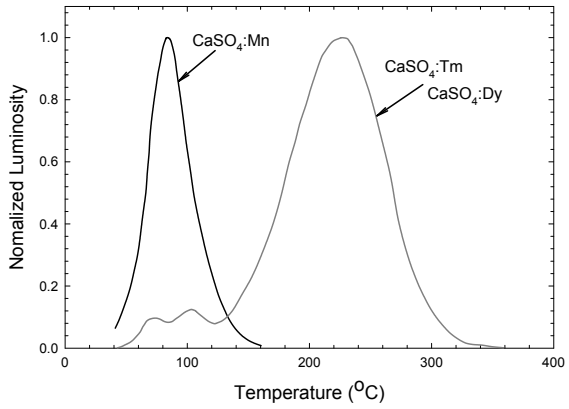

Figure 19.23. Normalized glow curves for typical $CaSO_4$:Mn, $CaSO_4$:Tm, and $CaSO_4$:Dy (TLD-900) for exposure measurements after gamma-ray irradiation. Data adopted and adjusted from those of Yamashita et al. [1971] and Ekdal et al. [2014].

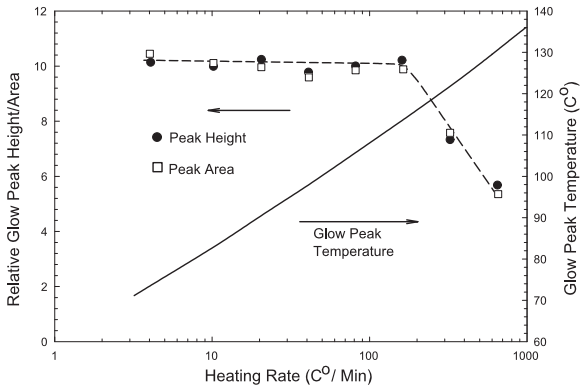

Figure 19.24. Comparative results for $CaSO_4$:Mn dosimeters, showing deviation in peak height and area as a function of the heating rate. The gamma-ray exposure was adjusted to be proportional to $1/R_T$ for the peak height, while the exposure was normalized for the peak area data. Also shown is the change in peak temperature with heating rate. Data are from Gorbics et al. [1969].

The main luminescent emissions from TLD-900 appear near 480 nm and 570 nm. By comparison, the luminescent emission maximum from $CaSO_4$:Tm is near 450 nm, a better match to traditional alkali metal PMTs, although $CaSO_4$:Tm is less sensitive to ionizing radiation than TLD-900. The luminescent response for TLD-900 is linear up to approximately 3×10^3 R. Supralinearity appears between 3×10^3 R and 10^4 R, beyond which sublinear behavior appears [Becker 1973]. As with many TLDs, saturation is reached at 10^5 R.

TLD-900 is significantly more sensitive than TLD-100 by about a factor of 30, and low gamma-ray doses below a mrad have been measured. Fading is minor, reportedly as low as 2% in the first month and 6% over a five-month period when stored at room temperature [Becker 1973]. Similar results were reported by Guelev et al. [1994], who observed approximately 5% fading over a six-month period. However, Harvey et al. [2010] report a much higher degree of fading near 30% in one month, attributed to low temperature glow peaks apparently not considered in the Guelev et al. [1994] study. The annealing procedure is straightforward, requiring no more than a 15-minute soak at 400°C. Yamashita et al. [1971] report that TLD-900 is significantly sensitive to thermal neutrons while $CaSO_4$:Tm is not and conclude that the use of $CaSO_4$:Tm is preferred in a mixed radiation field because of the high response that TLD-900 has to thermal neutrons.

Lithium Borate ($Li_2B_4O_7$:Mn)

Lithium borate (LBO) is mainly attractive as a thermoluminescent dosimeter because of it low Z components and low mass density. As a result, the response is nearly flat from 10 keV to 10 MeV, as shown in Fig. 19.10. Its low density is closer to bone and soft tissue than most other TLD materials, which helps to simplify dose conversions. $Li_2B_4O_7$ is water soluble and hygroscopic, unless mixed and processed with 0.25% SiO_2 by weight, which seems to stabilize it [Becker 1973].

Mn is the best known activator for $Li_2B_4O_7$ and is often named TLD-800 for short. The emission spectrum maximum for TLD-800 is reportedly at 605 nm [Gorbics 1966], a relatively long wavelength for most PMTs. This maximum can be shifted to shorter wavelengths by doping with Cu (or Ag). $Li_2B_4O_7$:Mn has emission maximum near 352 nm [Tiwari et al. 2010]. TLD-800 has a linear response to gamma rays up

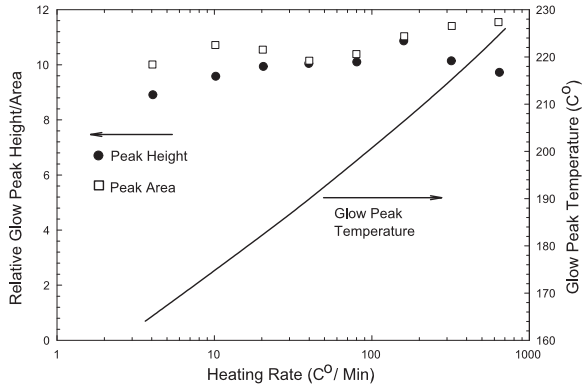

Figure 19.25. Comparative results for $Li_2B_4O_7$:Mn dosimeters, showing deviation in peak height and area as a function of heating rate. The gamma-ray exposure was adjusted to be proportional to $1/R_T$ for the peak height, while the exposure was normalized for the peak area data. Also shown is the change in peak temperature with heating rate. Data are from Gorbics et al. [1969].

to 150 R, becomes supralinear between 150 R and 10^5 R, eventually saturating at $\times 10^5$ R. TLD-800 has lower sensitivity to gamma rays than LiF, generally ten times less sensitivity than TLD-100. West et al. [1967] report that TLD-800 sensitizes when irradiated with 10^5 R gamma rays and annealed for 15 minutes at 300°C (see Fig. 19.13), achieving approximately 4 times the sensitivity for gamma-ray doses below 200 R. Becker [1973] reports that annealing is simple, requiring only a 15-minute soak at 300°C.

Gorbics et al. [1969] report that the peak height and peak area are relatively constant over a wide range of heating rates; however, this result is markedly different from that reported by Kafadar et al. [2014], who report large changes in peak area for TLD-800 when heated at rates above 120°C/min. Both Gorbics et al. [1969] and Kafadar et al. [2014] report glow peak temperature changes from below 170°C to nearly 220°C over heating rates ranging between 10°C/min to 500°C/min as shown in Fig. 19.25. Two glow peaks are prevalent shortly after irradiation for both TLD-800 and $Li_2B_4O_7$:Cu. TLD-800 has one glow peak appearing at approximately 100°C and the other at approximately 225°C (see Fig. 19.26). $Li_2B_4O_7$:Cu has a lower temperature glow peak near 120°C, and also has a higher temperature peak reported as 205°C by Takenaga et al. [1980], but reported as much higher at approximately 240°C by Aydin et al. [2013]. For all cases the lower temperature glow peak fades rapidly, usually disappearing within a day [Schulman et al. 1967; Aydin et al. 2013]. The higher temperature peak for TLD-800 fades by approximately 8% over a 30-day period [Cameron et al. 1968], but there are differing fading results reported for $Li_2B_4O_7$:Cu. Wall [1982] reports rapid fading for $Li_2B_4O_7$ that was doped with Cu or co-doped with Cu and Ag. However, Aydin et al. [2013] reports fading is approximately the same as TLD-800, fading about 10% over a 40-day period. Most likely the preparation method is responsible for these differences, as demonstrated by Christenson [1967] who increased the dosimetric response and range of TLD-800 by changing the preparation method.

Because of the constituent elements B and Li, the thermal neutron response of TLD-800 is relatively high [Gambarini 2003], higher than TLD-100, but less than TLD-600 and TLD-900. Sunta et al. [1972] report that the fast neutron response (from recoil protons) to gamma-ray response ratio was nearly 3 while TLD-100 and TLD-900 response ratios were much less at 1.24 and 1.6, respectively.

Beryllium Oxide (BeO)

Another low density thermoluminescent material is BeO, generally regarded as a "tissue equivalent" material. The often quoted effective Z (or Z_{eff}) is 7.12.[8] BeO is toxic in powdered form, but not as a ceramic, and comes in three main forms, namely hot pressed (HP), slip cast (SC), and nuclear quality (NQ) [Scarpa 1970]. These three forms have different densities, with SC at 2.2 g cm^{-3} and the other forms approaching 2.8 g cm^{-3}. It is relatively chemically inert and resistant to mechanical shock.

The glow curve spectra and the peak temperatures were observed to shift according to TLD manufacturing process [Scarpa 1970]. Three different emission spectra were observed by Scarpa [1970] with peaks centered differently at 210°C, 240°C, and 290°C for SC, NQ, and HP BeO, respectively (see Fig. 19.27). The response to gamma rays is fairly linear from 10 mR up to approximately 100 R, beyond which the output becomes supralinear (see Fig. 19.12). Although HP BeO showed up to 20% fading in three days, the other forms demonstrated approximately 4% fading within 24 hours with no significant fading thereafter.

Measurements conducted by Crase and Gammage [1975] indicate that various forms of BeO all produce spectra in the UV region, generally between 200 nm to 400 nm with a peak near 265 nm. Consequently, most commercial PMTs are insensitive to much of the spectrum, and special PMTs (or TL readers) with deep UV sensitivity must be used (see Sec. 14.1.2 for more information on PMT windows).

BeO is more sensitive to gamma rays than $Li_2B_4O_7$, but much less so than LiF by about a factor of 3 [Shani 1991]. The sensitivity of SC BeO is practically linear for gamma-ray energies ranging from less than 20 keV to over 1 MeV, while the other forms are slightly higher in response for energies below 500 keV [Scarpa 1970]. Although linear at low doses, competition from non-radiation induced emissions from pyroelectric incandescensce contribute to background, making it difficult for accurate low-dose measurements. Exposure to light can depopulate BeO traps, inducing fading. Consequently, BeO TLDs should be handled carefully and not exposed to light during exposure or readout.

Aluminum Oxide (Al_2O_3)

Aluminum oxide is the chemical name for a mineral often regarded as a precious gem. If it has a small amount of Cr impurity (Cr_2O_3) it is called ruby. Other gem quality samples are called sapphires, associated with a wide range of colors according to the residual impurities. Otherwise, the common name for Al_2O_3 is corundum. Aluminum oxide is one of the hardest known substances, rated as 9 on the Mohs hardness scale. Aluminum oxide is mostly chemically inert and it is water insoluble. It has high electrical resistance and its melting point is extremely high at 2072°C.

Aluminum oxide was first studied for its thermoluminescent properties by Rieke and Daniels [1957], and later as a dosimeter by McDougall and Rudin [1970]. Samples with Cr contamination (ruby) produced a glow curve peak between 350°C and 400°C with a maximum emission wavelength near 650 and 700 nm. Unfortunately, at such high temperatures infrared emissions contaminate the luminescent emissions, and the emission wavelength is well beyond the sensitivity range of most photomultiplier tubes.

Pure Al_2O_3 has a thermoluminescent glow peak wavelength near 410 nm. Portal et al. [1980] report several glow peaks for Al_2O_3 with 0.7% Na and 4% Ti, appearing at approximately 140°C, 265°C, 450°C, and 630°C. See Fig. 19.28 for example glow curves. The lowest temperature glow peak fades quickly, while the higher two glow peaks have IR contamination during readout. It is the peak at 265° that has importance

[8] For the purpose of gamma-ray attenuation through a compound material, a fictitious Z_{eff} is often used. This number is often determined by the empirical relation [Murty 1965]

$$(Z_{\text{eff}})^{2.94} = \sum_{i=1}^{N} f_i Z_i^{2.94},$$

where f_i is the fraction of electrons associated with element i having atomic number Z_i. Although often used, the reader is cautioned that this is an empirical expression, and the exponent of 2.94 may not be accurate. In fact, Murty [1965] states in his publication that measurements indicate that 3.1 instead of 2.94 for the exponent yields improved results.

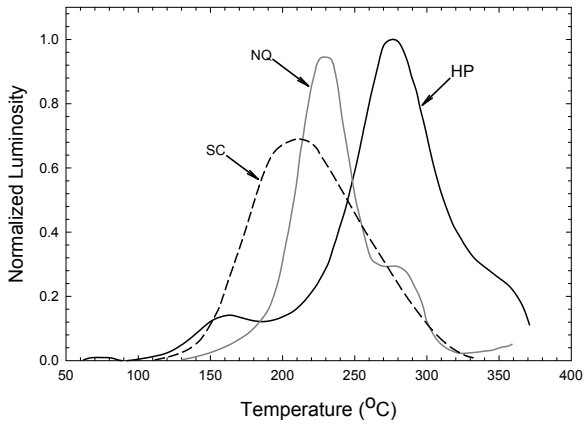

Figure 19.27. Normalized glow curves for typical BeO exposure measurements after gamma-ray irradiation. Data are adopted and adjusted from Scarpa [1970].

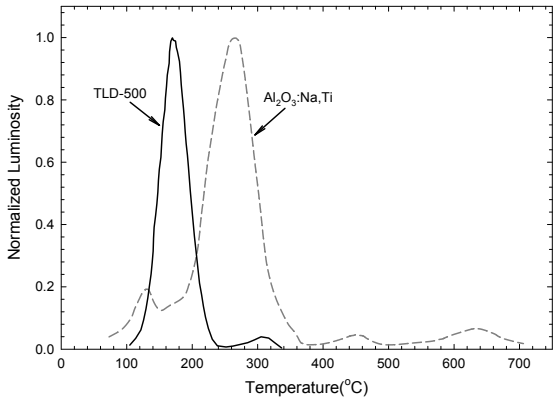

Figure 19.28. Normalized glow curves for typical Al_2O_3 measurements after gamma-ray irradiation. Data are adopted and adjusted from those of Portal et al. [1980] and Kortov and Ustyantsev [2013].

in dosimetry. The effective Z is 10.2, and below 200 keV Al_2O_3 has higher sensitivity than TLD-100, but less so than CaF_2 (Fig. 19.10).

When doped with carbon, Al_2O_3 has relatively good thermal stability, and is often denoted as TLD-500. The peak emission wavelength is 420 nm, well matched to the response function of common PMTs. Further, the thermal fading is approximately 3% per year and the dosimetric sensitivity can be as low as 5 μR. Kortov and Ustyantsev [2013] report multiple different glow curves dependent on the dose level. For instance, a single salient glow peak appears near 185°C at a dose of 800 mR from ^{60}Co, shifting downward to 165°C at a dose of 10^6 R. Several high temperature glow peaks appear for doses above 3×10^6 R, the main one appearing near 425°C. Although Al_2O_3:C functions as a thermoluminescent material, Akselrod et al. [1998] note that thermal quenching changes luminosity with heating rate. Consequently, because optically stimulated luminescence (OSL) demonstrates increased sensitivity and also the lack of thermal quenching, TLD-500 has instead gained popularity as an OSL dosimeter.

19.1.2 Optically Stimulated Luminescent Dosimeters

Closely related to thermally stimulated luminescence is optically stimulated luminescence (OSL) [McKeever 2001], with the main difference being in the method used to induce photon emissions. Both an OSLD and a TLD use a ceramic material in which intrinsic or activated traps store charge produced from radiation absorption events. However, instead of using thermal methods to release electrons from traps and into luminescent centers, energetic photons of sufficient energy are used to accomplish this task. Because the OSLD is not heated, problems with thermal destruction of the dosimeter are nearly eliminated. Further, select portions of the dosimeter can be sampled with a focused UV laser, a feature not possible with the uniform heating used in thermoluminescent dosimetry. Hence, an OSLD may have only a portion of the sample area illuminated, leaving other areas of the dosimeter unaltered for later measurements if required.

TLDs produce a glow curve that corresponds to light emissions from increasing trap energies as a function of increasing temperature. As temperature is increased, definitive features in the glow curve appear in the output spectrum. However, OSL dosimeters are illuminated with a light source that can affect shallow and deep traps simultaneously. This illumination is usually in the form of focused laser light. The output response, i.e., the emitted light, depends on several characteristics of the input illumination such as the wavelength, light intensity or power, and transient nature of the illumination.

Because of the similarities between TL and OSL dosimetry, Fig. 19.1 adequately depicts the initial process of radiation absorption. However, the stimulated emission process is quite different, as illustrated in Fig. 19.29. Instead of heat, energetic photons of energy greater than or equal to the trap energies are used to depopulate the dosimeter traps. The ejected electrons can then fall into luminescent centers accompanied by photon emissions, or the electrons may instead fall back into traps. However, if the electrons fall back into traps, they can subsequently be re-emitted by the optical stimulation, and can still contribute to the output signal if they fall into a luminescent center. To obtain a useful output signal, it is important that the stimulation wavelength be longer than the emission wavelengths, thereby facilitating filtering and reducing induced emissions unrelated to the radiation dose. For instance, the most commonly used commercial OSL dosimeter is Al_2O_3:C, which emits a broad wavelength spectrum centered at 420 nm (violet-blue). However, the stimulation wavelength is larger, optimized at 525 nm (green light). In this manner the stimulated luminescence can be separated from the interrogation light.

Modeling the Stimulated Emission

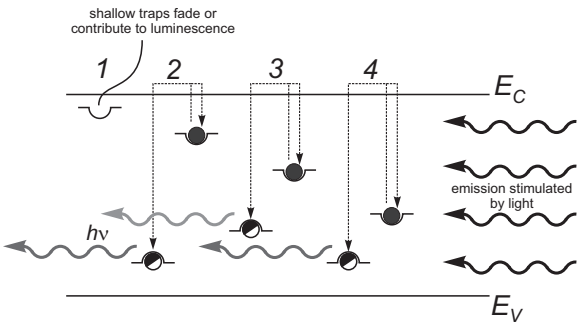

Figure 19.29. Band diagram depicting detrapping and emission during the stimulation time. The shallow traps (1) fade or can contribute partially to the OSL. Dosimeters traps, (2 and 3) contribute to the dosimetry measurements. With adequately energetic optical stimulation, deep traps (4) can also contribute to the dosimetry signal. Also, retrapping can occur at all trap states (2,3,4), yet they can also be simultaneously optically excited, thereby continue to provide dosimetry information.

Electrons in an excited state can go to a lower energy state with or without photon emission with probabilities p_r and p_{nr}, respectively. Recall from the configuration coordinate diagram of Fig. 13.2, there is a probability p_{nr} that an electron in an excited state can move directly to the ground state at the crossover $D \rightarrow D'$ without any photon emission. This probability is described by

$$p_{nr} = p_0 e^{-\Delta E/kT}, \tag{19.24}$$

where ΔE is the activation energy required to move an electron from the bottom of the conduction band C to reach the crossing point at DD' in Fig. 13.2 and p_0 is a scaling constant referred to as the frequency factor. The radiative transition probability p_r is unaffected by temperature.

The optical luminescent efficiency is defined as

$$\eta = \frac{p_r}{p_r + p_{nr}} = \frac{\tau_{nr}}{\tau_r + \tau_{nr}}, \tag{19.25}$$

where $\tau_r = 1/p_r$ is the mean radiative lifetime and $\tau_{nr} = 1/p_{nr}$ is the mean non-radiative lifetime. Substitution of Eq. (19.24) into this definition gives

$$\eta = \frac{p_r}{p_r + p_0 e^{-\Delta E/kT}} = \frac{1}{1 + c e^{-\Delta E/kT}}, \tag{19.26}$$

where $c = p_0/p_r = p_0\tau_r$, a constant.

From Eq. (19.26), it is readily apparent that as the temperature of the OSL material increases, the luminescent efficiency should decrease. The loss of luminescence with temperature is referred to as *thermal quenching*. The total lifetime of excited charges is also a function of the radiative and non-radiative transition probabilities, namely

$$\tau(T) = \frac{\tau_r \tau_{nr}}{\tau_r + \tau_{nr}} = \frac{\tau_r}{1 + \tau_r p_0 e^{-\Delta E/kT}}. \tag{19.27}$$

From this result it is seen that the total lifetime also decreases as the temperature increases. Akselrod et al. [1998] show that a plot of τ versus temperature can yield both the values of the frequency factor p_0 and the activation energy ΔE.

The use of OSL as a dosimetry technique was first explored by Huntley et al. [1985] as a method to date geological samples. The test samples were natural quartz irradiated with 514.5 nm light. The technique was developed over several years for geology, and years later was recognized as a potential technique that can be used for radiation dosimetry [Bøtter-Jensen and McKeever 1996]. Numerous materials have been investigated for use as OSL dosimeters, including many traditional TLD materials. The most successful, and most popular, is carbon activated alumina, Al_2O_3:C.

For constant illumination, the rate of stimulation from a trap, with units s^{-1}, for photons of energy E_{ph} is given by

$$R_{te} = \sigma_t \phi_{ph} = \frac{1}{\tau_d}, \tag{19.28}$$

where τ_d is the decay constant, σ_t is the photoionization cross section, and ϕ_{ph} is the photon flux of energy E_{ph} [Bøtter-Jensen et al. 2003]. For simplicity, suppose all electron traps are at the same energy level and all luminescence centers, likewise, are at a single lower energy level. Because there is no charge on the material (the *charge neutrality* condition), the concentration n of electrons in the conduction band and the concentration N_{te} of electrons in traps must equal the concentration p of holes in the valence band and the concentration N_{rh} of holes stored in recombination centers. After the OSLD has been exposed to radiation, the free electrons and holes either fall into traps or recombine so that $n = p = 0$. Here it is assumed that there is a wide band gap with negligible thermal generation of free charges and that the stimulation photons have insufficient energy to excite electrons from the valence band to the conduction band.

However, upon illumination this equilibrium balance is altered. The rate of gain of electrons in the conduction band equals the rate at which electrons leave their traps plus the rate at which electrons fall from the conduction band into recombination centers, i.e.,

$$\frac{dn(t)}{dt} = -\frac{dN_{te}(t)}{dt} + \frac{dN_{rh}(t)}{dt}. \tag{19.29}$$

The rate of increase in the density of trapped electrons equals the rate per unit volume that electrons are excited out of the traps (negative change) plus the rate per unit volume that free electrons fall into the traps, namely

$$\frac{dN_{te}(t)}{dt} = -R_{te}\left[\frac{N_{te}(t)}{N_t}\right] N_t + p_{ec}\left[\frac{N_t - N_{te}(t)}{N_t}\right] n(t) N_t, \tag{19.30}$$

where p_{ec} is the free electron capture probability per unit time, N_t is the trap concentration and $(N_t - N_{te})/N_t$ is the fraction of traps that are empty and able to receive an electron. The rate of decrease in the hole concentration at recombination centers is the rate at which electrons from the conduction band fall into open recombination centers, i.e.,

$$\frac{dN_{rh}(t)}{dt} = -p_{er}\frac{N_{rh}(t)}{N_r} N_r n(t), \tag{19.31}$$

where p_{er} is the probability, per unit time, of an electron in the conduction band recombining with a hole at a recombination center, which has a concentration of N_r, and N_{rh}/N_r is the fraction of recombination centers which contain a hole and are able to receive an electron from the conduction band.

To obtain an expression for the intensity of the stimulated luminescence beginning at $t = 0$, two simplifying assumptions are made. First, it is assumed that the probability of exciting an electron out of a trap and falling into a recombination center is much higher than that of a free electron returning to a trap center. Hence Eq. (19.30) is simplified to

$$\frac{dN_{te}(t)}{dt} = -\sigma_t \phi_{ph} N_{te}(t), \tag{19.32}$$

whose solution is

$$N_{te}(t) = N_{te}^0 \exp[-\sigma_t \Phi_{ph} t], \tag{19.33}$$

where N_{te}^0 is the trap-filled population at $t = 0$. The second assumption is that the change in recombination center population equals the change in trap population, i.e., $dn/dt \approx 0$. Thus, from Eq. (19.29) the stimulated luminescence can be described by

$$I = -C\frac{dN_{rh}(t)}{dt} = -C\frac{dN_{te}(t)}{dt}. \tag{19.34}$$

where C is a constant to account for the size of the interrogation volume and the luminescence efficiency. For a constant optical stimulation for $t \geq 0$ with a constant photon flux of energy E_{ph}, the luminescent intensity is found by substitution of Eqs. (19.32) and (19.33) into Eq. (19.34) to give

$$I = CN_{te}^0 \sigma_t \phi_{ph} \exp[-\sigma_t \phi_{ph} t], \qquad t > 0, \tag{19.35}$$

where N_{te}^0 is the trap-filled population at $t = 0$. Constant power illumination is referred to as CW-OSL (continuous wave OSL) in which the OSL dosimeter is illuminated with a selected bandwidth of wavelengths at constant power for a specific time. Electrons depopulate the storage traps, fall into recombination centers, and produce luminescence. Under CW operation, Eq. (19.35) indicates that the expected luminescent output is a rapidly decaying exponential function of time. This behavior is expected because light emissions decrease with time as the traps are depopulated. These trap emissions are concurrent. Spectral emissions develop simultaneously according to the trap emission probability.

The integrated luminescence I_{lum} over time period t_1 is

$$I_{lum} = \int_0^{t_1} CN_{te}^0 \sigma_t \phi_{ph} e^{-\sigma_t \phi_{ph} t}\, dt = -CN_{te}^0 e^{-\sigma_t \phi_{ph} t}\Big|_0^{t_1} = CN_{te}^0 \left[1 - e^{-\sigma_t \phi_{ph} t_1}\right]. \tag{19.36}$$

This result shows that the luminescent yield is proportional to the initial filled trap density N_{te}^0. If the initial filled trap density is a linear function of radiation dose, then this integrated luminescence can be used to measure the dose [Yukihara and McKeever 2008].

Multiple Traps for Electrons and Holes Because an OSL dosimeter usually has multiple trap energies as well as several luminescent center energies, the output spectrum is, therefore, not a simple exponential function of time. Instead it is superposition of emissions from multiple trap energies and luminescence of different energies. Other factors that contribute to the spectral output are competing trapping centers, thermally induced emission (usually from shallow traps), retrapping, and photo-excitation of electrons from deep to shallower traps. In some circumstances, the combined output spectrum may be best modeled as an inverse power function rather than as a simple exponential dependence [Yukihara et al. 2004].

The effect of shallow traps in an OSL dosimeter is to produce a concentration of competing traps that initially reduces the luminescence. These shallow traps fade rapidly after irradiation and a large fraction of the centers depopulate before optical stimulation. Consequently, these empty traps compete with luminescent centers for electrons during the optical stimulation step, causing a reduction in the emitted luminosity. As the intensity measurement continues, a steady-state condition is reached in which trapping at shallow traps is matched by detrapping and results in an increase in luminosity. As the measurement continues further, the luminosity characteristic eventually decreases with time, similar to the ideal case without shallow traps.

The effect of deep traps is similar to that observed with TLDs and causes an apparent increase in dose sensitivity, or sensitization. Upon irradiation, a new and pristine OSL dosimeter has energetic electrons excited across the band gap. Many of these electrons diffuse through the material and drop into traps, including shallow, medium, and deep traps. In the present case, the medium level traps that participate

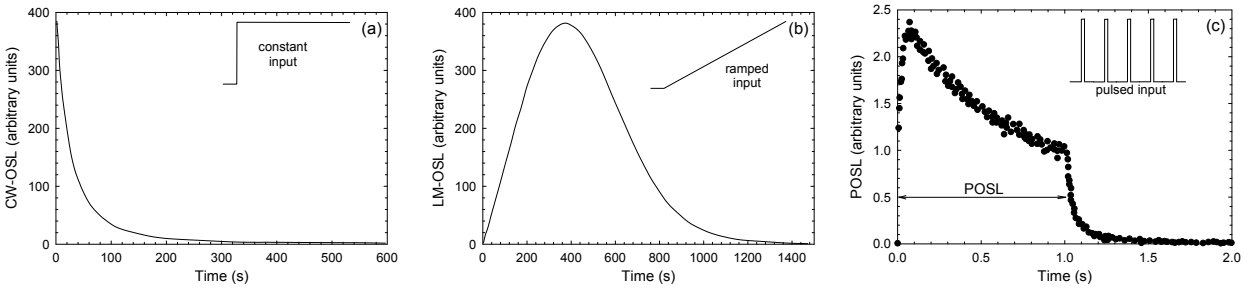

Figure 19.30. Luminescent output from Al_2O_3:C OSLDs for three types of laser stimulation, (a) CW-OSL, (b) LM-OSL, and (c) POSL. The OSLDs in (a) and (c) are Al_2O_3:C (Luxel^{TM}) and in (b) it is a Al_2O_3:C TLD-500. After Bøtter-Jensen et al. [2003].

in the dosimetric signal are referred to as dosimetry traps. During optical stimulation, a large percentage of shallow and dosimetry traps are emptied, but the deep traps are not. As these deep traps are filled, and remain filled, they are eliminated as competing traps. Consequently, subsequent irradiation of an OSL produces a higher percentage of filled dosimetry traps because there are fewer competing deep traps. The end result is higher luminosity per unit dose during optical stimulation.

The excitation wavelength is selected to correspond to sub-bandgap energies. The purpose for this choice is simple; the stimulation process is responsible for exciting more electrons into dosimetry traps. However, it is still possible for photons during the optical stimulation process to excite electrons across competitive traps. For instance, electrons in deep traps may be transferred to dosimetry traps.

OSL Systems

OSL readers have at least two main components, namely, a light source to stimulate the dosimeter and a photosensitive receptor to detect the stimulated luminescence. A challenge for these components is the vast difference in luminescent intensity between the light stimulation source and the luminescent emissions, a difference that can span over 14 orders of magnitude ranging between 10^{16} photons cm^{-2} s^{-1} for stimulation and 10^2 photons cm^{-2} s^{-1} for low dose luminescence [Yukihara and McKeever 2011]. OSL systems are designed to reduce photo-ionization and photo-transference of electrons. A long-pass filter[9] is placed between the light source (usually a laser, photodiode, or lamp) and the OSL dosimeter. Another filter is also placed between the OSL dosimeter and the light collection device (typically a PMT), usually a bandpass filter which transmits photons with wavelengths between 290 nm to 370 nm [Yukihara and McKeever 2008]. The bandpass filter reduces scattered light from the light source from entering the PMT, while passing the prominent wavelengths from optically stimulated luminescence. Additional components may include optical components, such as mirrors and lenses, to guide and focus the light, both stimulated and luminescent. There are at least three types of stimulation systems in use for OSL, listed as continuous wave (CW-OSL), linear modulation (LM-OSL), and pulsed (POSL). These systems are briefly described here but more detailed descriptions can be found in the literature [Bøtter-Jensen et al. 2003; Yukihara and McKeever 2011].

CW-OSL The CW system focuses light of constant power onto an OSL dosimeter in a step input, as depicted in Fig. 19.30(a). CW-OSL remains the most popular method to sample an OSL dosimeter, mainly because of its simplicity and reliability. The output response is described by Eq. (19.35) in which the expected output signal is largely modeled as an exponentially decreasing function. The output signal is mainly a function of the initial trap filled density N_{te}^0, the stimulation intensity ϕ_{ph}, and the time duration of the stimulation t. For a fixed illumination time period $t_1 = \Delta t$ with constant power ϕ_{ph}, the integrated

[9] These filters are used to filter short wavelengths that may excite electrons across a bandgap or produce prominent photo-transference while at the same time passing longer wavelengths that still can excite electrons out of dosimetry traps.

intensity produces a luminescent output proportional to the initial trap-filled population. A sample taken over a short time period, 1 second for instance, is sufficient to gain the required information on dose. After such a short sampling time, many of the trap states may remain filled. The OSL can then be stored and re-read if so required, taking into account the time period of the prior optical stimulation.

Notably, integration of Eq. (19.35) for the total luminescence I_{tot}, i.e., $\Delta t \to \infty$, is solely a function of the initial number of filled traps N_{te}^0, namely

$$I_{tot} = C \int_0^\infty N_{te}^0 \sigma_t \phi_{ph} e^{-\sigma_t \phi_{ph} t}\, dt = C N_{te}(t_0). \tag{19.37}$$

Consequently, the intensity of the stimulation light ϕ_{ph} does not affect the total luminescence or resulting measured dose. Hence, the light stability and intensity of the stimulation source have, theoretically, no effect on the measured output or dose provided that the volume of the OSL dosimeter is cleared of all trapped electrons by this long-term stimulation. However, the initial luminescence $I(t = 0^+)$ emitted by the stimulated OSL dosimeters is in fact a function of the intensity ϕ_{ph} of the light source, as shown in Eq. (19.35), and the total light output for a finite Δt is, from Eq. (19.36), also a function of ϕ_{ph}. Hence, if the user reads only part of the OSL dosimeter traps during a measurement, it is important that the light source be stable during the measurement time to obtain reliable results.

The simple model of Eq. (19.36) does not take into account the possibility of different trap energies participating in the luminescent output. Further, it does not consider retrapping of charges, effectively prolonging the stimulated luminescence. Curve fitting indicates that a power function may in fact describe better the luminescent behavior of a real OSLD than does a simple exponential.

POSL Although filters are used to reduce contamination from scattered light from the source, these same filters can also absorb some of the optically stimulated light. If there is significant overlap between the stimulation spectrum and the OSL spectrum, then part of the OSL signal is sacrificed to eliminate scattered light from the laser source. Because the intensity of the stimulation light is orders of magnitude greater than the OSL output, the *stimulation* light leakage that arrives at the light sensor may still have an intensity comparable to that of the optically *stimulated* luminescent light reaching the sensor.

Pulsed mode systems were developed as a readout system that can reduce scattered light from contaminating the OSL signal. The technique involves the use of a pulsed laser to stimulate luminescence from the OSL dosimeter, while measuring the luminescence between pulses [McKeever et al. 1996]. Such a system still has filters to reduce the detection of scattering photons. However, between pulses, the counting system is gated such that current from the PMT is measured only while the laser is off. During the pulse, the electrons in traps are elevated to the conduction band and can drop into luminescent centers. When the light is switched off, these free electrons continue to fall back into luminescent centers and traps, hence continue to produce luminescence. If the concentration of electrons in excited luminescent centers, before decay and photon emission, is N_{re}^*, the process can be modeled as

$$\frac{dN_{re}^*(t)}{dt} = -\frac{N_{re}^*(t)}{\tau_d} - \frac{dN_{te}(t)}{dt}, \tag{19.38}$$

where the change in the excited luminescent center population is equal to decay of the luminescent centers with time constant τ_d plus the decrease of trapped electrons into luminescent centers. Substitution of Eq. (19.32) and Eq. (19.33) into Eq. (19.38) gives

$$\frac{dN_{re}^*(t)}{dt} + \frac{N_{re}^*(t)}{\tau_d} = R_{te} N_{te}(t) = N_{te}(0) R_{te} \exp[-R_{te} t], \tag{19.39}$$

where the stimulation rate $R_{te} = \sigma_t \phi_{ph}$ has units s^{-1}. The solution of this differential equation is

$$N^*_{re}(t) = A \exp[-t/\tau_d] + \frac{N_{te}(0) R_{te} \tau_d}{1 - R_{te}\tau_d} \exp[-R_{te} t], \tag{19.40}$$

where A is a constant defined by an initial condition.

Now apply this result to the POSL chain of laser pulses shown in Fig. 19.31. Suppose that at the beginning of a pulse at time t_b, the concentration $N^*_{re}(t_b)$ of luminescence centers is known. Then from Eq. (19.40) the constant A is found to be

$$A = e^{t_b/\tau_d} \left[N^*_{re}(t_b) - \frac{N_{te}(0) R_{te} \tau_d}{1 - R_{te}\tau_d} \exp[-R_{te} t_b] \right]. \tag{19.41}$$

Substitution of A into Eq. (19.40) gives for $t \geq t_b$

$$N^*_{re}(t) = N^*_{re}(t_b) e^{-(t-t_b)/\tau_d} + \frac{N_{te}(t_b) R_{te} \tau_d}{1 - R_{te}\tau_d} \left\{ e^{-R_{te}(t-t_b)} - e^{-(t-t_b)/\tau_d} \right\}, \tag{19.42}$$

where $N_{te}(t_b) = N_{te}(0) \exp[-R_{te} t_b]$. The decay of the excited luminescent center, and the emitted luminescent intensity, during a laser pulse, is $I(t) = C N^*_{te}(t)/\tau_d$ or

$$I(t)/C = \frac{N^*_{te}(t_b)}{\tau_d} e^{(t_b - t)/\tau_d} + \frac{N_{te}(t_b) R_{te} \tau_d}{\tau_d (1 - R_{te}\tau_d)} (e^{R_{te}(t_b - t)} - e^{(t_b - t)/\tau_d}), \quad t_b \leq t \leq t_e$$

$$\text{where } t_b = (m-1)(t_p + \Delta t), \quad m = 1, 2, \ldots, M. \tag{19.43}$$

Here Δt is the time duration between pulses and t_p is the optical pulse width. Between pulses, there is no optical stimulation ($R_{te} \to 0$), and the emitted luminescent intensity is

$$I(t)/C = \frac{N^*_{te}(t_e)}{\tau_d} e^{(t_e - t)/\tau_d}, \quad \text{where } t_e = t_b + t_p = (m-1)\Delta t + m t_p. \tag{19.44}$$

During the stimulation time $t_p = t_e - t_b$, it is usual to close the electronic gate on the PMT signal, thereby avoiding the inclusion of scattered light. Consequently only the light emitted during the time period between pulses Δt is measured. Examples of the emitted luminescence are shown in Fig. 19.31.

Consider the light emitted during Δt to that over a single period $(t_p + \Delta t)$. For a constant measurement/period ratio, the ratio of measured light to the total luminescence increases with frequency. If the stimulation time is relatively long, followed by decay, a large fraction of light is lost during stimulation, with the luminescence decaying to low values. In the example of Fig. 19.31(left), the amount of light emitted after a stimulation pulse is approximately 40% for a frequency of 6.67 Hz. Because the optical signal is not measured during stimulation, this result means that 60% of the signal is lost. By increasing the frequency, the ratio of lost luminescence decreases. From the example of Fig. 19.31(b), with all parameters the same except that the frequency is increased a hundredfold to 667 Hz, the percentage of measured light increases to approximately 80%. Although Fig. 19.31 serves to demonstrate the general trend for POSL, the duty cycle[10] in the example is only 33.3%. In practice, the duty cycle is often shorter and on the order of 10%.

The ratio of lost luminescence decreases as the decay constant τ_d increases. To improve the measurements, it is best to select a stimulation pulse width t_p equal to or less than the luminescence decay constant τ_d.

[10] The fraction of a period that the stimulation source is active.

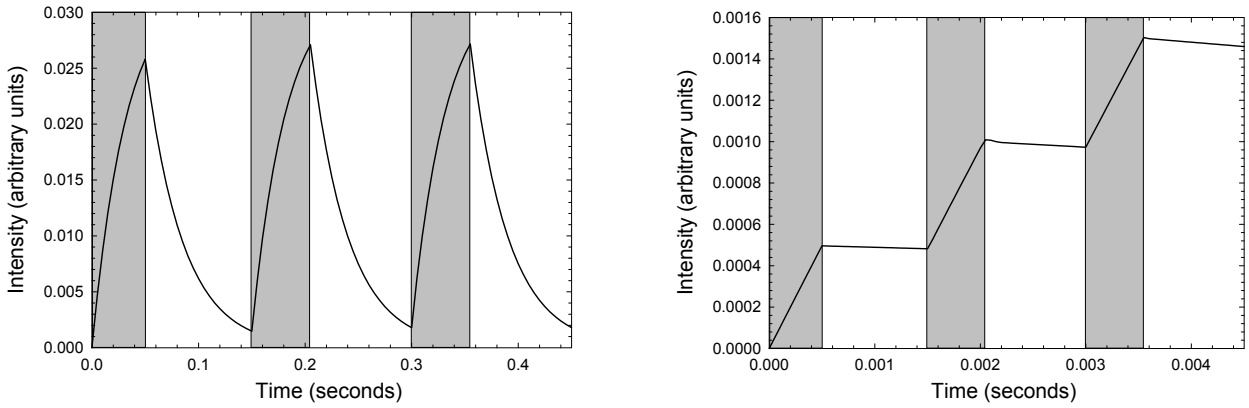

Figure 19.31. POSL luminescence signal with the stimulation pulse width equal to 1/3 of the total period. The gray region indicates the time t_p when the laser pulse is activated and the output signal is switched off, and the clear area represents the time period Δt when the luminescence is measured. On the left, the period is 150 ms (6.67 Hz) with $t_p = 50$ ms and on the right the period is 1.5 ms (667 Hz) with $t_p = 500$ μs. All other parameters are the same.

For a given value of τ_d, the pulse frequency and pulse width t_p can be adjusted to optimize the light yield while reducing contamination from scattered light. The general luminescent trend for a POSL measurement is shown in Fig. 19.30(c) where it is seen that the luminescence initially increases, and begins to decrease as the filled traps depopulate. At the end of the measurement, when the laser is switched off after a series of pulses, the remaining excited luminescent centers decay away.

LM-OSL Linear modulation is an optical stimulation method in which the optical intensity is linearly increased over time so that the stimulation rate (s^{-1}) of removing a trapped electron is

$$R_{te}(t) = \sigma_t \phi_{max} \frac{t}{T}, \tag{19.45}$$

where ϕ_{max} is the maximum optical power and T is the stimulation time period which begins at $t = 0$. The luminescent decay time constant is now a function of time

$$\tau_d(t) = \frac{1}{R_{te}} = \frac{T}{\sigma_t \phi_{max}}. \tag{19.46}$$

The trapped electron concentration is given by

$$\frac{dN_{te}(t)}{dt} = -R_{te}(t) N_{te}(t), \tag{19.47}$$

whose solution is

$$N_{te}(t) = N_{te}(0) \exp\left[-\frac{\sigma_t \phi_{max} t^2}{2T}\right]. \tag{19.48}$$

The optical luminescence produced is thus

$$I(t) = -C\frac{dN_{te}(t)}{dt} = C N_{te}(0) \sigma_t \phi_{max} \frac{t}{T} \exp\left[\frac{-\sigma_t \phi_{max} t^2}{2T}\right]. \tag{19.49}$$

The intensity maxima is easily found to be,

$$t_{max} = \sqrt{\frac{T}{\sigma_t \phi_{max}}}. \tag{19.50}$$

Substitution of Eq. (19.50) into Eq. (19.49) yields the maximum luminescence

$$I_{max} = N_{te}(0)\sqrt{\frac{\sigma_t \phi_{max}}{T}} \exp\left[-\frac{1}{2}\right]. \tag{19.51}$$

The general luminescent shape is shown in Fig. 19.30(b), where it is seen that the luminescence increases from zero to a maxima and then decreases as the traps depopulate. It is these maxima features that Bular [1996] argues as advantageous, especially in the presence of multiple traps. Unlike the CW-OSL method in which multiple traps blend together to produce a single decay curve, each trap level shows a maxima with the LM-OSL method, thereby making identification of the individual traps possible. Nonetheless, for the same sample material, the total area under the luminescence curves are the same for CW-OSL and LM-OSL. Although numerous groups have experimented with LM-OSL (see references in Yukihara and McKeever [2011]), it has not yet received widespread acceptance. Complications arise from non-linear light increase associated with the stimulation source, spectral shift of the stimulated luminescence as the power is increased, and changes in background light leakage measured by the PMT as the light source power is increased.

OSL Materials

Materials for optical stimulation luminescence include a variety of synthesized and natural minerals. Many of the synthesized materials can be used for radiation measurements, mainly because the storage traps and luminescent centers can be controlled during synthesis. Of these synthetic materials, Al_2O_3:C is the most popular for dosimetry. Many natural minerals that exhibit OSL characteristics can be used to determine post-factum doses and are used for geological dating. A select few of these materials are described here.

Aluminum Oxide (Al_2O_3:C) Carbon activated aluminum oxide (Al_2O_3:C) was originally proposed as a TLD, yet has gained popularity as an OSL dosimeter [McKeever and Akselrod 1999; Akselrod and McKeever 1999]. Al_2O_3 has a high sensitivity to low radiation doses, and is now in wide-spread use as a commercial dosimeter, having replaced TLD materials for many applications. Carbon doped alumina has a main emission line near 420 nm with a decay constant of 35 ms, and a lesser fast emission at 335 nm with a time constant less than 7 ns. Both of these emissions are produced by stimulation of the dosimeter traps with green light, optimized at 525 nm. Reported sensitivity ranges from 1 mrem (10 μSv) up to 10^4 rem (100 Sv); however, the uncertainly for low doses can be greatly affected by the environmental background radiation [Gilvin and Perks 2010]. When stimulated with CW-OSL, the maximum luminescence occurs with a stimulation wavelength near 500 nm as shown in Fig. 19.32. Shown in Fig. 19.33 is a decay curve for Al_2O_3:C after a dose of 60 mGy from a ^{90}Sr source. Room-temperature thermal fading is reportedly not appreciable up to 85 days after irradiation. Bøtter-Jensen et al. [1997] report fading is approximately only 1.8% after 27 days and, subsequently, becomes relatively stable [Schembri and Heijmen 2007].

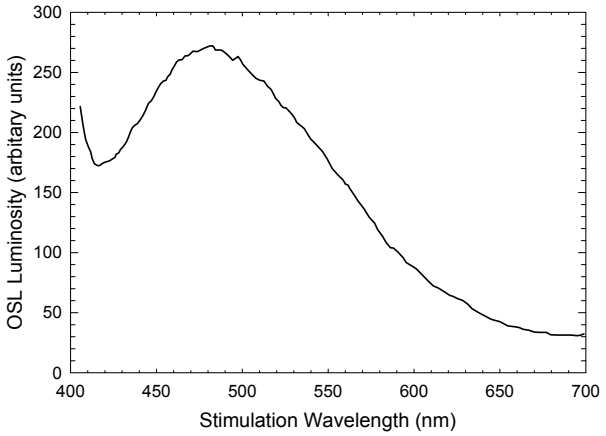

Figure 19.32. OSL luminosity versus the stimulation wavelength for Al_2O_3:C. Data are from Bøtter-Jensen et al. [1997].

Although the fast UV emission at 335 nm increases the total optical stimulated luminescence, it is the longer wavelength emissions with maxima near 420 nm that are usually used for dosimetry. The 420 nm emission is attributed to F-center luminescence [Yukihara and McKeever 2008]. Optical excitation from

the dosimeter traps produces free electrons that recombine with F^+-centers. The inclusion of carbon in the growth process enhances the formation of these F^+-centers by replacing a fraction of the trivalent Al^{3+} ions with C^{2+} ions [McKeever et al. 1999]. The capture of an electron produces an excited F-center, and these excited F-centers de-excite by releasing a photon. Dosimetric linearity of up 5×10^3 rad (50 Gy) has been reported for the F-center emission from Al_2O_3:C OSL dosimeters [Yukihara and McKeever 2006]. Without proper filtration, the contribution to the total signal by the UV emission can be significant, approximately 20% of the F-center signal for low doses and increasing to nearly the same as the F-center emission at high doses. Bandpass filters designed to pass F-center emission wavelengths can be used to reduce the influence of the UV emission.

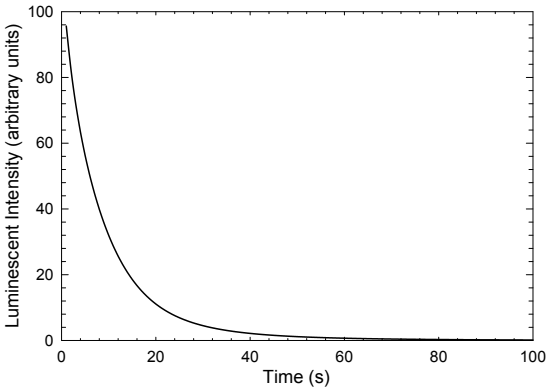

Figure 19.33. An OSL decay curve for Al_2O_3:C after irradiation with 60 mGy from a ^{90}Sr beta particle source. The OSL decay curve is for constant power stimulation (16 mW cm^{-2}) with wavelength band of 420 to 550 nm. Data are from Bøtter-Jensen et al. [1997].

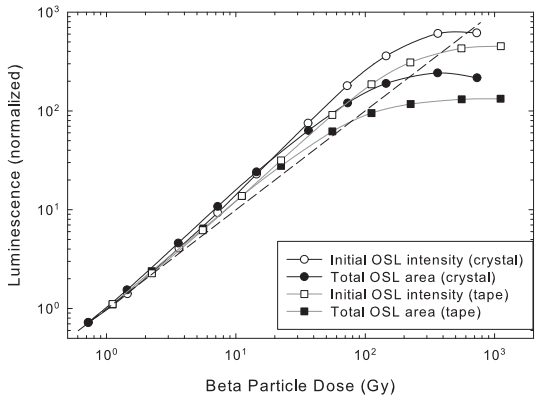

Figure 19.34. OSL beta particle dose response from a Al_2O_3:C single crystal and from a Luxel Al_2O_3:C tape. Initial OSL response is for the first 3 seconds of optical stimulation. Total OSL area is for the integrated response over 300 seconds of optical stimulation. Data are from Yukihara et al. [2004].

The CW-OSL responses (Fig. 19.34) reveal sensitization (superlinearity) with both the initial intensity (measured within the first 3 seconds of stimulation) and the total luminescence (integrated over 300 seconds of stimulation). Experiments that remove the UV component indicate that these emission centers are responsible for the supralinearity observed for doses above 10^3 rad (10 Gy). Because of the short time constant, the UV component can be eliminated from the measurement by using POSL. During the stimulation pulse, most of the UV component is released and does not contaminate the measurements between pulses. Sublinearity is observed for doses above 10^4 rad (100 Gy) for both UV and F-center emissions.

The dose response can be affected by the dose history as deep traps become filled over time and are not emptied by annealing. An advantage of single crystal Al_2O_3:C dosimeters over OSLD formed from powder on tape is that crystals can be annealed at high temperatures to remove electrons from deep traps, up to 900°C [Bøtter-Jensen et al. 1997]. This annealing procedure ensures that background and sensitization from deep traps does not build up over time. However, much like TLDs, the uniformity of the carbon doping determines the variability of response, and large variations can be present within and between batches. Hence, crystalline Al_2O_3:C OSL dosimeters can have a large variance in luminescence among samples.

Just as with TLDs, commercial Al_2O_3:C OSL material can be pulverized after crystal growth and mixed with multiple batches to improve uniformity amongst samples. The pulverized materials are bound with plastic to produce a length of tape. This tape is then sliced into sections for commercial use as OSL dosimeters. These OSL dosimeters cannot be annealed at high temperatures because the plastic binder is destroyed. Although optical bleaching can be used to empty most of the dosimeter traps, it is not adequate to empty the deepest traps. Consequently, the background luminescence increases with integrated dose.

Drawbacks to the use of Al_2O_3:C OSL dosimeters include the high effective Z number and the presence of shallow traps that makes the material sensitive to light. The effective Z number is 11.3, and the low energy response to gamma rays can be quite high, comparable to SiO_2 (see Fig. 19.10), so that Al_2O_3:C OSL dosimeters overrespond to x rays and low-energy gamma rays. The shallow traps can affect the total light output, but generally fade rapidly at room temperature. Edmund and Andersen [2007] report that shallow traps in Al_2O_3:C can affect the luminescent yield. If the irradiation temperature cannot be maintained at a constant temperature, they recommend a correction factor between -0.2% to 0.6% per °C over a range from 10°C to 50°C.

Beryllium Oxide Beryllium oxide (BeO), or beryllia, is a thermoluminescent material and has been used as an OSL dosimeter. The luminescent spectrum reported by Bular and Göksu [1998] has a broad spectrum, ranging from 420 to 550 nm, with a maximum peak at 435 nm. Sommer et al. [2008] report the use of 455 nm light to stimulate these emissions and a Schott DUG11X optical filter to make luminescence measurements. BeO OSL dosimeters are linear over a wide range, extending from 100 μrad (1 μGy) [Sommer et al. 2007] up to 1000 rad (10 Gy) [Bular and Göksu 1998]. Sub-linearity appears at approximately 2000 rad (20 Gy), and the onset of saturation is evident at approximately 10 krad (100 Gy) [Sommer et al. 2008]. The low effective Z of 7.14 makes these OSLDs almost "tissue equivalent" and they have a relatively flat response for low- to high-energy gamma rays (see Fig. 19.10) with only a slight under-response to low-energy gamma rays.

Short-term fading from shallow traps amounts to approximately 6% loss within the first few hours of irradiation. The fading becomes almost negligible thereafter and is less than 1% over a 6-month period [Sommer et al. 2007]. There is a temperature dependence on the decay constant τ_d of the main luminescent centers, ranging from 27 μs at room temperature down to 800 ns at 140°C [Yukihara and McKeever 2011]. This decrease in decay time constant is largely due to non-radiative transitions. Also, the luminescent efficiency decreases with temperature and, characteristically, higher temperatures decrease the total luminescent yield [Akselrod et al. 1998]. Bular and Göksu [1998] and Sommer et al. [2008] investigated the use of Thermalox®, a commercial form of BeO,[11] for dosimetry with promising results.

Other Synthetic Materials There are numerous other synthetic materials that have been investigated for OSL dosimetry. However, none are as promising as Al_2O_3:C and BeO, mainly because of the high fading from shallow traps exhibited by these other materials. These alternatives include MgO:Tb^{3+} [Bos et al. 2006], $MgSi_2O_4$:Tb, Al_2O_3:Cr,Mg,Fe, $MgAl_2O_4$ (cubic spinal crystals), Brazilian fluorite (CaF_2), and various barium aluminoborate glasses ($20Al_2O_3 \cdot 50B_2O_3 \cdot 30BaO$) [Yoshimura and Yakihara 2006]. Potassium compounds, such as KBr:Eu, KCl:Eu, KBr:Cu^+, and KBr:Cu^+, have also been investigated as OSL materials [Nanto et al. 1993; Douguchi et al. 1999; Bandyopadhyay et al. 1999] and they all have relatively short decay times of about 1 μs. All have a luminescent emission near 420 nm and the optimum stimulation wavelength for KBr:Eu is 620 nm and for KCl:Eu is 560 nm. Problems associated with these potassium-based materials include substantial fading and the high effective Z of 18.1 and 31.5 for KCl and KBr, respectively, and thus they overcompensate for doses from low-energy gamma rays.

Kearfott et al. [2015] studied several known thermoluminescent materials for application in OSL dosimetry, namely LiF:Mg,Tl, $Li_2B_4O_7$:Cu, $CaSO_4$:Tm, and CaF_2:Mn. Of these materials, only $CaSO_4$:Tm produced appreciable optically stimulated luminescence; however, its luminescent yield was only 10% of the yield from commercial Al_2O_3:C OSL dosimeters.

Natural Materials Luminescent spectra from several minerals can be used for dating and dosimetry characterization [Krbetschek et al. 1997]. Both thermoluminescence and optically stimulated luminescence have been used to characterize these minerals, mainly to obtain information on recombination site energies,

[11] Developed by Brush Wellman, Inc., for the thermal and electrical properties of BeO, Thermalox® is now produced by the renamed Materion Corporation. However, there is no indication of its use for OSL dosimetry in the Materion literature.

possible information on trap energies, and also for use in retrospective dosimetry. Possibly the two most investigated minerals for OSL dosimetry applications are quartz and feldspar, originally studied by Huntley et al. [1985]. However, difficulties with using natural minerals for dosimetry arise from compositional differences, activator differences, and various inclusions which usually contaminate natural crystals. Consequently, luminescent spectra are variable and depend on the origin of the mineral. Further, OSL emissions are a function of the thermal history of the samples, with samples exposed to high temperature having much lower luminosity [Bøtter-Jensen and McKeever 1996].

For quartz samples taken from archaeological fired clay, Bluszcz and Bøtter-Jensen [1995] determined that gamma-ray doses of less than 100 mrad (1 mGy) can be measured. Optical stimulation from long wavelength light (541 nm or 647 nm) produces a single emission band from quartz near 365 nm [Huntley et al. 1991]. The luminescent lifetime τ of this 365 nm emission is approximately 35 μs. Although Huntley et al. [1985] first studied feldspar with 514 nm light stimulation, Hütt et al. [1988] discovered that IR stimulation produced superior results. The optically stimulated emissions from feldspar are much more complex, with multiple emissions reported by various researchers [Krbetschek et al. 1997], mainly at 280 nm, between 320 to 340 nm, 400 nm, between 560 to 570 nm, and in some cases a broad emission band between 330 nm and 620 nm, with results depending on the choice of OSL filters [Clarke and Rendel 1997; Huntley et al. 1985; Krbetscheck and Rieser 1995]. Anomalous fading is another problem with feldspars in which trapped charges are lost by mechanisms other than thermal quenching.

Luminescent Detector Summary

High heating temperatures can lead to non-ideal behavior for some TLDs. IR radiation from the heat source can cause interference and alter the measured TL spectrum. Also, because several TLD materials may suffer irreversible damage to the TLDs at high temperatures, a thermal heating limit is often imposed to prevent such damage. Consequently, deep traps that require temperatures above this thermal limit cannot be efficiently depopulated. Further, buildup within these deep traps over time causes sensitization of the TLD and this buildup can also become a source of background emissions during readout.

There are several advantages of OSL over TL. Commercial OSL dosimeters can also suffer damage if heated to too high a temperature because of damage to the binding material. However, because the read-out process does not require a heating step, OSL dosimeters generally are unaffected by this encumbrance. With sufficient energy of the stimulation photons, many of these deep traps not only can be depopulated, but can also be used in the dosimetry measurement. This increased density of useful trapping centers improves the radiation sensitivity of OSL dosimeters.

The luminescence from OSL dosimeters is very faint by comparison to the stimulation light source, hence filters must be used to reduce background light. POSL can be also be used to reduce or almost eliminate this background light, provided that the decay time of the luminescent centers is much longer than the optical pulse and the stimulation light source duty cycle is relatively small. As with a TLD, once the OSLD is read, the dose information is lost. However, an OSLD does not necessarily need to be completely cleared during the measurement process. A spot on the OSLD can be read with a focused laser, leaving the remaining unilluminated regions for later measurements. Also, an OSL dosimeter may be illuminated for a time that is small compared to the mean decay time of the trap and can, thus, leave a high density of filled dosimetry traps for a later measurement.

19.2 Photographic Film

Somehow it seems fitting that near the end of the long journey through this book, which began with the discovery of x rays from exposed photographic plates, the use of photographic film as a radiation detector is finally described with some respectable amount of detail. Radiation exposure of photosensitive emulsion was first observed in 1842 by Ludwig Moser who reported that when certain bodies were brought into contact

with a silver iodide plate in darkness, an image would still form. He concluded that some materials must be "self-luminous". There is evidence that natural radiation had also been observed from uranium salts by Claude Félix Abel Niépce de Saint-Victor, in which a uranyl nitrate sample had been brought into close proximity of a photo sensitive silver bromide paper sheet [Niépce de Saint-Victor 1857, 1859]. The Niépce de Saint-Victor experiments were reported to the French Academy of Sciences in 1858, and apparently Antoine Henri Becquerel was aware of the work, primarily through work of his father, Edmond Becquerel, who mentioned the findings of de Saint-Victor in his book *La Lumiére: Ses Causes et Ses Effets*. Regardless, A. Henri Becquerel was apparently the first to explain and understand the significance of the discovery, having observed images formed from uranium salts on photographic plates in 1896.

19.2.1 Basics of Photographic Film

Photographic film consists of a photosensitive emulsion spread upon a base material. This base is either made of glass or a cellulose material such as cellulose acetate.[12] Photographic emulsions consist of a binder and a photosensitive compound, usually a distribution of microscopic silver halide crystals suspended in gelatin. Silver bromide (AgBr) is the photosensitive compound usually used for nuclear emulsions. The process for producing photographic film has some interesting aspects. A photographic emulsion can be produced by adding the two reacting solutions

$$\mathrm{KBr\ (Aq) + AgNO_3\ (Aq) \rightarrow AgBr\ (s) + KNO_3\ (Aq)}$$

to a gelatin. The mixture is heated between 50°C to 70°C to cause *Ostwald ripening* of the mixture [Becker 1966]. It is also usual to add ammonia (NH_3) to the solution, which produces various amine complexes and forms an ammoniacal emulsion. During this ripening process, the size of AgBr crystals, referred to as grains, increases by growing between 100 to 1000 times in size. Larger grain sizes are usually associated with *faster* emulsions. The *speed* of the film can be increased by adding a small amount of mustard oil to the solution,[13] which forms particles of silver sulfide (Ag_2S) on the AgBr grains. Afterwards, the emulsion is shredded and washed to remove excess KNO_3. During a reheat process, in which the product is melted, more gelatin is added to the emulsion along with dyes and stabilizers. The process of "after-ripening" increases the sensitivity and affects the contrast, fogging, and storage properties of the emulsion. The finished emulsion is then applied to the base. The thickness of the finished emulsion varies with the intended use and ranges from 5 microns up to 600 microns. The AgBr content in common photographic emulsions is approximately 30%, but is increased to up to 80% for nuclear emulsions.

The silver halide grains in the emulsion are believed to be in the ionized state, even though they are in crystalline form. Exposure to ionizing radiation can cause the ejection of an electron from the halide ion and the electron subsequently is trapped at an impurity location. It is believed that the silver sulfide specks in the emulsion may be such locations. A positive silver ion can migrate to a trapped electron site and combine with the electron, becoming neutral silver. A single silver atom is unstable, and eventually decomposes back to a silver ion unless more silver atoms accumulate together. The neutral silver atom may also acquire an extra electron, thereby becoming a negative ion. If a second positive silver ion migrates to the negative silver ion, they can combine to form a two-atom cluster. This process continues as long as there are free electrons. Stability requires accumulation of at least three to four silver atoms. The sensitized silver grains that acquired neutral silver clusters produce a *latent image* in the emulsion, and it is this latent image that can then be developed to form a darkened image.

[12] Nitrocellulose is considered a much better base for film emulsions. Is it produced by soaking cotton in nitric acid. Unfortunately, it is also extremely flammable, almost explosively flammable. For this reason, cellulose acetate, a much slower burning base formed from soaking cotton in acetic acid, is a preferred choice.

[13] This process was discovered when film speeds were observed to increase for gelatin bases made from the collagen of cows that had eaten mustard plants.

The development process consists of several chemical treatments after the latent image is formed. In the case of nuclear emulsions used for dosimetry, the latent image may be accumulated over an extended period, weeks for instance. Photographic films are generally sensitive to visible light and must be developed in total darkness. The photographic film can be slipped into a light-tight development container for easier handling. Chemical developers are used to change positive silver ions in the emulsion into stable neutral silver atoms. This conversion is done more efficiently for silver grains already having silver atom clusters. The developer chemical has *reducing* agents attached to a benzene ring. Here the act of reducing refers to lowering the positive charge of an ion, in this case changing positive silver ions to neutral silver atoms.[14] The reduction potential of a chemical indicates the relative ability to reduce the photographic film. It is also usual to blend two or more reduction agents together to increase the activity [Becker 1966], and two popular reduction agents that are used together are metol and hydroquinone. Because the unexposed silver grains can also become developed, the developer temperature and development times must be strictly controlled to avoid over- or under-developing the film.

Most developers have several components, consisting of a reducing agent, an accelerator, a preservative, a restrainer, and a solvent. Because the reducing agent can be slow, an accelerator usually consisting of an alkali metal compound is added to the developer. Although KOH and NaOH work well as accelerators, they can also cause softening of the emulsion [Larmore 1965]. Effective accelerators include Na_2CO_3 and K_2CO_3, but release CO_2 gas that can cause film blistering if the development temperature is above 27°C. Less effective, but adequate accelerators that do not soften the gelatin and do not release gases include $Na_2B_4O_7$ (borax) and $NaBO_3$ (sodium metaborate). Because the developer is designed to chemically reduce the silver halide, it also has a strong affinity for oxygen, and can become ineffective over time. Preservatives are added to the developer to mitigate oxidation and prolong the developer lifetime. Sodium sulfite (Na_2SO_4) is one of the most commonly used preservatives. Although Na_2SO_4 reacts with oxygen, it does not adversely affect the development process, and it also prevents oxidation products (such as negative bromine ions) from accumulating on the film. These halogen ions decrease the pH of the developer. Further, the excess alkali metal ions added to accelerate the emulsion development can also *fog* the film, an effect that appears as a general darkening of the emulsion. Hence, a restrainer is also added to balance the pH during development, which, interestingly, turns out to be more bromine ions (often KBr). An overall chemical balance is achieved by adding excess alkali metal ions to the developer, which is compensated by the excess bromine ions. The addition of the small number of bromine ions released during development is insufficient to upset the chemical balance. Finally, a solvent is used to dilute the developer concentrate and, in most cases, is simply water.

To quickly stop the film development, the film is soaked in a *stop bath* solution, usually an acetic acid solution, that neutralizes the development process. Although the stop bath step is not strictly necessary, and thorough rinsing with water can be substituted, the development process continues, even if it is at a lower rate, unless a stop bath is used. Once the film is developed, the remaining undeveloped AgBr must be removed and is accomplished by *fixing* the emulsion. Otherwise, the film continues to darken when exposed to light. The fixer step is performed by soaking the film in a solution of sodium thiosulfate ($Na_2S_2O_3$), which dissolves the remaining AgBr crystals. The film is then thoroughly washed in water and dried. The darkness of the image that is formed gives a measure of the ionizing dose absorbed by the film and can be measured with a *densitometer*.

19.2.2 Photographic Film Characteristics

There are several important film properties that determine the adequacy of a film to perform well as a nuclear emulsion. Among these properties are the contrast, film speed, and the linearity of the film with exposure.

[14] Contrarily, *oxidation* is a chemical process that causes an atom or ion to lose an electron to become more positive.

These properties are discussed below through a description of the general characteristics of photographic film.

The Characteristic Curve

The passage of ionizing radiation through photographic film generally deposits only a small amount of energy in the emulsion. For visible light, the film may actually absorb all energy of the incident radiation. However, for x rays, gamma rays, and beta particles, generally only a small portion of the radiation energy is deposited. The absorbed energy produces a proportional amount of ionization in the emulsion. Hence, film provides a measure of the total ionization produced in the film over a period of time, and so film should be thought of as a type of time-integrating radiation detector.

After exposure, the opacity of a film emulsion is measured to determine the absorbed ionization. The opacity is measured by the amount of visible light transmitted through the film. The film density D is the ratio of incident and transmitted light, or I_0/I_t. Traditionally for most radiation absorption applications, this relationship is determined by an exponential expression, but this is not so for photographic film. Instead, the density is determined from the transmitted intensity on a base 10 logarithmic scale. Hence, the density of the image on film is generally expressed as

$$D = \log_{10}\left[\frac{I_0}{I_t}\right]. \tag{19.52}$$

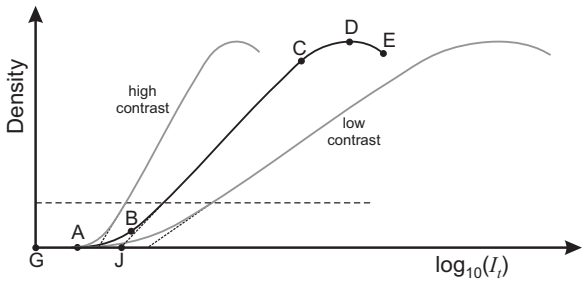

Figure 19.35. The characteristic, or H-D, curves for high, medium, and low contrast films depicting typical features. The dashed line indicates a location on the H-D curves all having the same density for different exposure intensities.

The density of unexposed film is 0, while film with a density capable of blocking 90% of light would have a density of 1. To achieve a density of 2, then 99% of light must be blocked, increasing to 99.9% for a density of 3, and so on. The response of film to ionizing radiation can be documented with the *characteristic curve* that is a plot of the film density versus $\log_{10}$ of the transmitted light intensity as depicted in Fig. 19.35. The characteristic curve was first reported and employed by Hurter and Driffield [1890] as a film characterization method.[15] The region between A and B in Fig. 19.35 is the *toe* of the curve, while the region between C and D is the *knee* of the curve. The region between B and C is a nearly linear function of density versus $\log_{10}(I_t)$ and is the most useful portion of the film characteristic. In the region between D and E, film overexposure causes the density to actually decrease because a latent image reverses from a negative image to a positive image, an effect referred to as a *solarized* image. The consequence for dosimetry is obvious, namely in this region a higher dose diminishes the density and results in an underestimate of the dose.

Contrast

The contrast of the film, denoted γ, is the slope of the characteristic curve region between points B and C, i.e.,

$$\gamma = \frac{D_1 - D_2}{\log_{10}(I_{t_1}) - \log_{10}(I_{t_2})}, \tag{19.53}$$

where D_1 and D_2 are any two different densities on the curve. High contrast films have $\gamma > 1$ while low contrast film has $\gamma < 1$. The implication is that high contrast film exhibits more sensitivity to small exposure differences than low contrast film. However, the dynamic range of exposure, referred to as the film *latitude*, is greater for low contrast film, that is, it takes more absorbed energy to push the density into the knee

[15] Sometimes the curve is referred to as the H-D curve after Hurter and Driffield.

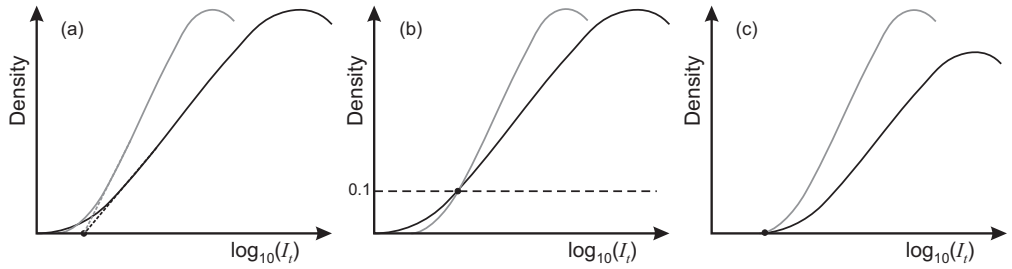

Figure 19.36. Ambiguity with early speed designations, showing H-D curves with (a) the same inertia but different latitudes, (b) the same intersection at D = 0.1, but with different latitudes, and (c) the same Scheiner speeds, but with different latitudes.

region. Although film has a characteristic latitude for the recommended development process, the contrast is also a function of developer type and development time. Hence, there is some degree of control over the film contrast through changes in the development process. Low contrast films often have a wide distribution of grain sizes with the large grains sensitive to low levels of light while the small grains require a greater exposure before accumulating enough stable Ag atoms to produce a developable image.

The Speed Index

The amount of absorbed energy that is required to produce an image is largely dependent on the speed of a film. Unfortunately, there are numerous speed indices for films. Three historically popular speed indices are depicted in Fig. 19.36. One system referenced the *inertia* of a film, which in Fig. 19.35 is the distance along the $\log_{10}(I_t)$ axis from point G (the origin) to point J where the linear portion of the characteristic curve, if projected, would intersect the abscissa. This speed rating presumes that a smaller inertia indicates a larger γ, but this is not necessarily true.

The Scheinergrade (Sch.) system was introduced by the German astronomer Julius Scheiner in about 1894. The Scheiner number is based on the minimum exposure threshold required to produce a latent image (point A in Fig. 19.35), but even this system for a speed index can produce ambiguous results, mainly because this index is based on an unused portion of the characteristic curve. The Scheiner number is reported in degrees between 1° (Sch.) to 20° (Sch.). A 19° increment produced a 100-fold increase in the sensitivity while a 3° increment almost doubles the sensitivity ($\sqrt[19]{100} = 2.06914... \simeq 2$).

The DIN (Deutsches Institut für Normung) speed index system, which replaced the Schneiner system in 1934, refers to the exposure required to produce an image density of 0.1 on the film. Similar to the Scheiner number, the DIN number is expressed in degrees, but the increment to 100-fold increase in sensitivity is 20° instead of 19°. Further, the system is based on a $\log_{10}$ scale so that the exposure increase is

$$S = 10^{\mathrm{DIN}/10}. \tag{19.54}$$

A DIN increase of 3° would indicate a doubling in speed ($10^{3/10} = 1.9953... \simeq 2$). For instance, a film with DIN 27 would be double in speed to film of DIN 24. Again, this system does not necessarily produce an accurate depiction of γ. This system, originally developed for black and white film, was superseded in the 1980s by the ISO system.

Edward Weston and his father founded the Weston Instrument Corporation which made one of the first photographic light meters. One of their employees, William Goodwin, who designed the light meter also invented the Weston film speed index which was based on the exposure required to make the image density equal to γ. This system was introduced in the early 1930s. About the same time, General Electric introduced its own film speed rating system called the GE film values. However, both the Weston and GE systems were replaced by the ASA system in the 1960s.

Based on early work by Kodak and inspired by the Weston and GE film speed systems the American Standards Association[16] produced the ASA system in the 1950s. The ASA system follows the rule of reciprocity in which the amount of energy needed to produce a specific density on the film on the linear portion of the characteristic curve was inversely proportional to the film speed. Hence, film with rating 400 ASA would be twice as fast as 200 ASA and require half the exposure to produce equal density on the characteristic curve.

The International Organization for Standardization combined the qualities of the DIN and ASA system to produce the ISO number for speed, which uses the linear ASA number and the DIN number in degrees, denoted as ASA/DIN. For instance, a DIN number of 21 is equal to ASA 100 and ISO 100/21°. This system with several revisions is the current system used by most film manufacturers.

Example 19.1: Given a film package marked DIN 24, what is the equivalent speed in ASA and ISO?

Solution:
Noting that DIN 24 is 3° greater than DIN 21, we know that the film is doubled in speed. Hence

$$\text{ASA} = 10^{(24-21)/10} \times 100\,\text{ASA} \simeq 200\,\text{ASA}.$$

Also, the ISO designation would then be 200/24°.

Fast films usually have large grain sizes in the emulsion, while slow films have substantially smaller grain sizes. The advantage to the fast film is that they are useful for low exposure situations, but have the disadvantage of compromised resolution (graininess). The slower films require more exposure to produce a latent image, but have much higher image resolution.

Non-Linear Effects

Photographic film fails in low light to record an image whose density is linear with accumulated exposure, an effect known as *reciprocity failure*. A classic example of this effect is encountered in astrophotography in which celestial images take several minutes to hours for proper exposure. If the time between the reduction of individual Ag^+ ions is long compared to the dissociation time of a single Ag atom, then a latent image takes longer to form than predicted by reciprocity. Further, during the exposure time, the photographic emulsions are exposed to oxygen and possibly moisture in the air. The gelatin is hygroscopic and can absorb water moisture, thereby incorporating contaminants in the film emulsion. These contaminants act as oxidizing agents and compete for the isolated Ag atoms, thus causing them to decompose to Ag^+ before stabilizing with Ag clusters. Consequently, absorbed energy information is lost, and the law of reciprocity fails. In some cases, reciprocity failure in a photographic emulsion can be so severe that no additional amount of low-level light exposure increases the density of the latent image. In such situations an equilibrium condition is established in which the number of Ag^+ ions capturing electrons is equal to the number of Ag atoms losing an electron.[17]

Because the radiation environment is usually low for most radiation workers, the period between ionizing interactions is typically long compared to an astrophotograph exposure. However, Becker [1966] and Herz [1969] note that a single energetic electron interacting in the film most likely produces enough localized

[16] Now the American National Standards Institute or ANSI.

[17] Complicated processes were developed to reduce reciprocity failure with astronomical emulsions, including reducing the photographic emulsion temperature with dry ice or LN2, and drying the film in a pure hydrogen environment. The former process used an instrument named a *cold camera* and the process was named *hypersensitization*.

excited electrons to effectively produce Ag clusters. Hence, the reciprocity failure effect is less pronounced for this type of exposure than for exposures produced by low intensity and low energy (optical) photons in which one photon statistically produces a single silver ion.

As a consequence, low-intensity reciprocity failure is of little concern with most photographic films used for dosimetry. For high-energy gamma rays, the energy passed to photoelectrons or Compton electrons, as well as secondary ionization electrons, leads to the asymptotic minimum ionizing power of 380 eV per micron. Chassende-Baroz [1961] demonstrated that such a low ionization power can cause reciprocity failure for slow photographic emulsions.

Another form of reciprocity failure is caused by excessive exposure that propels the film density past the knee region of the characteristic curve, producing a solarized image of reduced density. Ehrlich and McLaughlin [1956] and Ehrlich [1956] show that the effect can be severe, and is a function of irradiation rate and dose. At high enough doses, x-ray films were shown to return nearly to zero density, as though the samples were barely exposed at all. The tested films reached the knee of the H-D curve at exposures between 10 R up to 200 R, depending on the irradiation rate (R s^{-1}).

Another source of dosimetric uncertainty is related to the variation in time of how the film is exposed to radiation, or the so-called intermittency. For low to medium exposures, the image density of the photographic film falls in the linear portion of the H-D curve. If the film is exposed to radiation intermittently over time, the density of the latent image increases additively with total exposure. In fact, it is this property that makes photographic film an important integrating dosimeter. However, for high total exposures generally exceeding 10 R, intermittent exposure can cause reciprocity failure and solarizes the film. Results from Ehrlich [1956] indicate that intermittent exposures can actually cause solarization at lower exposures than continuous exposures, even though the irradiation rates are identical during the exposure periods.

19.2.3 Film Dosimetry Badges

Personnel dosimetry film badges once were widely used, although TLDs and OSLDs have now replaced film in many applications. Regardless, photographic film emulsions can be used to measure dose from x rays and beta particles. If a neutron reactive foil is placed adjacent to the film, it can also be used for neutron detection. The film is contained inside a film holder or film badge which serves as a light proof, vapor proof envelope that protects the film from light, chemicals, and water moisture which would otherwise alter the response or fog the film.

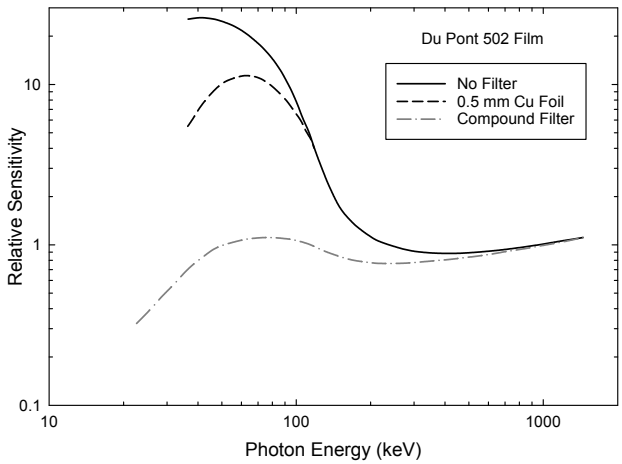

Figure 19.37. Photon energy dependence on image density for bare and filtered Du Pont 502 film. The compound filter is composed of 0.5 mm Cu, 0.74 g cm^{-2} Bi, 0.117 g cm^{-2} Au, 0.114 g cm^{-2} Ta, 0.148 g cm^{-2} Er, and 0.148 g cm^{-2} Gd. Data are extracted and adopted from Storm and Shlaer [1965].

Dosimetry film has two emulsion layers, one on each side of a backing layer. One layer is a fast large grain emulsion, while the other is a much slower small grain emulsion. Hence, the large grain emulsion is sensitive to low radiation exposures, while the smaller grain emulsion is sensitive to high radiation exposures. Should the fast emulsion be overexposed to radiation, it can be removed and the slower emulsion be used to interpret the dose.

Filters can be used to distinguish among different radiations. For instance, a shield can be used to block beta particles while allowing

gamma rays to interact in the film. Also, filters can be used to flatten the energy response of gamma rays by attenuating a portion of low energy photons interacting in the film (see Fig. 19.37). With different attenuators over one or more films and with knowledge of the film energy response with each attenuator, a crude energy response to the total photon fluence can be calculated.

Photographic film has the advantage that it can be preserved as a permanent record of dose, with accurate response down to 100 mrem. However, disadvantages include the added processing with chemical development, data interpretation (densitometer readings), and the fact that doses less than 20 mrem are difficult to analyze. Low doses may be susceptible to reciprocity failure, a form of fading. Also, photographic film can be fogged if left in relatively high heat for too long.

The position of a film badge on the human body is important. Usually the badge should be worn on the torso, often clipped to a shirt pocket, a belt near the wasteline, or clipped to a lanyard around the neck. For persons working in a radiation area with their hands, such as a beam port or with laboratory sources, special rings loaded with photographic film can be used to measure dose to fingers and hands.

19.3 Track Detectors

Track detectors belong to a class of sensors that can provide visual evidence of radiation interactions. For instance, the cloud chamber that was introduced in Sec. 9.5.8 is a type of gaseous detector that produces visible ion tracks made by charged particles. In fact, discussion of the cloud chamber could have been deferred to this chapter, but because it operates with a cooled saturated vapor and often has a voltage applied to counter gravitation effects, the authors chose to include it in the chapter on ion chambers. There are numerous other types of track detectors, many described here, all providing visual evidence of the passage of radiation through the detector.

19.3.1 Nuclear Track Emulsions

For a photographic film to be used as radiation dosimeters, it is assumed that the film is uniformly exposed to a radiation field so as to produce a uniform density over the developed film. However, it is also possible to detect the passage of individual radiation particles from the tracks they make in the emulsion. Nuclear track emulsions are a special type of film with a higher density of nanoparticle silver halide (AgBr) crystal grains. The silver halide density can be up to 82% by weight with grain sizes of about 300 nm. To increase the probability that incident radiation particles or reaction products produced by interactions in the emulsion are completely captured in the film, these emulsions may be up to 600 microns thick. Individual tracks are produced by high LET particles, and the developed tracks are tediously visually counted through a microscope. Yet, much information can be extracted from the tracks, including trajectory, energy, and LET. Examples of alpha particle tracks in film are shown in Fig. 19.38 for film that has been permeated with fine thorium and uranium dust.

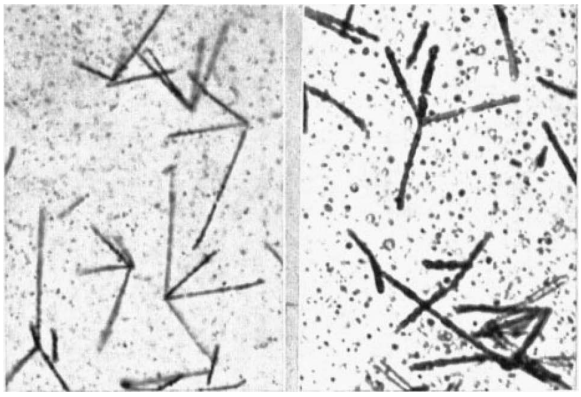

Figure 19.38. Photomicrographs with 8 mm apochromat (x20) and x10 periplanatic eyepiece. (left) Thorium alpha-particle stars; (right) similar tracks after uranium intensification. Reproduced from Powell et al., *J. Sci. Instrum.*, **23**, 102–106, (1946). Copyright IOP Publishing. Reproduced with permission. All rights reserved.

Several charged-particle ranges as a function of energy and mass are shown in Fig. 19.39 for a specific nuclear emulsion (Ilford C2). Except at low energies below 1 MeV, particle ranges are almost proportional to the initial energy of the particle. Note also that 1-MeV particles have ranges of 2 to 15 microns.

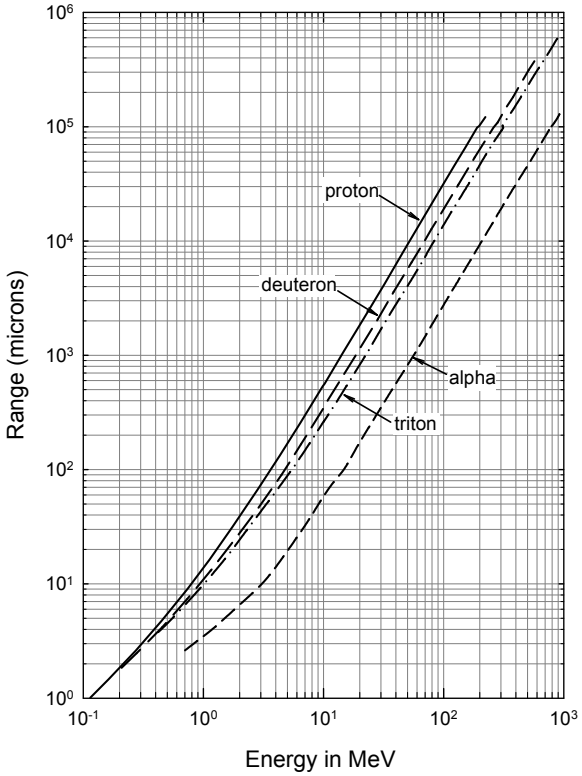

Figure 19.39. The range-energy curves for protons, deuterons, tritons, and alpha-particles in Ilford C2 photographic emulsion. Data are extracted and adopted from Vigeron [1953].

At higher energies, generally above 20 MeV, emulsions exceeding 600 microns are needed, a thickness that can be realized by stacking several film emulsions together [De Serio et al. 2005]. Such an emulsion stack allows the entire track of a particle to be followed. Also, because the intrinsic interaction efficiency can be low for a single emulsion layer, use of a stack of emulsion layers, therefore, increases the detection efficiency.

Each film layer is called a *pellicle*, and it records the track of a particle as it traverses the emulsion of the pellicle. The stack layers are pressed together to form a 3-dimensional block of emulsion and may consist of several hundred pellicles. Because of non-uniformities across the emulsion surface, the pellicles must be pressed together with a uniform pressure, recommended as 44 lbs per square inch [Barkas 1963]. At room temperature, with the relative humidity kept below 60%, the pellicles should not stick together. Each pellicle is indexed so that, after the pellicle stack is developed, the track image sequence can be followed through the different levels.

To develop a stack, the pellicles are separated and all are developed simultaneously with or without a backing. The simultaneous developing ensures that each pellicle experiences the same development conditions. If developed without backing, each pellicle is suspended in a frame protected by a wire mesh on each side. Development of a pellicle without a backing produces a more uniform result throughout the emulsion than if a backing were used, and the developing time is shortened because development proceeds from both sides of the emulsion. Further, unequal emulsion swelling, a consequence of attaching pellicles to a glass backing before development, is greatly diminished. Also, the ionization tracks can be viewed from both sides of a pellicle without backing. However, pellicles without backings seldom return to their original dimensions after fixing and drying and this can distort the actual length and geometry of the tracks. Free pellicles must be handled with great care, and it is possible that they adhere to each other or other surfaces during the processing. Finally, a free developed pellicle usually does not lay flat, and so may still require adhesion to a stiff backing.

If the emulsion is developed after attachment to a glass plate backing, the film receives mechanical support and can be developed in special processing racks. However, during the preparation process that requires washing of the pellicles, water can be trapped and distort the image. Further, unequal shrinkage can alter the image. An indexing grid printed on the pellicle can be used to correct distortions. Also, it is usual for the emulsion thickness to shrink after the development and drying process. This shrinkage changes the measured track length from that in the original emulsion. However, irradiation with x rays or other ionizing particles, shadow shielded to enter a select location at a 45° angle, can be used to determine the thickness change [Barkas 1963]. The shrinkage factor can be determined from

$$S = \frac{lD}{Ld}, \tag{19.55}$$

where the variables l, L, d and D are defined in Fig. 19.40.

Nuclear track emulsions can be used to study nuclear reactions because a reaction in the emulsion preserves the energy deposition as a function of position. Measurements of these tracks can be conducted by visual inspection under a microscope, but automated processes relieve this tedious method. The track angle into the emulsion is important to correct for the foreshortened projected length. Emulsions are used to measure the track length of a particle, the angle and curvature of a particle, scattering angles, star formation, and various other reaction product results. An example of a nuclear reaction captured on film is shown in Fig. 19.41.

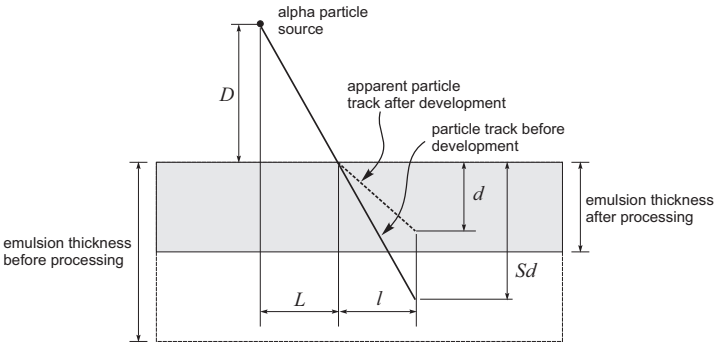

Figure 19.40. Determination of shrinkage for nuclear emulsions. After Becker [1966].

When exposure is conducted in a magnetic field, the curvature of the track yields charge and mass. Star formation is an indicator of a reaction, with the resulting reaction products emitted in various directions. The star formation products may be simultaneous, or the result of decay chains. Neutrons can be measured by way of recoil protons from the water in the emulsion. Also, reactive materials can be incorporated in the emulsion to enhance specific reactions of interest (^{10}B, for instance). Photographic track film was used to discover a number of subatomic particles, including the π^+ and π^- mesons (pions),[18] the K^+ and K^- mesons (kaons), the Σ^+ baryon, and the Λ^0 baryon.

19.3.2 Track Etch Detectors

In 1958, Young reported on a technique of etching out the damaged tracks left behind by heavy ions penetrating a solid material. The substrate under investigation was a LiF crystal bombarded by fission fragments. After etching in a solution of hydrogen fluoride (HF) and water, pits appear where the fission fragments damaged the crystal. A few years later, Price and Walker [1962] reported on a similar experiment with mica that was irradiated by recoil ions from spallation reactions, also etched in hydrofluoric acid. Shortly thereafter, Fleischer and Price [1963] used the method to investigate damage tracks in polymers, which they noted could be applied to radiation dosimetry. This technique is recognized as an important alternative detection method for ionizing radiation dose, and is referred to as *track etching* [Fleischer et al. 1965a].

Fleischer et al. [1972] point out that the technique of particle track counting is simple, the result produces a straightforward permanent record (a hole), and there is a natural sharp discrimination between particles that leave tracks and those that do not. Track etch measurements are useful in radiation dosimetry, as well as other applications, including dating of geological samples and archaeological artifacts, quantitative chemical analysis for fissionable nuclei or nuclei susceptible to (n, α) reactions, uranium concentrations in water and other substances, the measurement of diffusion coefficients in metals, the production of uniform pores in filters, and many other applications as listed elsewhere [Fleischer et al. 1972; Becker 1973; Fleischer et al. 1975].

Track Formation

Energetic ionizing particles that interact in a substance can produce a dense track of material damage, an effect that can be observed in organic and inorganic materials. There are at least four models used to describe

[18] Cecil Frank Powell discovered the pion by photographic means in 1946, and was awarded the Nobel Prize in Physics in 1950 for the development of the photographic method to study nuclear processes and the discovery of the pion.

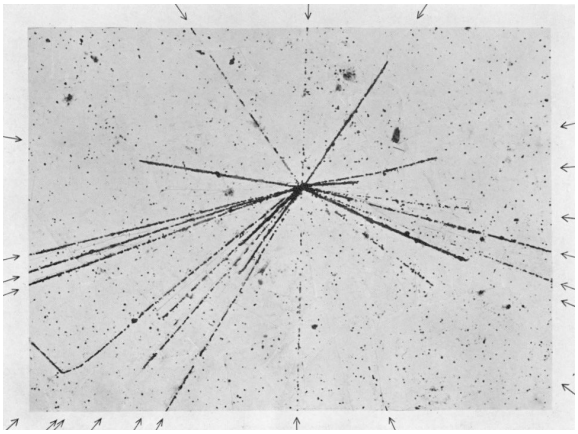

Figure 19.41. Mosaic of photo-micrographs of the 'explosive' disintegration of the nucleus of a silver atom by a cosmic-ray particle of great energy. The tracks of twenty-five fragments can be distinguished under the microscope, including those of protons, α-particles, and heavier nuclei. Many of the tracks 'dip' steeply and end in one of the surfaces of the emulsion. Reproduced from Powell and Occhialini, *Nuclear Physics in Photographs*, Oxford, Clarendon, 1947; by permission of Oxford University Press.

the observed tracks in inorganic solids, namely the *ion-explosion spike model*, the *atomic displacement model*, the *thermal spike model*, and the *total energy loss model*. The latter three models may contribute some to the damage formation, but Fleischer et al. [1975] argue that they are ultimately improbable explanations of the observed results.

In the displacement model track formation is due to elastic collisions with the material lattice, which causes a column of displacements along the ion path. This model predicts that damage paths should appear more prevalently toward the end of the particle range and that these paths should appear equally for nearly all materials. However, the theory fails to explain the observed results for most ion tracks in materials. Fleischer et al. [1975] point out that there are some special cases where ion displacement does participate as an important mechanism for track formation, mainly for heavy low-energy particles and heavy recoil fragments from alpha particle decay.

The thermal spike model is based on the assumption that intense ionization and excitation of electrons along the ion trajectory causes rapid heating of the material. This heat is initially confined to a small cylindrical core around the ion path, which is then rapidly dissipated and cooled by conduction to the surrounding material lattice. It is proposed that the action of rapid heating and cooling produces distortions and disorder in the material lattice [Seitz 1949; Bullough and Gilman 1966]. However, the model fails to explain observed results, and Fleischer et al. [1975] discard this model as an explanation of track formation.

The total energy loss model is based on the stopping power equations of Bethe and Bloch (from Chapter 4). This model assumes that the ion tracks form above a critical stopping power $S(E) = -dE/dx$, which depends on the radiation particle, its energy, and the target material [Fleischer et al. 1964]. Below this critical dE/dx, the tracks become distorted and eventually disappear at sufficiently low particle energies. However, Fleischer et al. [1965] also discard this model in favor of the ion-explosion model, mainly because the total energy loss model fails to predict observed results.

The ion-explosion spike model maintains that a heavy ion of sufficient energy causes the dense removal of electrons from host nuclei by Coulombic attraction. Because of the large mass differences, the electrons are easily removed and ionized, while the heavy ion trajectory remains unchanged along a straight path. The remaining dense concentration of positive charge left behind causes repulsion along a cylindrical core, thereby producing lattice distortions usually on the order of several atomic spacings [Fleischer et al. 1965b; Fleischer et al. 1975; Nordlund et al. 1998]. Ultimately, the end result is the production of a strained lattice with vacancies and interstitials produced along the ion path. These weakened regions etch in caustic chemicals at a faster rate than undamaged regions, and consequently produce a residual visible track. There are various other theories for track formation [Fleischer et al. 1975], but it is the ion-explosion model that remains the favored explanation. Price and Fleischer [1971] describe a track formation metric J that depends on the particle's atomic number Z and its relative speed $\beta = v/c$ where c is the speed of light in vacuum, namely

$$J = \frac{\alpha Z_e^2 \left[\ln\left(\beta^2/(1-\beta^2)\right) + K - \beta^2 - \delta(\beta)\right]}{\beta^2}, \tag{19.56}$$

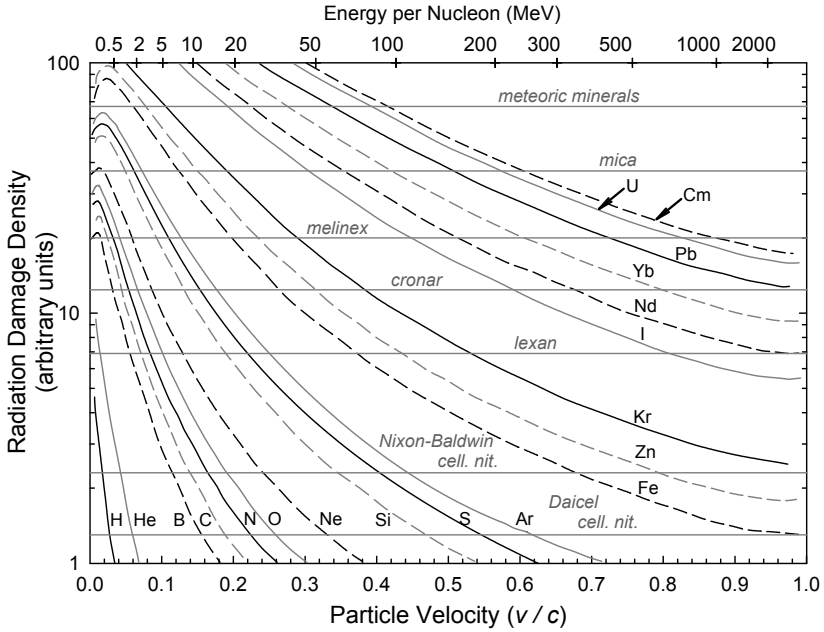

Figure 19.42. The relative density of radiation damage as a function of velocity for various nuclei. Horizontal lines indicate the approximate threshold required for several materials before a track forms. After Price and Fleischer [1971].

where K and α are constants, Z_e is the effective charge of the projectile ion, and $\delta(\beta)$ accounts for relativistic corrections. For $\beta \lesssim 0.8$, the term $\beta(\delta)$ is zero. The constant K is chosen experimentally with the boundary condition that the etch rate depends solely on J (within experimental error). Shown in Fig. 19.42 are a set of curves, developed from Eq. (19.56) with $K = 16$. Also shown are experimentally established ionization thresholds for a variety of materials, showing the dependence on ion mass. Price and Fleischer [1971] note the actual value of K changes with the type of track material with K being higher for organic materials such as Lexan than for glass and minerals such as flint glass. Just as fission fragments capture ambient electrons as they slow (see Sec. 4.5.6), the effective charge Z_e of a heavy ion changes, decreasing as the ion loses energy and captures ambient electrons, an effect that is included in Fig. 19.42.

Visible tracks in organic polymers are apparently related to delta-ray electrons in the specific channel region of the ion trajectory (see Fig. 19.43). The local dose in the ion track channel can exceed several Mrad, caused mainly by these delta-ray electrons [Becker 1973]. Further, measurements indicate that the bulk etch rate of plastics can increase with gamma-ray and electron irradiation [Goland and Mateosian 1973]. Hence, the formation of tracks in organic polymers is mainly attributed to a radiochemical damage mechanism. The etchable tracks are formed by radiolytic scission of polymer chains into short fragments. The resulting lower molecular weight fragments are far easier to dissolve than the surrounding undamaged material. Consequently, etched pits appear as these localized regions etch faster than the surrounding undamaged plastic.

Track Etching

The damage region from a heavy ion is approximated as a cylinder with a diameter of approximately 5 nm (50 Å). The highest damaged region is at the center of the track with the damage becoming less with increasing

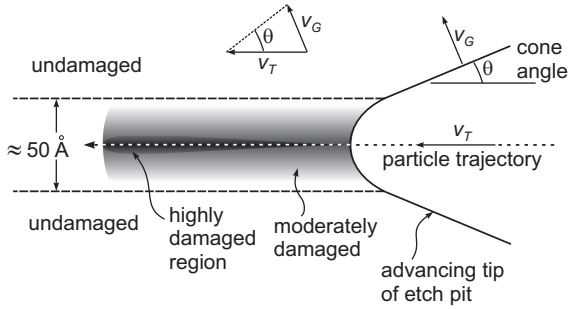

Figure 19.43. Ion damage track and etching on a submicroscopic scale. After Henke and Benton [1971].

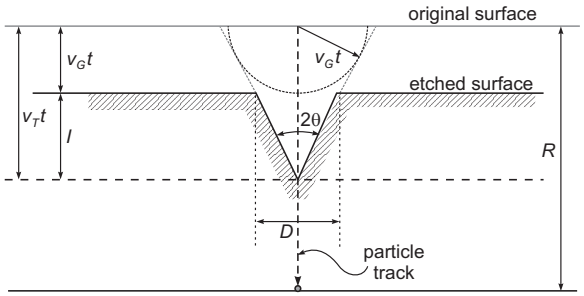

Figure 19.44. Track geometry with constant V_T and V_G for a vertical incidence. After Price and Fleischer [1971].

radial distance from the track axis to the track edge, beyond which the substrate remains undamaged (see Fig. 19.43). The substrate in which the tracks occur and which subsequently are made visible by etching is often referred to as a *track etch foil* or simply foil.

The etch rate in the track center is denoted as v_T while the etch rate of the undamaged substrate is denoted as v_G. Because the damaged region diminishes radially from the track core, the etch rate in the track region varies between these two extremes from the track axis to the edge of the track. However, for the sake of simplicity, consider the case in which the etching rate within the track is constant at v_T. With the notation shown in Fig. 19.44, the depth of the substrate etched away, within time t, from the original substrate surface is $v_G t$ while the depth etched along the ion track is $v_T t$. For an ion trajectory normal to the track substrate, the net depth l of the etched track is

$$l = v_T t - v_G t, \tag{19.57}$$

in which some of the original ion track is etched away during the chemical etching process. The diameter of the track at the widest point, after etching, is

$$D = 2v_G t \left[\frac{v_T - v_G}{v_T + v_G}\right]^{1/2}. \tag{19.58}$$

Note that both Eq. (19.43) and Eq. (19.44) vanish if $v_T = v_G$.

The ratio of the two etch rates is

$$\frac{v_T}{v_G} = \frac{2}{D}\left[\left(\frac{D}{2}\right)^2 + l^2\right]^{1/2} = \csc\theta. \tag{19.59}$$

Note also, by simple trigonometric manipulations [Price and Fleischer 1971]

$$v_G t = \frac{D}{2l}\left[\frac{D}{2} + \left[\left(\frac{D}{2}\right)^2 + l^2\right]^{1/2}\right] = \frac{D}{2}\left[\tan\theta + \sec\theta\right], \tag{19.60}$$

and

$$v_T t = \left[\left(\frac{D}{2}\right)^2 + l^2\right]^{1/2}\left[\frac{D}{2l} + \frac{1}{l}\left[\left(\frac{D}{2}\right)^2 + l^2\right]^{1/2}\right] = \frac{D}{2}\csc\theta\left[\tan\theta + \sec\theta\right]. \tag{19.61}$$

If the etch is allowed to progress for too long, the track broadens and eventually becomes undiscernible from background pits. This is especially true if the depth $v_G t$ becomes greater than the original ion range R.

For track orientations at angles less than 90° to the target surface, the conic section that intersects the surface forms an ellipse instead of a circle (Fig. 19.45). The actual track position becomes displaced from the center, more so as angle ϕ decreases. Also, as ϕ decreases towards the angle θ, the major axis of the ellipse increases towards infinity. With the notation of Fig. 19.45, the geometric relations are

$$\phi = \frac{1}{2}\left[\arctan\left(\frac{r}{a+p}\right) + \arctan\left(\frac{r}{p}\right)\right], \qquad (19.62)$$

and

$$\theta = \frac{1}{2}\left[-\arctan\left(\frac{r}{a+p}\right) + \arctan\left(\frac{r}{p}\right)\right]. \qquad (19.63)$$

Note that the vertical track etch depth becomes less than the substrate etch depth if

$$v_G > v_T \sin\phi \qquad (19.64)$$

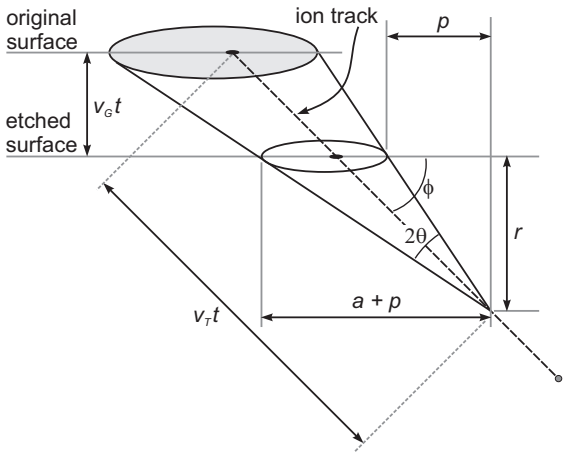

Figure 19.45. Track geometry with constant V_T and V_G for angled incidence at ϕ. After Henke and Benton [1971] and Price and Fleischer [1971].

so that a visible etch pit does not form. Hence, no etch pit forms for angles less than the critical angle, defined by

$$\phi_c = \arcsin\left(\frac{v_G}{v_T}\right). \qquad (19.65)$$

Thus to be useful as a track etch material, the track etch speed v_T should be much greater than the etch speed of the substrate v_G. As v_T becomes greater than v_G, the etch pit contrast improves while also the critical angle ϕ_c decreases. Goland and Meteosian [1973] showed for organic polymers that the ratio of etch rates v_G/v_T decreases as the total sample gamma-ray dose increases, ultimately becoming unity at a high enough dose. Under such a condition, where $v_G/v_T = 1$, no etch pits form; however, the threshold to enhance bulk etchability is relatively high, quoted to be above 10 Mrad [Attix 1986].

There are a multitude of etch formulas for the various track etch materials, several of which are listed in Table 19.2. The etch rate can be altered by changing the solvent concentration and also varies significantly with the foil type. Although the general trend is an increase in etch rate with increasing solvent concentration, not all foils exhibit this dependence. For instance, the etch rate for cellulose nitrate does not increase for concentrations above 6N NaOH solutions and remains relatively constant for higher concentrations [Blanford et al. 1970]. Other polymers exhibited increasing etch rates with solvent concentration, but with varying concentration dependences. Not surprisingly, periodic agitation or stirring of the etchant solution also increases the etch rate [Becker 1973], most likely a benefit from the physical removal of solute which, otherwise, would obstruct the fresh polymer surface.

Besides the etchant concentration, other environmental factors can have significant influence on the etch rate and foil sensitivity. For instance, increasing the etchant solution temperature can significantly increase the etch rate, and the user should be careful to terminate the process well before the tracks disappear. There are experimental results that showed a dramatic increase in sensitivity, i.e., number and size of pits, for some organic foils when irradiated in dry oxygen as opposed to irradiation in a vacuum or nitrogen gas

Table 19.2. Etching conditions for several track etch materials. From Becker [1973], Fleischer et al. [1975], and associated references.

Detector Material	Etchant	Time	Temperature (°C)
Minerals			
lepidolite mica	15% HF	20 sec	50°
	48% HF	3-70 sec	23°
muscovite mica	20% HF	2 h	23°
	20% HF	12 m	52°
	15% HF	20 m	50°
	48% HF	10-40 m	23°
phlogopite mica	20% HF	5 m	23°
	15% HF	1 m	50°
	48% HF	1-5 m	23°

Table 19.3. Relative sensitivity of various track etch materials. From Fleischer et al. [1975].

Detector Material	Atomic Composition	Least Ionizing Observable Ion
Minerals		
Hypersthene	$Mg_{1.5}Fe_{0.5}Si_2O_6$	100 MeV ^{56}Fe
Diopside	$CaMg(SiO_3)_2$	170 MeV ^{56}Fe
Augite	$CaMg_3Fe_3Al_2Si_4O_{19}$	170 MeV ^{56}Fe
Oligoclase	$Na_4CaAl_6Si_{14}O_{40}$	4 MeV ^{28}Si
Bytownite	$NaCa_4Al_9Si_{11}O_{40}$	4 MeV ^{28}Si
Orthoclase	$KAlSi_3O_8$	100 MeV ^{40}Ar
Muscovite Mica	$KAl_3Si_3O_{10}(OH)_2$	100 MeV ^{40}Ar
Glasses		
Flint Glass	$18SiO_2$:4PbO:$1.5Na_2O$:K_2O	2-4 MeV ^{20}Ne
Quartz	SiO_2	100 MeV ^{40}Ar
Silica Glass	SiO_2	16 MeV ^{40}Ar
Soda Lime Glass	$23SiO_2$:$5Na_2O$:5CaO:Al_2O_3	20 MeV ^{20}Ne
Organics		
Amber	$C_2H_3O_2$	Fission Frag.
Bisphenol A-polycarbonate (Lexan^{TM}, Makrofol®)	$C_{16}H_{14}O_3$	0.3 MeV ^{4}He
Cellulose Nitrate (Daicell®)	$C_6H_8O_9N_2$	0.55 MeV ^{1}H
Poly-Allyl-Diglycol Carbonate (CR-39)	$C_{12}H_{18}O_7$	13 MeV ^{1}H†
Polyethylene	CH_2	Fission Frag.
Ionermeric Polyethylene (Surlyn®)		36 MeV ^{16}O
Polyimide	$C_{11}H_4O_4N_2$	36 MeV ^{16}O
Polyoxymethylene (Delrin®)	CH_2O	28 MeV ^{11}B
Polypropylene	CH_2	1 MeV ^{4}He
Polymethylmethacralate (PMMA, Plexiglas®, Lucite®)	$C_5H_8O_2$	3 MeV ^{4}He
Polyvinylacetochloride	$C_6H_9O_2Cl$	42 MeV ^{32}S
Polyvinylchloride + Polyvinyledene Chloride	$C_2H_3Cl + C_2H_2Cl_2$	42 MeV ^{32}S

†Lounis et al. [2001].

environment [Becker 1968]. Becker [1968] also found that exposure to water before irradiation increases the etching speed of the solvent and the number of visible tracks, and is especially pronounced if the track etch foil is first soaked in a H_2O_2 solution before irradiation. Heinzelmann and Haschke [1971] also observed an increase in sensitivity when the track etch foils are soaked in ethanol/ammonia before the etching process.

Another method shown to increase sensitivity is to expose the track etch foil to specific wavelengths of UV light in the presence of oxygen before conducting the etching process [Henke et al. 1970]. This improvement in sensitivity was found to increase with shorter wavelengths of the sensitizing light. The etch rate also increases in the presence of an electric field [Tommasino 1970; Tommasino et al. 1981; 1982], with methods and results reported for various track etch foils [Somogyi 1977; Tommasino 1981; Sohrabi 1981]. Other factors that can affect the etch rate are bake hardening and foil aging, both methods causing a reduction in size and number of visible etch tracks [Becker 1973]. A probable cause for the reduction in etch pit density is thermal annealing of track damage, which causes tracks made by low LET radiation to disappear before those made by high LET radiation [Attix 1986].

Track Etching for Neutron Dosimetry

The high threshold gamma-ray dose required for track formation makes track etch foils impractical for gamma-ray dosimetry. Further, heavy charged particles have relatively short ranges in air. Combined with energy attenuation through the dosimeter package, track etch detectors are a poor choice for heavy charged-particle dosimeters. Although beta particles may penetrate the encapsulate, it takes high doses before notable changes occur in the track etch foil [Becker 1973]. However, track etch detectors have utility in fast and thermal neutron detection, mainly through absorption and scatter reactions. The relative insensitivity to other radiation interactions is a natural discrimination benefit. Neutron-induced track dosimetry is performed by (a) first using energy conversion radiator foils to produce energetic neutron-reaction ions that subsequently enter the track etch foil, or (b) producing neutron-reaction ions from elastic scattering in the track etch foil itself.

There are a few clear advantages of track etch foils for neutron dosimetry. First, as already stated, they naturally discriminate background radiations. Second, after etching, they provide a relatively permanent dose record, and are largely unaffected by the environment if kept at room temperature (no fading). The development process is straightforward and can be automated, including the readout, which can also yield highly sensitive measurements. Aside from the obvious visual method, many readout methods have been developed, including automated optical, radiation, and spark transmission methods [Becker 1973; Fleischer et al. 1975]. For track etch foils coupled to radiator foils, the dose range is adjustable according to the density of the fissile element. Finally, the sensitivity can be functionally reduced by separating the radiator foil from the track foil.

Many materials have trace amounts of uranium, which can produce fission fragments from fast or slow neutrons. Fissions from slow neutrons depend on the presence of ^{235}U, which has a much higher fission cross section than does ^{238}U but has a significantly lower natural abundance. Hence, the track density depends on the atomic density and the absorption cross sections of the fissionable nuclides [Becker 2003]. It is by this means that many of the natural minerals are used for geological age and historical dose calculations, and many useful minerals are listed in Tables 19.2 and 19.3.

Personnel neutron dosimetry can be performed by outfitting users with a track etch badge. The badge has track etch foils coupled to radiator foils, often consisting of two samples, one with ^{232}Th for fast neutrons and the other with ^{235}U for slow neutrons. Other candidate converter foils include ^{237}Np, ^{239}Pu, and ^{32}S, all having different cross sections and threshold energies. The $1/v$ absorbers ^{10}B and ^{6}Li can also be used as converter foils. By combining different foils with separate track etch dosimeters, a crude estimation of neutron dose as a function of neutron energy can be determined.

Track Etch Materials

Cellulose nitrate was once a favorite for nuclear track etch dosimeters, mainly because it is relatively sensitive to low LET ions (see Table 19.3). Direct fast neutron interactions in cellulose nitrate produce energetic H, C, N, and O recoil ions. The recoil protons do not produce etchable tracks (unless the energy is below 550 keV), yet tracks from the other recoil ions can be resolved. Recall from Sec. 18.3 that fast neutrons transfer only a small fraction of their energy to the recoiling heavy ion, the fraction increasing as the neutron scattering angle increases. Consequently, the energy of these recoil ions is much smaller than that of the initial neutron energy and the track lengths the ions travel are relatively small. However, the visible size of the tracks can be enhanced by electrochemical etch methods (mentioned above). Recall from Sec. 19.2 (footnote 12) that cellulose nitrate (nitrocellulose) is explosively flammable, and has been largely replaced with cellulose acetate as a track etch material. Listed in Table 19.3 are numerous other track etch materials that have utility in dosimetry.

Despite the success of many organic foils, one that stands out as a most useful track etch material for neutron dosimetry is the polymer poly-allyl-diglycol carbonate ($C_{12}H_{18}O_7$ or PADC), or by the more

common name, CR-39.[19] It has a relatively low-energy threshold and is capable of forming etch pits from 13 MeV protons [Lounis et al. 2001], a capability significantly better than that of cellulose nitrate and cellulose acetate. Attix [1986] points out that a direct correlation between radiation dose and the track density from proton recoils is not actually possible, although superficially it may seem so. The main reason for the discrepancy, given by Attix [1986], is that protons of high enough energy do not produce etchable tracks until their energy is reduced below a threshold.[20] Consequently, the track does not correctly represent the total amount of energy dissipated in the foil. There is also a low energy threshold, below which ions are undetectable. Although the specific ionization may be high, the small residual track is not visible when etched [Cross 1986]. When etched by electrochemical assistance at 25 kV cm^{-1}, the practical lower energy limit is approximately 50 keV for protons in CR-39.

19.3.3 Spark Chambers

A moving charged particle produces a column of electron-ion pairs in a gas medium. In the earlier discussion on gas filled proportional and Geiger-Müller counters, it was seen that electrons in a high electric field were accelerated by the field and could produce even more ionization and excited atoms that ended in a Townsend avalanche. When the excited atoms deexcite, they can give off visible light which can, in turn, produce further ionization. This light-producing phenomenon can also be used to create a different type of particle detector. Such an application was first reported by Greinacher [1934] who described the detection of alpha-particles with a point electrode near a planar surface. Years later, Chang and Rosenblum [1945] devised a wire spark counter that accomplished the same task, while eliminating many of the problems associated with Greinacher's original design [Payne 1949; Eichholz 1952]. Their device had a single wire stretched parallel to a metal plate. In 1949 Keuffel devised a counter with parallel metal plates (either Mo or Cu) spaced 2.5 to 3 mm apart. The surface areas for these parallel plate detectors ranged up to 35 cm^2 in order to create a large electrically active region.[21] These types of devices are conventionally named *spark counters*. Although early versions of spark counters operated in air, pure noble gases are preferred with a mixture of He and Ne frequently being used [Rice-Evans 1974].

Wire grids or plates stacked parallel to each other can be used to record the tracks of high energy particles over a very large volume. Such a structure is called a *spark chamber*. One example is shown in Fig. 19.46. The wire grid design allows charged particles to pass through the gas while encountering far less solid material than in the parallel plate design. These devices had multiple stacked planes of wires or plates so as to produce a large detection volume [Henning 1957]. Early reviews of these chambers were published by Roberts [1961] and Higenbotham [1965]. A neutron sensitive parallel plate spark chamber (no wires) which used corrugated metal sheets for the plates was reported by Eicholz [1966; 1969].

Suppose that the high electric field is produced between two parallel plates, with a gas between them, and an ionizing particle can pass relatively perpendicular to the inner surfaces. In a parallel plate configuration, the electric field is relatively constant for an applied voltage, and liberated electrons can produce avalanches along the entire particle path. As the avalanche grows, the build-up of space charge shields the inner-most charge pairs from the externally applied potential, while the outer most electrons and ions are rapidly drifted towards their respective electrodes. Hence, the outermost electrons gain energy and produce more ionization. Rice-Evans [1974] notes that a single avalanche must produce at least 10^8 free electrons as a condition for an arc to form. As the charges drift in the gap, these avalanches can combine to produce a relatively dense

[19] Columbia Resin number 39.

[20] Attix [1986] puts this lower energy limit at 4 MeV; however, the work of Lounis et al. [2001] indicates that it can be as high as 13 MeV in CR-39.

[21] Roberts [1961] notes that Keuffel [1949] was the first to report a parallel plate spark counter, but this work was largely unnoticed. Not until several others published similar works did it become recognized as important.

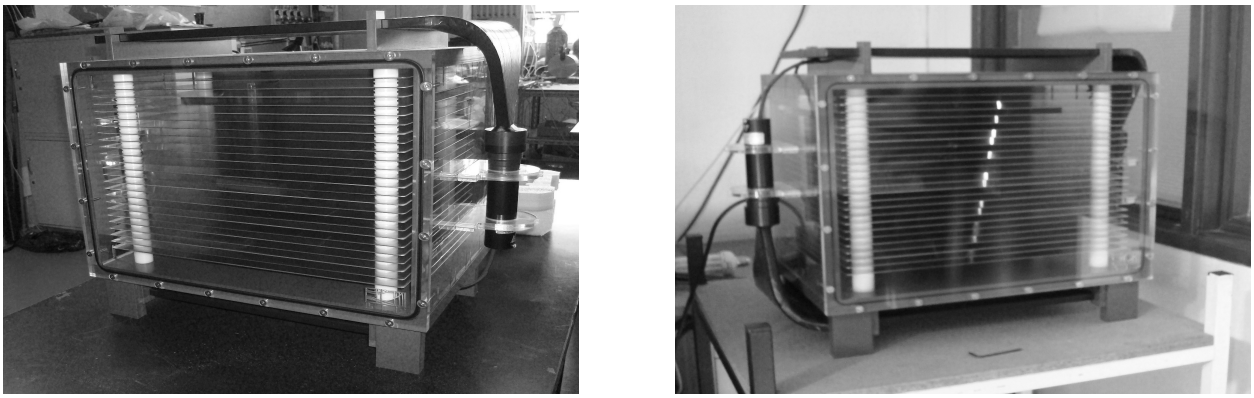

Figure 19.46. (left) A parallel plate spark chamber. (right) A cosmic ray track in a spark chamber. These spark chambers were manufactured and demonstrated by the Physics Department at the University of Coimbra, Portugal.

columnar track of electron-ion pairs creating a low resistance track between the plates so that electrons and ions can move freely between the plates much like a lightning strike. The excited ions produce light upon returning to their ground state, light which is observed as an arc or spark discharge. These stages in the development of a spark are illustrated in Fig. 19.47. The voltage across the gap is usually too low to cause coronal discharge, but high enough to produce an arc if an ionizing particle crosses the gap.

It is notable that the basic spark counter structure is similar to a simple Geiger-Müller counter. However, the data recording method is different and much faster for the spark counter than the Geiger-Müller counter. Recall that the rise time and collection time of a GM Counter is relatively slow, usually having resolving times between tens to hundreds of microseconds. The process that produces a spark, however, is significantly faster and does not rely on charge collection. In fact, spark counter responses can be on the order of 10 ns [Roberts 1961].

Spark chambers can be used to image the passage of cosmic rays and highly penetrating ionizing particles a shown in Fig. 19.46(right). In order to reduce sporadic arcing and possible damage from coronal discharge, they are typically not operated under constant high voltage. Instead a gate detector triggers a coincidence circuit that applies additional voltage to the spark chamber stack, high enough to produce avalanching. The gate detector can be a pair of scintillators over the top and bottom of the device (depicted in Fig. 19.48). After the spark occurs, the chamber still has mobile ions between the gaps. These ions can be rapidly removed with a "clearing field" that is a voltage applied across the spark chamber after the spark event. Usually the clearing field voltage is applied in the opposite direction to the high voltage and lasts no more than a few milliseconds. Images of the trajectory of the high energy particle as it travels through the detector, producing sparks between the plates, can be recorded with a photograph. The device, for instance, can be operated in darkness and a time-extended photograph can record multiple events. Individual events can also be recorded by acoustic methods, video, and magnetic sampling methods as explained by Rice-Evans [1974].

19.3.4 Bubble Chambers

Another track detector, the bubble chamber, is closely related to cloud chambers (see Sec. 9.5.8), and these devices were once important instruments for tracking particles. A reduction of pressure or an increase in temperature of a liquid can drive the liquid into the gaseous state (see Fig. 19.49). However, under some circumstances, a liquid can be slowly increased in temperature across the liquid/vapor phase boundary (from point 1 to 3 in Fig. 19.49), and still exist as a liquid in a metastable state. The same is true if the pressure is reduced (point 2 to 3 in Fig. 19.49), again producing a superheated liquid in a metastable state.

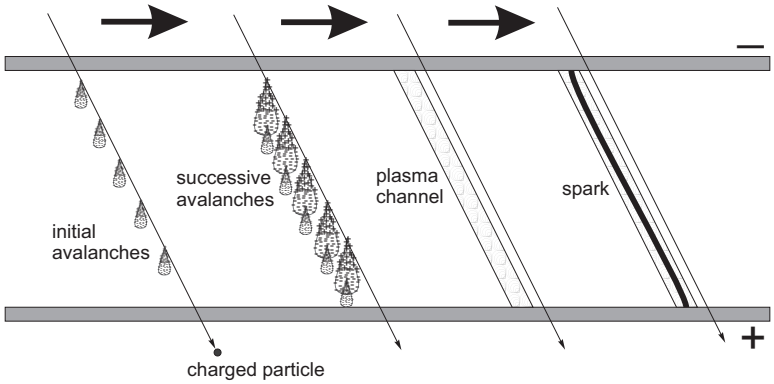

Figure 19.47. Formation of a spark channel at four different times.

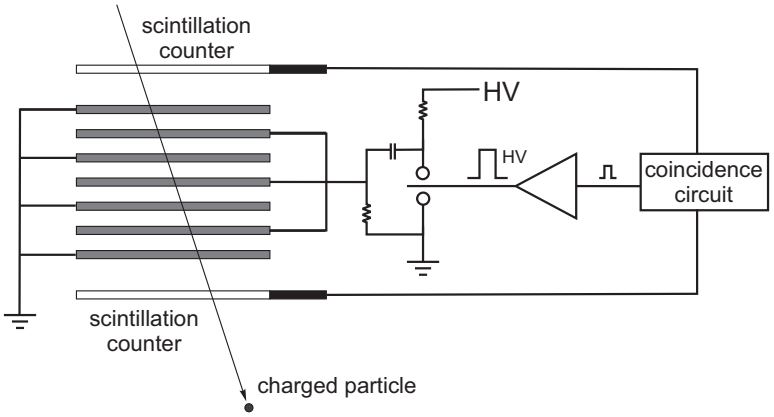

Figure 19.48. Depiction of basic spark chamber components. After Rice-Evans [1974].

Once in a metastable superheated state, a disruption can cause instantaneous boiling as the liquid converts to vapor. Examples of disruptive stimuli include small bubbles in the liquid, contaminants, and ionization produced by radiation interactions.

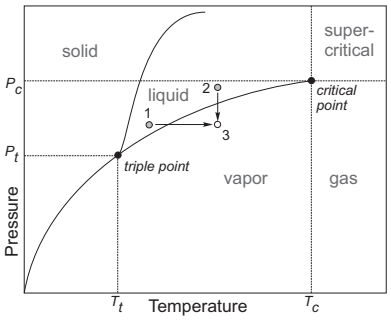

Figure 19.49. A P-T phase diagram, showing the triple and critical points.

Like the cloud chamber, a bubble chamber has an expansion chamber whose pressure can be changed by an attached piston. Unlike a cloud chamber containing supersaturated vapor, the bubble chamber is filled with a liquid brought up to a temperature just below vaporization (boiling point). If the piston is rapidly withdrawn, the liquid becomes spontaneously superheated, and charged particles interacting in the liquid produce ionization events that erupt into small vapor pockets, or bubbles [Glaser 1952].[22] These bubbles continue to grow in size as the piston is further withdrawn. Cameras are used to photograph the bubble tracks, much as is done with the cloud chamber. Incorporating multiple cameras around a transparent chamber, or a chamber with view ports, can be used to produce a three-dimensional image of the bubble

[22] Donald Glasser received the 1960 Nobel Prize in Physics for the invention of the bubble chamber.

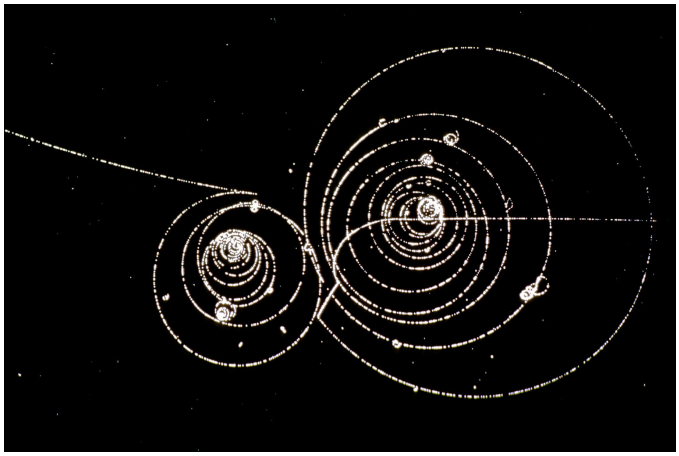

Figure 19.50. This image is taken from one of CERN's bubble chambers and shows the decay of a positive kaon in flight. The decay products of this kaon can be seen spiraling in the magnetic field of the chamber. Photo courtesy of CERN [1973].

tracks in the chamber. A magnetic field can also be applied to the chamber to cause charged particles to spin about the magnetic field described by $\mathbf{F} = q\mathbf{v} \times \mathbf{B}$ (see Fig. 19.50). Hence, the force on the particle changes with velocity, and the curvature of the bubble paths can be used to determine the particle velocity and momentum. Liquid hydrogen is probably the most used medium in a bubble chamber. Other liquids used include liquid deuterium, a mixture of liquid neon and hydrogen, liquid propane, and bromotrifluoromethane ($CBrF_3$). Laboratory bubble chambers may be only a few liters in size, while bubble chambers used for high energy physics can be very large. For instance, the Gargamelle bubble chamber was designed to hold approximately 12 cubic meters of liquid, while the volume of the Big European Bubble Chamber (BEBC) contains almost 35 cubic meters. While bubble chambers at one time played an important part in high energy physics, they have been largely replaced by multiwire gas-filled chambers.

19.3.5 Superheated Drop Detectors

Another type of bubble chamber is the superheated drop detector (SDD), shown in Fig. 19.51. First introduced by Apfel [1979], the device consists of a closed vessel backfilled with polymerized gel saturated with liquid droplets, usually a type of halocarbon with a boiling point well below room temperature. For instance, an elastic polymer or gelatin may be saturated with liquified R-12 refrigerant (dichlorodifluoromethane, CCl_2F_2) droplets. The saturation process is usually performed under high pressure [Roy et al. 1987].

These superheated droplets are on the order of 25 microns in diameter. At room temperature, the halocarbon liquid droplets would ordinarily convert to the vapor phase. However, the pressure on the gelatinous polymer provides sufficient surface force around the droplets to keep them in the liquid state at a temperature above their ordinary boiling point. By physically separating and suspending the superheated droplets in the gel, the phase change of a single drop from superheated liquid to vapor does not cause additional eruptions. Consequently, the other droplets stay in the superheated state.

Neutron interactions in the fluid produce recoil ions, and these ions can track near or through a superheated drop. Recoil ions can produce a trail of vapor embryos inside a drop, which are small vapor bubbles

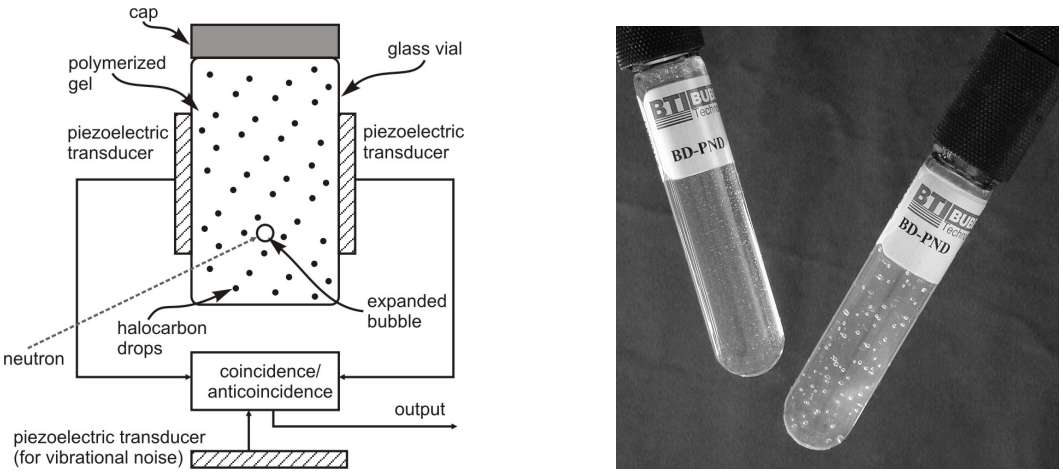

Figure 19.51. (left) Components of a superheated drop detector. (right) Before and after neutron irradiation of a superheated drop detector. Photo courtesy of Bubble Technology Industries, Inc., [2018].

on the order of 100 nm diameter. Consider a vapor embryo at a specific temperature T and pressure P. The critical energy required for bubble nucleation is [Roy et al. 1987; Seth et al. 2013]

$$E_c = \frac{16\pi\sigma^3(T)}{3(P_v(T) - P_0)^2}, \tag{19.66}$$

where $\sigma(T)$ is the surface tension[23] of the droplet at temperature T, $P_v(T)$ is the vapor pressure of the liquid at T, and P_0 is the pressure of the emulsion suspension (and the droplet fluid). If the radius of the droplet exceeds a certain critical radius r_c, then the droplet expands until it is entirely converted to vapor. If instead the radius is less than r_c, then it shrinks back into the superheated liquid drop. This critical radius is given by [Seitz 1958; Roy et al. 1987]

$$r_c = \frac{2\sigma(T)}{P_v(T) - P_0}. \tag{19.67}$$

Through this expansion process, particle interactions within the volume, by both charged and neutral particles, cause the spontaneous state change of liquid to vapor, forming suspended vapor bubbles on the order of 1 mm diameter. These bubbles appear at the particle interaction locations, and the density of bubbles yields a measure of the particle interaction density, imparted dose, and, in some cases, the particle flux. Cooling or repressurizing the emulsion in the vial can, in some designs, return the gas bubbles back into small droplets in the superheated liquid state and so render the device usable for subsequent measurements.

Unlike the bubble chamber, these detectors are portable and do not require moving parts (such as a piston). Superheated drop detectors are extremely sensitive to epithermal and fast neutrons, but virtually insensitive to gamma rays. If chlorinated halocarbons are used, superheated drop detectors can also be sensitive to thermal neutrons through the ^{35}Cl(n,p)^{35}S reaction [d'Errico 2001]. Readout of the devices can be conducted optically or acoustically.

The optical measurement mode consists of counting the bubbles formed in the chamber, either manually or with an optical scanner. Another measurement method is to incorporate a graduated expansion tube as

[23] Here σ should not be confused with the same symbol used throughout this book for a microscopic cross section.

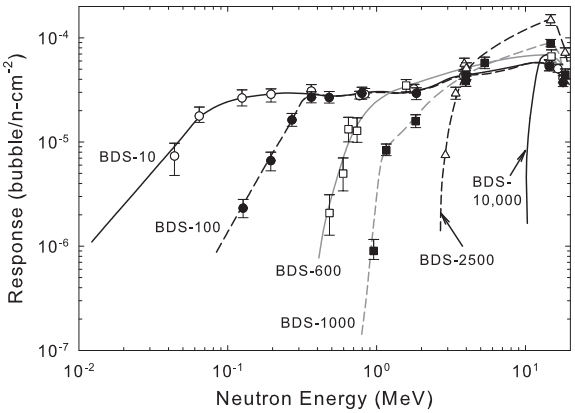

Figure 19.52. Response of a superheated drop detector threshold spectrometer set (Bubble Detector Spectrometer or BDS) from Bubble Technology Industries. Data are from Ing [2001].

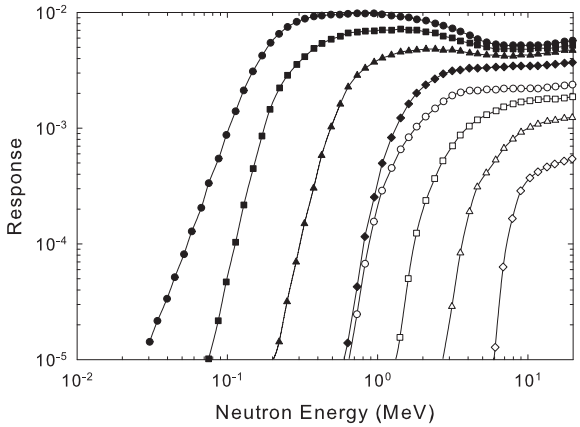

Figure 19.53. Thermal response dependence for two types of threshold superheated drop detectors. Black data are for SDD-1000 and white data are for SDD-6000. Here $\circ$ = 40°C, $\square$ = 35°C, $\triangle$ = 30°C, and $\diamond$ = 25°C. Data are from Apfel and d'Errico [2002].

part of, or extending from, the vial, much like a thermometer [Apfel 1992]. As bubbles are produced, the emulsion expands and moves along the metered tube, yielding a rapid measure of the number of bubbles or the neutron dose. Because the bubbles in the vial are measured after irradiation, these SDDs are considered to be *passive* counters that accumulate a radiation response over their exposure time.

If the SDDs are used acoustically, the noise produced by an expanding bubble is measured by transducers arranged around the chamber during radiation exposure. These transducers are connected in coincidence mode to discriminate out background acoustical noise. An additional acoustical detector can be added to operate in anticoincidence to discriminate out vibrational noise from electronics and the readout system. In some cases, the transducers can be connected at opposite ends of the vile, and the arrival time of the sound wave at each transducer can be used to localize the 1-dimensional position of the erupted bubble to within approximately 1 mm [Lim and Wang 1995; 1996]. By adding more microphones, including one inside the vial, a 2-dimensional localization method can produce a spatial resolution as small as 1.21 mm^2 [Felizardo et al. 2009]. SDDs that report counts in real time are considered *active* counters.

The threshold for reactions is a function of halocarbon type, emulsion pressure, and the operating temperature. As the temperature is increased, the bubble density for a given neutron exposure may change significantly [d'Errico 2001]. The neutron energy threshold for bubble formation decreases with increasing temperature [Apfel and d'Errico 2002], and increases with increasing pressure [Rezaeian et al. 2015]. The cause may be understood with Eq. (19.67) which shows that an increase in temperature causes the vapor pressure in the embryo bubble to increase and so results in a reduction in r_c. For example, d'Errico [2001] reports that the value of r_c decreases from 326 nm at 18°C down to 77 nm at 40°C for R-114 (ClF_2CCF_2Cl) refrigerant. Consequently, a larger fraction of embryos erupt as the emulsion temperature increases and r_c decreases. To counter the effect caused by pressure changes in the nucleated embryos, a small amount of volatile solvent can be added into the vial above the polymerized gel so as to increase the pressure P_0 on the gel as the temperature rises. This addition helps to counteract the increase in $P_v(T)$ and a reduction in the threshold for r_c [Apfel 1992]. Although not perfect, Apfel [1992] reports that this method decreases the bubble formation variation from 0.05 °C^{-1} to 0.01 °C^{-1} for the temperature range of 15°C to 35°C. In another application, d'Errico et al. [1996] added cooling strips to the vial to keep the temperature constant during the measurement, thereby eliminating variation in neutron sensitivity with temperature.

The strong dependence on halocarbon type, pressure, and temperature can be used to produce a type of threshold neutron spectrometer based on a set of different SDDs [Bonin et al. 1993; Ing 2001]. Such a spectrometer is very similar in concept to the foil activation and Bonner sphere methods, discussed in Ch. 18, for determining the energy spectrum of neutrons. The SDD method uses a set of (usually) six different SDDs with an unfolding algorithm to provide a relatively rough estimate of important aspects of a neutron energy profile. Data from a set of superheated drop detectors, named a "bubble detector spectrometer" (BDS), are shown in Fig. 19.52.

A similar active, acoustically operated, form of superheated drop detector was also described by d'Errico et al. [1995] and called the bubble interactive neutron spectrometer (BINS). The SDD response to neutron energy is shown in Fig. 19.53 for two different superheated drop detectors.[24] The change in neutron energy required to trigger an event is large, decreasing by an order of magnitude for both detectors for a temperature increase from 25°C to 40°C. This version of a neutron spectrometer has two temperature controlled SDDs that complement each other over the range of neutron energies to be investigated. This range can be adjusted for each SDD by changing the SDD temperature. Notice that the threshold energy for SDD-1000 at 25°C is the same as that of SDD-6000 at 40°C (see Fig. 19.53) and, thus, provides a smooth transition of sensitivity over a wide range of neutron energies. Spectral unfolding with the BINS detector can theoretically yield on the order of 10% FWHM energy resolution for monoenergetic fast neutrons between 250 keV to 5 MeV [d'Errico 2002].

Superheated drop detectors, or bubble detectors, are used for dosimetry measurements, and match well to the ICRP 60 recommendations [Portal and Dietze 1992]. Commercial dosimeters and threshold spectrometer sets are available, along with automatic reading systems.[25] The bubbles can be counted and subsequently recompressed into superheated droplets so that the device can be reused for future measurements. There is a practical limit on the total neutron fluence that can be measured and is reached when the radiation dose is so large that bubbles become so numerous that they begin to coalesce. If the bubble density becomes too high, then it becomes difficult to accurately count the number of bubbles in the vial. For a commercial unit, this limit corresponds to approximately 300 bubbles. Also, after the initial eruption, the bubbles continue to slowly grow is size. At some point, it is possible that the bubble grows large enough to damage the elastic emulsion surrounding the bubble by exceeding the elastic limit. Consequently, the vapor bubble cannot be recompressed into a superheated droplet. Generally, it is best that the SDD be read and recompressed on a short time schedule. Ing [2001] recommends resetting on a daily basis.

19.4 Cryogenic Detectors

As discussed throughout this book, there are many detector characteristics to be considered in the design of an "ideal" energy spectrometer system. Factors such as good intrinsic efficiency and short dead times are important; but probably the paramount factor is the energy resolution. HPGe systems have largely replaced NaI:Tl systems as energy spectrometers because of the significantly higher resolution of the former. To obtain high resolution, a detector must have a small excitation energy to produce a signal carrier so that the statistical noise is reduced. However, thermal excitation of these signal carriers must be reduced to minimize electronic noise. This latter requirement means the detector can be operated only at low temperatures. Sometimes liquid nitrogen temperatures are sufficient as, for example, with HPGe detectors. To achieve even better resolution, several types of detectors have been designed to operate at temperatures of about 0.1 K. Such detectors are termed *cryogenic* detectors.

[24] These two SDDs originally commercialized by Apfel Enterprises, Inc., are no longer available. The superheated halocarbons in SDD-1000 and SDD-6000 are C-318 and R-114, respectively [d'Errico et al. 1995], and neither of these superheated halocarbons is sensitive to gamma rays or thermal neutrons.

[25] Bubble Technology Industries, Inc., manufactures these detectors and systems.

Cryogenic detectors can be separated into two broad categories: (1) *thermal* detectors that measure temperature changes caused by radiation interactions in the detector, and (2) *athermal* detectors that measure charge (or some other signal carrier) produced by the radiation [Friedrich 2006]. Examples of each of these two types of cryogenic detectors are discussed below. A much more comprehensive presentation by experts in the field is provided by Enss [2005].

19.4.1 Methods of Cooling

There are several methods used to achieve the low temperatures required for the different types of cryogenic detectors. In some cases, detectors such as HPGe need only be cooled to temperatures near 77K, achievable with a liquid nitrogen (LN2) bath, a relatively simple and inexpensive technique by contemporary standards. Yet, a key requirement for many cryogenic detectors is a means to cool the detector to operating temperatures below 0.1 K. Typically, cooling to such low temperatures is performed in two or more steps. For lower temperatures near 4 K, liquid He can be used as the cooling bath which is often surrounded by a LN2 jacket. Liquid He is more expensive than LN2, yet laboratory compressors are available that can provide this liquid. Although many He-based refrigerators are designed for laboratory use, portable precooling systems have become available. Finally a second cooling step is used to take the detectors from about 4 K to mK temperatures. Several such cooling techniques are summarized below.

Precooling Pulse-Tube Refrigerators

Over the past 20 years refined versions of the pulsed-tube refrigerator, introduced in 1954 by Gifford and Longsworth [1964], offer an attractive method for the initial precooling of cryogenic detectors. The pulse-tube refrigerator is a He closed-cycle, vibrationless, "dry" device with no moving parts. The lack of vibrations is critical for most cryogenic detectors. The original pulsed-tube device of Gifford and Longsworth cooled only to 174 K. In 1984 Mukulin added an orifice to provide resistance to the He flow and, thereby reached a temperature of 105 K. Since then, various design refinements have continued to lower the temperature of the cold end of the device to about 4 K, just below the boiling point of He (4.2 K). With a two-stage double-inlet pulse tube cooler, Wang et al. [1997] achieved a temperature of 2.23 K. Then in the early 2000s an even lower temperature of 1.73 K was achieved by replacing the He gas, which is mostly ^{4}He, by ^{3}He. Today commercial pulse-tube refrigerators are available from several vendors.[26] Hence, replacement of traditional cryogenic liquids by a modern mechanical cryocooler for precooling makes cryogenic detectors truly portable.

^{3}He Refrigerators

Many cryogenic detectors require temperatures below a few tenths of a degree kelvin, and various refrigerators have been developed to produce such low temperatures [Lounasmaa 1974]. A ^{3}He refrigerator operates by evaporative cooling of ^{4}He to produce a 1 K reservoir or *pot* of ^{3}He. The liquid ^{3}He is further evaporatively cooled to reduce the pot temperature to about 0.2 K. Due to the rarity and high cost of ^{3}He, it is recycled in a closed loop within the system. Single-stage ^{3}He refrigerators go down to about 0.3 K and two-stage ^{3}He refrigerators can go down to about 0.2 K.

Adiabatic Demagnetization Refrigerators

A relatively compact system, by comparison to a dilution refrigerator, is an adiabatic demagnetization refrigerator (ADR). Adiabatic demagnetization is a single cycle method of cooling, unlike a dilution refrigerator that operates continuously. Adiabatic demagnetization is also the oldest known method of reducing temperatures below 1 K [Lounasmaa 1974] and was originally introduced by Debye [1926] and Giauque [1927]. The magnetocaloric effect operates by first heating a paramagnetic material with magnetism, a process in which the entropy is lowered in a magnetic field. The heat is removed by a liquid He bath through a contact

[26] see starcryo.com, entropy-cryogenics.com, bluefors.com, oxint.com, and leiden-crygenics.com

switch. After opening the switch, the magnetic field is slowly lowered, adiabatically, to keep the entropy of the coolant paramagnet constant, thereby causing the temperature to decrease. The device can produce low temperatures on the order of 1 mK. Seminal work for development of the ADR was made by Hagmann and Richards [1994] whose device sustained temperatures of 100 mK for 100 hours. These refrigerators may have more than one type of paramagnet. Friedrich et al. [2001] describes such a refrigerator with two paramagnet stages. The first stage is cooled to about 1 K with a gadolinium gallium garnet ($Gd_3Ga_5O_{12}$ or GGG), and a second stage is cooled to approximately 0.1 K with a paramagnetic salt $Fe(NH_4)(SO_4)\cdot 12H_2O$ or FAA. The entire system has LN2 and liquid He cooling tanks. ADRs with CPA (chromium potassium alum) can go down to about 12 mK and those with CMN (cerium magnesium nitrate) can theoretically reach 2 mK. However, few cryogenic detector researchers use ADRs. The exception is those in NASA who need them because ADRs work in zero-gravity environments.

Dilution Refrigerators

The $^3He/^4He$ dilution refrigerator can produce temperatures down to 2 mK. It has no moving parts in the low temperature region of the refrigerator, relying solely on the phase change of ^3He and ^4He. For He mixtures containing more that 6% ^3He, a phase separation occurs at 870 mK. The "denser" phase is composed almost entirely (100%) of ^3He floating atop a "dilute" phase composed approximately of 94% ^4He and 6% ^3He. Cooling is achieved by forcing the pure ^3He to move across the phase boundary to the lower dilute phase, much like evaporation in which the denser phase of ^3He is the liquid and the dilute phase is vapor. This continued action is achieved by circulating the ^3He with a room temperature pump. The ^3He is recirculated, going through an LN2 precool step, a liquid helium 4 K precool, finally through several heat exchangers before arriving at the phase separation and mixing chamber, the coldest part of the refrigerator. The process of moving ^3He through the dilute phase is endothermic, and consequently, heat is removed from the system. Dilution refrigerators are effective in producing temperatures below 1 K, but are relatively bulky devices.

19.4.2 Cryogenic Microcalorimeters

There are a few basic configurations of cryogenic detectors, generally described as thermal/equilibrium detectors and athermal/nonequilibrium detectors [Friedrich 2006]. Thermal/equilibrium cryogenic detectors can be described as either bolometers or microcalorimeters, with the distinction that a bolometer measures the amount of radiation incident upon the device (similar to a current mode device) and a calorimeter measures the energy of individual interactions in the device (similar to a pulse mode spectrometer). The origin of the bolometer dates to Langley, who in 1880 invented the device to measure small quantities of infrared radiation [Langley 1880]. Much later, Andrews et al. [1942] introduced a superconducting version of the bolometer fabricated from tantalum wire operated at its superconducting transition temperature (3.22 K to 3.23 K).

Cryogenic detectors, bolometers and microcalorimeters, measure thermal energy deposited in a low temperature (mK) absorber. The increase in heat in the absorber is converted into a signal and is, thus, a measure of the energy deposited by incident radiation. Low temperature operation is required to reduce thermal noise that would otherwise mask the small signal. There are a variety of thermal detectors, some of which are reviewed in this section.

The simplest cryogenic detector, and possibly the oldest, is a radiation absorber attached to a thermometer. The absorber and thermometer together are weakly attached to a low temperature reservoir bath or heat sink. These detectors are called, interchangeably, *bolometers*, *calorimeters*, *thermal detectors*, and other variants. However, there is a distinct difference in the way that bolometers and microcalorimeters operate. In either case, a cryogenic thermal detector has an absorber attached to a thermally sensitive electronic

component, usually a thermistor.[27] Some designs are monolithic so that temperature sensor is the radiation absorber itself.

Consider the simple cryogenic detector depicted in Fig. 19.54. The absorber is heated by incident radiation interacting in it at the rate $P_{in}(t)$ (J s^{-1}). The total heat capacity of the absorber is denoted by c_a (J K^{-1}) and the total heat conductance between the absorber and heat sink by g (J K^{-1} s^{-1}). A small constant current I flows through the thermistor of resistance R and creates a voltage V across it. The current in the thermistor generates a small thermal power of $P_o = IV = I^2/R$, which at equilibrium, causes the absorber/thermistor to have a temperature T_o. Incident radiation interacting in the absorber raises the absorber/thermistor temperature and, thus, the resistance of the thermistor changes. This change produces a change in the voltage V that is measured and used to infer the temperature change of the absorber/thermistor from its equilibrium value as well as to record the occurrence of a radiation interactions in the absorber.

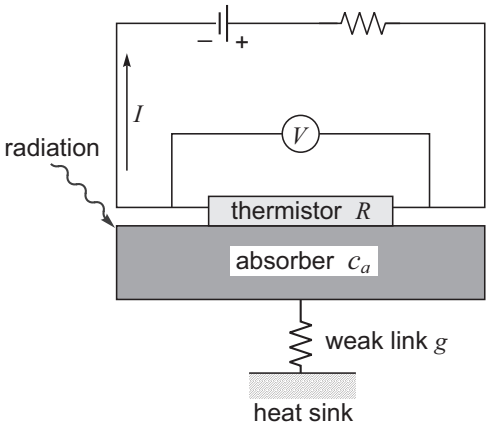

Figure 19.54. A cryogenic detector has a absorber with heat capacity c_a coupled to a thermistor, both weakly attached with conductance g to a low-temperature heat sink.

The behavior of the detector depends on its design. Consider a detector at thermal equilibrium with $P_{in} = 0$ for $t < 0$ with the absorber/thermistor at temperature T_o. At $t = 0$ radiation begins to heat the absorber, producing a change in temperature $\Delta T(t) = T(t) - T_o$ that is measured by the thermistor circuitry. Conservation of energy requires

$$\frac{\Delta T(t)}{dt} = \frac{1}{c_a}\left[P_{in}(t) - g\Delta T(t)\right]. \tag{19.68}$$

The general solution of this first order differential equation with constant coefficients subject to the initial condition $\Delta T(0) = 0$ is

$$\Delta T(t) = \frac{\exp[-t/\tau_F]}{c_a}\int_0^t \exp[t'/\tau_F]P_{in}(t')\,dt', \qquad t > 0, \tag{19.69}$$

where the time constant $\tau_F = c_a/g$.

If a quantum of radiation deposits energy E in the absorber at $t = 0^+$, i.e., $P_{in}(t) = E\delta(t - 0^+)$, the output temperature pulse is found from Eq. (19.69) as

$$\Delta T(t) = \frac{E}{c_a}\exp(-t/\tau_F). \tag{19.70}$$

Typically these devices are used for measurement of low energy infrared and x-ray photons which deposit the photon energy E in the absorber in a single interaction, although other particles can be detected. Thus the output from the detector is a pulse with an amplitude proportional to the energy deposited in the absorber by a radiation particle. The decay tail of the pulse can be made small by making τ_F very small. If the average time τ_γ between radiation interactions in the absorber is large so that $\tau_F/\tau_\gamma \ll 1$ then the cryogenic detector produces a train of output pulses whose amplitudes are proportional to the energy deposited by each incident photon from which the energy spectrum of the incident radiation can be formed. Thus the device can be used as an energy spectrometer, i.e., a microcalorimeter.

[27] A type of resistor in which the resistance is a function of the temperature.

However, if $\tau_\gamma \ll \tau_F$, the output pulses pile up upon the tails of earlier pulses and the device behaves more like a detector operated in current mode. For steady incident illumination with a flux of particles ϕ which, on average, deposit an energy E per interaction in the absorber, the incident power $P_{in} = \phi\mu V_a E$, where μ is the interaction coefficient and V_a is the volume of the absorber. If the illumination of the absorber begins at $t = 0$, then, from Eq. (19.69)

$$\Delta T(t) = \frac{\phi\mu V_a E}{g}\left[1 - \exp(-t/\tau_F)\right]. \tag{19.71}$$

Thus, for times greater than a few τ_F, the output is a signal that is constant and proportional to the incident flux ϕ. Thus in this case the cryogenic device is seen to act as a bolometer. In this simple analysis it is assumed that the time for deposited energy to be manifested as heat is negligible compared to τ_F or τ_γ.

Consequently, by changing the readout circuit of a thermal detector, the device can be operated as either a bolometer or calorimeter. For radiation energy spectroscopy, it is the microcalorimeter that is of most interest. There are many types of microcalorimeters, yet these devices are separated into two classes, thermal/equilibrium detectors and athermal/non-equilibrium detectors. Disadvantages of these detectors include their small volume, which places a practical limit on measurable photon energies, their relatively slow responses (which limit the measurable gamma-ray interaction rates), and their need for low operating temperatures. Friedrich [2006] describes these various microcalorimeters in a review article, summarized here in the following subsections.

Energy Resolution Thermal or equilibrium cryogenic detectors consist of a radiation absorber with heat capacity c_a attached to a thermometer (usually a thermistor). The absorber and thermometer are *weakly* coupled to a cold bath by a conductance g. Photon absorption increases the absorber temperature according to Eq. (19.70) in proportion to the absorbed energy E. The resulting temperature change is measured by the thermometer before the absorber relaxes to the bath temperature. However, thermal fluctuations of $4gkT^2$ limit the energy resolution. These resolution-limiting thermal fluctuations are a result of the random exchange of phonons across the weak thermal link.

For a fixed absolute T, the total energy of the absorber is c_aT and the average energy of the phonons is kT. The ratio of these terms gives the average number of phonons, $\overline{N}_p = c_a/k = \sigma^2(\overline{N}_p)$ if a Gaussian distribution is assumed. The variance in the phonon energy is $\sigma^2(E) = \sigma^2(kT\overline{N}_p) = k^2T^2c_a/k$. The energy resolution limit, measured by the FWHM of the phonon energy distribution, is [Kerson 1987]

$$\Delta E_{\text{FWHM}} = 2\xi\sqrt{2\ln 2}\,\sigma(E) = 2.355\xi\sqrt{kT^2c_a}. \tag{19.72}$$

Here ξ is a dimensionless parameter that depends on the temperature dependence of c_a [Moseley et al. 1984] which otherwise would be unity. However, the lattice heat capacity is a function of the absorber volume with a T^3 dependence [McClintock et al. 1984], i.e.,

$$c_a = \left(\frac{12\pi^4 N V_a k}{5}\right)\left(\frac{T}{\theta_D}\right)^3 \text{ J K}^{-1}\text{ mol}^{-1}, \tag{19.73}$$

where N is the atom density and V_a is the volume of the absorber. Here

$$\theta_D = \frac{\hbar}{k}\left(6\pi^2 v^3 N\right), \tag{19.74}$$

referred to as the Debye temperature, in which v is the mean thermal atomic speed.

From Eqs. (19.72) and 19.73, it is seen that the energy resolution improves both as the temperature decreases and as the absorber volume decreases (to make c_a smaller). However, a smaller absorber volume

means fewer radiation quanta interact in the absorber so the efficiency of the detector decreases. This decrease in efficiency then leads to the use of arrays of small absorbers in an effort to offset the decrease in efficiency of each absorber. The need for high energy resolution means *all* microcalorimeters must operate at temperatures as low as possible and with absorbers that are as small as possible, but with sufficient size to produce an acceptable detection efficiency.

Early microcalorimeters used semiconductor thermistors as the temperature sensor. An x-ray absorption causes the resistance in the thermistor to increase which produces a change in voltage across the thermistor for current biased devices. These measured voltage changes can be used to infer the ΔT change in the detector as a result of a radiation interaction in it. Although effective, as shown by a measured energy resolution of less than 8 eV for 5.9 keV gamma rays from ^{55}Fe, the resolution is limited by the heat capacity of the absorbers.

Microcalorimeters are operated at such low temperatures, near 0.1 K, and with small absorber volumes that energy resolution of a few eV FWHM is possible only for low energy x rays. The maximum achievable energy resolution is also a function of Johnson noise in the thermistor, amplifier noise, and photon background [McCammon 2005a]. Moseley et al. [1984] show that a practical limit is approximately twice the predicted value of Eq. (19.72). The thermal coupling g between the microcalorimeter is weak at low temperatures, and consequently these detectors are relatively slow. The thermal pulse decay time $\tau_F = c_a/g$ is generally on the order of 1 ms.

Semiconductor Microcalorimeters

Semiconductor thermistors based on doped Si or Ge are used for high resolution x-ray spectroscopy, and are probably the oldest type of cryogenic microcalorimeter [Low 1961; Moseley et al. 1984]. These thermistors require a relatively large change in resistance with temperature (dR/dT). The absorber can be formed from a high Z material to improve both the photon absorption efficiency and heat capacity c_a; however, the material may experience a decrease in thermal conductance between the absorber and the thermistor, g_a. Consequently, the added noise degrades the energy resolution by [Bühler et al. 1994],

$$\Delta E_{\mathrm{FWHM}} = 2.355\xi\sqrt{4kT^2c_a}\left[\frac{g}{g_a} + \left(\frac{g}{g_a}\right)^2\right]^{1/4}. \tag{19.75}$$

As discussed Sec. 12.5.3, the intrinsic charge carrier concentration of a semiconductor increases exponentially with temperature. At low temperatures the number of free charge carriers diminishes to zero, effectively causing the semiconductor to become an insulator so that it no longer is useful as a thermistor. The conductivity can be increased by doping the semiconductor with shallow donors or acceptors so the semiconductor retains some conductivity even at lower temperatures. However, at the very low temperatures required for high resolution microcalorimeters, even shallow dopants enter the "freeze-out" region and thermal ionization becomes negligible. The work of Anderson [1958] and Mott and Twose [1961] describes the conduction mechanism of doped semiconductors, including their low temperature behavior. There is a critical doping concentration below which a semiconductor at 0 K is an insulator but for $T > 0$ the semiconductor retains conductivity [McCammon 2005b]. If the semiconductor is doped slightly below the limit, the conduction mechanism is governed by phonon-assisted tunneling between impurity sites called "variable range hopping" (vrh) [Shklovskii and Efros 1984].

For vrh, the electrical resistance can be described by,

$$R(T) = R_0 \exp\left[\frac{T_o}{T}\right]^p, \tag{19.76}$$

where p is approximately 1/2 [Efros and Shklovskii 1975] with R_0 and T_0 fitting parameters. Equation (19.76) indicates that $\ln R(T) \propto T^{-1/2}$ and is valid over the very low temperature operating range of the detector.

Note that Eq. (19.76) indicates that R_0 is the resistance at very high temperatures; but Eq. (19.76) is an approximation valid over only a limited low temperature range and fails at high temperatures. The variation of resistance with temperature is characterized by the temperature coefficient defined as

$$\alpha = \frac{d \ln R}{d \ln T} = \frac{T}{R}\frac{dR}{dT}. \tag{19.77}$$

For $R(T)$ given by Eq. (19.76)

$$\alpha = -p \left(\frac{T_0}{T}\right)^p. \tag{19.78}$$

The utility of the temperature coefficient is that, for small temperature changes ΔT, the associated change in resistance ΔR can be estimated from Eq. (19.77) as

$$\Delta R = \alpha \frac{R}{T} \Delta T. \tag{19.79}$$

The temperature dependence of R for Si and Ge, at first, did not appear to follow the model of Eq. (19.76). The experimental data varied between samples, at least at the time when measurements were first made. However, neutron transmutation doped (NTD) semiconductors on Si and Ge [Haller et al. 1996] do, in fact, follow the prediction of Eq. (19.76) [McCammon 2005b]. This improvement is probably a consequence of the superior dopant uniformity of NTD along with the reduction of interstitial defects.[28] Uniform doping with deep ion implantation also yields good results [Friedrich 2006].

For high energy resolution, the absorber heat capacity must be kept low, on the order of 10 pJ K^{-1} [Friedrich 2006]. Bryant and Keesom [1961] found that this requirement for Ge limited the absorber volume to about 0.001 mm^3. With a typical thermal conductance g of 10 nW K^{-1} between the absorber and heat sink, the decay time $\tau_F = g/c_a$ is approximately 1 ms [Bühler et al. 1994]. The absorber and thermistor volumes are kept small to sustain high energy resolution and good performance.

The relatively high specific heat of doped semiconductors, even at low temperature, reduces the sensitivity of the detector. Kelly et al. [1993] describe a *monolithic* semiconductor device in which only a small portion of the semiconductor absorber is doped. Hence, the absorber is the undoped region, and the thermistor is the smaller doped region, all a part of a single substrate. The *composite* microcalorimeter has a separate low c_a absorber and thermistor. The combined pair can be optimized to produce a larger device while reducing τ_F. To increase the overall volume, these small individual detectors can be fabricated into arrays with individual absorbers atop each thermistor [Stahle et al. 2004].

Superconducting Transition Edge Microcalorimeters

The electrical resistance of a superconducting material is zero below a transition temperature T_c and exhibits a characteristic increase in resistance as the temperature is increased above the transition temperature as shown in Fig. 19.55. The transition temperature changes in a magnetic field, decreasing as the B field is increased [Rose-Innes and Rhoderick 1978]. Above a critical magnetic field H_o for a Type I superconductor, superconduction is not possible, even at 0 K. A Type II superconductor has two phases defined by two limiting B fields. Below T_C and the boundary defined by H_{c1}, the material superconducts as observed with a Type I superconductor. However, between magnetic field boundaries defined by H_{c1} and H_{c2}, the material

[28] NTD transforms Ge or Si into dopant atoms through activation, typically n-type dopants, whereas diffusion and implantation doping replace Ge or Si by forcing them from their lattice locations by the impurities introduced during either the diffusion drive-in or implantation process.

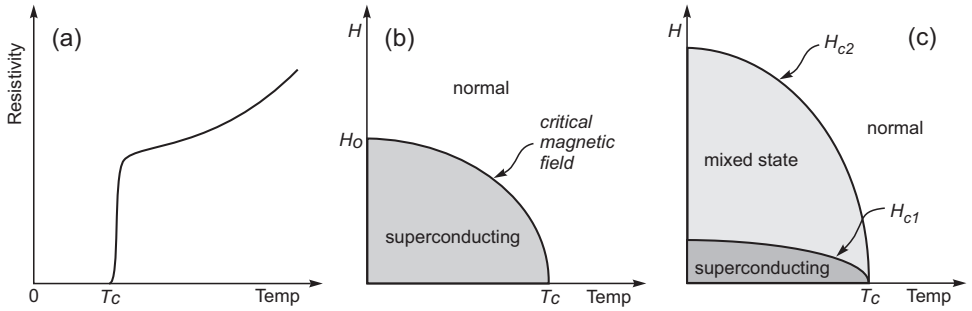

Figure 19.55. (a) Superconductivity abruptly occurs below a transition temperature T_c. (b) Type I superconductivity in which the transition temperature T_c is also a function of the applied magnetic field, with a critical field H_o above which superconductivity is not possible. (c) Type II superconductor with H_{c1} defining the boundary of the mixed state and H_{c2} defining the critical field above which superconductivity is not possible.

transitions into the mixed state, in which both superconductivity and normal conductivity coexist. Consequently, for magnetic fields bounded by H_{c1}, Type II superconductors may have two transition temperatures defined by T_{c1} (superconducting) and the other T_{c2} (mixed state) above which superconductivity vanishes.[29]

If a superconductor is set slightly below T_c, then heat added to the system moves the superconductor above the transition temperature so it no longer has zero resistance. Consequently, current flow through the material (no longer superconducting) now produces a voltage, which gives a measure of the energy deposited in the absorber. This type of calorimeter is called a transition edge superconducting (TES) spectrometer. In normal operation, the device is chilled well below the transition edge, and heated ohmically by applying a constant voltage bias to the superconducting film that is in contact with the absorber. The bias is adjusted such that the temperature of the device is maintained slightly below the transition edge. The absorption of an x ray causes the superconducting film to become normal conducting, thereby increasing the resistance and decreasing the current.

Because the TES film in contact with the absorber increases in resistance with temperature (just opposite of that for a doped semiconductor calorimeter), the TES detector can use electrothermal feedback (ETF). With ETF, the power $P = V^2/R$ decreases as the resistance increases. Consequently, with lower power, the return to the cryogenic bath temperature is quicker and the energy resolution is improved [Irwin 1995],

$$\Delta E_{\text{FWHM}} = 2.355 \left[\frac{4kT^2C}{\alpha} \sqrt{\frac{n}{2}} \right]^{1/2}, \tag{19.80}$$

where n is a parameter characterizing the temperature dependence of the thermal conductance as given by [Irwin 1995]

$$g = \frac{dP}{dT} = nKT^{n-1}. \tag{19.81}$$

Here K is a material and geometry related parameter. When an interaction event heats the film, the return to equilibrium is described by

$$c_a \frac{d\Delta T}{dt} = -\frac{P_0 \alpha}{T} \Delta T - g\Delta T, \tag{19.82}$$

[29] The normal state is confined to threads of *normal cores* of conductivity in a triangular pattern with each core surrounded by superconducting material [McClintock et al. 1984].

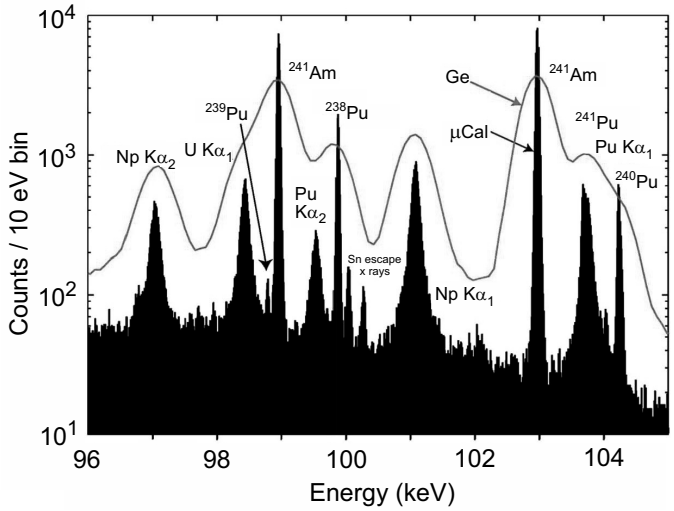

Figure 19.56. Pu spectrum from a microcalorimeter array using data from 11 of 13 active pixels. The combined array resolution is approximately 45 eV. At this resolution, the broad x-ray peaks can be readily distinguished from gamma-ray peaks. The solid curve is a spectrum taken with a conventional HPGe detector. ©[2009] IEEE. Reprinted, with permission, from Bacrania et al., *IEEE Trans. Nucl. Sci.*, **56**, 2299–2302, [2009].

where P_0 is the equilibrium Joule power. When the superconducting film is well below the transition temperature, $P_0 = KT^n = gT/n$, and the pulse time constant is [Irwin et al. 1998],

$$\tau_F = \frac{c_a}{g}\frac{n}{n+\alpha\varphi_b}. \tag{19.83}$$

Here φ_b is a measure of how far the detector is biased above the bath temperature T_b and is defined as

$$\varphi_b \equiv 1 - \left(\frac{T_b}{T_e}\right)^n, \tag{19.84}$$

where T_e is the equilibrium temperature of the TES calorimeter. Equation (19.83) indicates that high values of α improve recovery time.

The current is measured through induction with a superconducting quantum interference device (SQUID) current amplifier. This device is used to reduce amplifier noise because a SQUID does not have voltage noise. TES calorimeters must have low resistance to ensure rapid and homogeneous thermalization of the absorber and superconducting film. Typically the choice of absorber depends greatly upon the photon energy of interest. An energy resolution of 2.37 ± 0.17 eV has been achieved for 5.9-keV gamma rays from Mn K_α lines using Mo-Au TES thermistors [Iyomoto et al. 2008]. Higher energy gamma rays, yet generally below 100 keV, produce good results with a Sn absorber bonded to superconducting bilayer of Mo and Cu with a transition temperature of 100 mK [Doriese et al. 2007]. The best reported energy resolution for a single device was 25 eV for 103-keV gamma rays. Arrays of microcalorimeters can be used to maintain a fast response time while increasing detection efficiency [Doriese et al. 2007; Iyomoto et al. 2008; Bacrania et al. 2009]. Shown in Fig. 19.56 are comparison x-ray spectra for a typical HPGe semiconductor detector and a TES microcalorimeter array.

Magnetic Microcalorimeters

Another type of low-temperature microcalorimeter measures the change in magnetism as small amounts of heat are added to the system. These devices have a radiation absorber coupled to a paramagnetic

sensor, together weakly attached to a low-temperature thermal reservoir [Fleischmann 2005]. Thermal energy absorbed by the system causes the magnetism to decrease, a decrease which can be measured by an inductively coupled SQUID.

Originally introduced by W. Seidel in 1986,[30] the technology was subsequently investigated for its potential as an ultra-high resolution x-ray spectrometer [Bühler and Umlauf 1988; Bühler et al. 1993; Fausch et al. 1993; Bühler et al. 1994]. In these original works, energy resolution of 320 eV was achieved for 5-MeV alpha particles with the compound cerium magnesium nitrate or CMN [see Fleischmann 2005]. However, the response times were slow with a 40-ms rise times and up to 10-s thermalization times. This slow response, which is a common problem with paramagnetic dielectric materials, is unsuitable for most x-ray spectroscopy applications. Bandler et al. [1993] suggested that the response problem can be overcome by embedding magnetic ions into a conductive metallic absorber, particularly gold doped with erbium. Fleischmann et al. [2000] adopted this concept and have extensively studied Au:Er metallic magnetic calorimeters (MMC).

The magnetization change from a paramagnetic sensor is described by [Fleischmann et al. 2005],

$$\delta M = \frac{\partial M}{\partial T}\delta T = \frac{\partial M}{\partial T}\frac{\delta E}{c_a} \tag{19.85}$$

clearly showing that a small value of c_a is required to produce a relatively large change in temperature and, consequently, a large change in magnetization. The energy resolution of the detector is limited by [Fleischmann et al. 2003]

$$\Delta E_{\mathrm{FWHM}} = 2.355\sqrt{4kT^2c_a}\left[\frac{4\tau_0}{\tau_1}\right]^{1/4}. \tag{19.86}$$

where $\tau_0 = c_a/g_a$, approximately equal to 1 μs, is the average time for deposited energy in the absorber to change the spin in the paramagnetic sensor. The time constant $\tau_1 = c_a/g$ describes the time needed for the (weak) thermal coupling to transfer heat to the low-temperature heat sink. It is notable that MMCs do not have a bias current, because they are inductively coupled to a SQUID amplifier and thus have no bias voltage, and therefore do not suffer from resistive heating or associated noise [Enss et al. 2004]. For a fixed value of c_a, MMCs can have better energy resolution than other types of calorimeters, or, instead, have the same energy resolution but with a larger absorber so that they have improved efficiency. Although these detectors are relatively slow, they are theoretically capable of less than 1 eV energy resolution. Fleischmann et al. [2004] reported energy resolution of 3.4 eV for 6.5-keV x rays with a Au:Er MMC, while Gastaldo et al. [2013] reported 2-eV FWHM for 6-keV x rays.

19.4.3 Athermal Cryogenic Charge Detectors

Another class of cryogenic detectors does not measure thermal effects produced by radiation but instead is based on measuring the number or the energy of quasiparticles produced by radiation in a superconductor. Before describing these athermal detectors, some more properties of superconductivity must be understood.

Properties and Mechanism of Superconductivity There is a distinctive difference between a perfect conductor and a superconductor in the presence of a magnetic field. If a perfect conductor is cooled to low temperatures to obtain zero resistance, and is then introduced into a magnetic field, according to Lenz's Law the magnetic field is canceled inside the conductor and effectively dispelled. A similar condition is observed for superconductors, where the magnetic field is expelled from the superconductor. However, if a perfect conductor is cooled while already in a magnetic field, the magnetic field continues to permeate the conductor, and remains trapped in the perfect conductor once the magnetic field is removed, causing the sample to become magnetized. However, if a superconductor is cooled below the transition temperature in the presence

[30] Fleischmann et al. [2005] reference the unpublished thesis of W. Seidel as the introduction of this concept.

of a magnetic field, it expels the magnetic field upon being reduced below T_c. This phenomenon associated with superconductors is called the Meissner effect. Upon removal from the magnetic field, a superconductor does not trap the magnetic field.

Superconductivity results from the pairing of electrons, called Cooper pairs, created at low temperature by phonon-electron interactions.[31] An electron can cause lattice distortions by attracting nearby positive atomic nuclei, causing them to move slightly closer to the electron, their movement producing a phonon, and ultimately appearing as a location with positive charge. This apparent positive charge attracts another electron, even at relatively long distances on the order of several hundred nanometers,[32] and overcomes the usual repulsion between electrons. These two electrons have opposite spin and momentum and temporarily form a pair, physically producing a composite boson particle with a lower potential energy than two single electrons. In fact, the sea of Cooper pairs are represented by a single wave function and follow Bose-Einstein statistics. They form a state of lowest energy called the condensed state with an energy gap ϵ_{gT} between this condensed state and the lowest energy of two unpaired electrons. This energy gap becomes nearly constant for temperatures below approximately $0.6T_c$.

Cooper pairs do not stay paired, but repair with other electrons, such that the superconductivity condition is preserved. The energy of the pair is on the order of 10^{-3} eV, and can be broken by sufficient thermal energy. Consequently it takes low temperatures to produce substantial numbers of Cooper pairs. If a Cooper pair is scattered, the total momentum of the pair is conserved and their motion along the electric field lines is unimpeded. To destroy a Cooper pair, an energy of at least $2\epsilon_{gT}$ is required, which is improbable at temperatures well below T_c. However, the value of ϵ_{gT} decreases at the temperature is increased, ultimately becoming zero at T_c.

Superconducting Tunnel Junction Detector

As just described, ϵ_{gT} is the small band gap formed between the Cooper-pair state and the normal state. The limiting energy gap at 0 K is denoted ϵ_{g0} and is on the order of 1 meV. A semiconductor, such as silicon, has a band-gap energy on the order of 1 eV, and so the superconducting band gap is 1000 times smaller. Consequently, the number of electrons changing from bound Cooper pairs into electrons can be vastly greater per unit absorbed energy. Much like a semiconductor, there is an average energy required to produce a *quasiparticle*[33] from a broken Cooper pair.

Although the minimum energy must be at least $2\epsilon_{gT}$ to make two quasiparticles, the average energy w_q needed to produce a single quasiparticle is slightly more than ϵ_{gT}. Initial estimates put the upper limit of w_q at $2\epsilon_{gT}$ per quasiparticle [Kurakado and Mazaki 1981a, 1981b]. Later estimates, produced by Monte Carlo calculations, put the average value of w_q closer to $1.7\epsilon_{gT}$ [Kurakado 1982]. Consequently, the average number $\langle N \rangle$ of quasiparticles produced per unit energy in a superconductor is extremely high, an effect which reduces the statistical fluctuations in the measured signal carriers.[34] Ultimately, because approximately 1000 times more quasiparticle charge carriers are produced than in a semiconductor, the energy resolution can be approximately $\sqrt{1000} \simeq 32$ times better.

Generally the voltage applied to a superconductor causes a current that renders undetectable the small current changes produced by radiation events. However, the quasiparticles can be measured with a superconducting tunnel junction (STJ) device. The basic construction of an STJ is a thin layer of insulating material

[31] The concept is credited to Leon N. Cooper, who described the idea in 1956. However, it was actually Richard A. Ogg, Jr., who first proposed the concept in 1946, ten years earlier than Cooper, but Ogg's work was apparently disregarded at the time.

[32] Yes, this distance is small, but typical lattice spacings are a fraction of a nanometer, so this distance is relatively large by comparison.

[33] A particle whose fundamental behavior is altered by its physical environment. For instance, electrons or holes in semiconductors are quasiparticles treated classically as particles traveling in vacuum by applying an effective mass.

[34] Here $\langle N \rangle = E_\gamma / w_q$.

sandwiched between two superconducting materials, in which the insulating barrier impedes current flow. The insulating barrier is made extremely thin such that electrons and holes produced from decoupled Cooper pairs can tunnel through the barrier. With a potential applied to the device, the tunneling current becomes a function of the quasiparticle population crossing the barrier [Rando et al. 1992].

To improve detection efficiency and reduce diffusion of quasiparticles away from the barrier, a multilayered superconducting STJ can be fabricated [Booth 1987; Frank et al. 1998]. The insulating barrier is sandwiched between two superconductors each with a band gap of ϵ_{gT1}. On the outside of these superconductors, a much thicker second superconductor with $\epsilon_{gT2} > \epsilon_{gT1}$ is applied on both sides. The structure forms quantum wells adjacent to the insulating layer, and thereby assists with confinement of quasiparticles at the barrier. At least one type of device has Al_2O_3 as the barrier ($\sim$ 2 nm thick), Al as the lower ϵ_{gT} superconductor ($\sim$ 50 nm) overcoated with Nb as the higher ϵ_{gT} superconductor ($\sim$ 265 nm) [Frank et al. 1998]. Other STJ detector configurations used Ta instead of Nb [Kraft et al. 1999]. Quasiparticles excited across the larger energy gap fall into the well by phonon emissions. If a phonon emission is of adequate energy, more quasiparticles can be excited across the lower energy gap [Mears et al. 1993]. Under a voltage bias, the quasiparticles tunnel through the barrier and can recombine as Cooper pairs on the other side (see Fig. 19.57).

Booth [1987] describes a quasiparticle multiplier device that increases the signal by fabricating successive layers of quantum well tunneling barriers. This layered structure enables multiple tunneling events to occur within some recombination time t_r [Mears et al. 1993]. The effect increases the overall measured signal, but also broadens the statistical spread in energy resolution. With corrections to the expected energy resolution including the Fano factor F (≈ 0.2) and statistical fluctuations in the number of tunneling quasiparticles $(1 + 1/\langle N \rangle)$, the overall energy resolution is described by,

$$\Delta E_{\mathrm{FWHM}} = 2.355\sqrt{w_q E\left(F + 1 + \frac{1}{\langle N \rangle}\right)}. \quad (19.87)$$

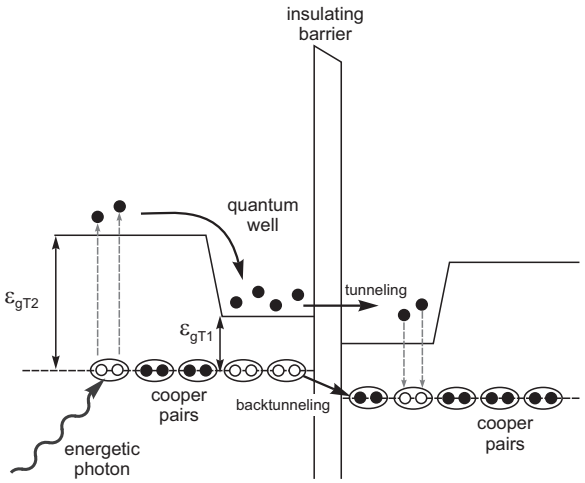

Figure 19.57. Band diagram of a bilayer superconducting tunnel junction (STJ) detector.

STJ detectors have been reported with energy resolution of 12 eV FWHM at 5.9 keV [Angloher et al. 2001]. Also, for lower energy photons, an energy resolution of 5.8 eV FWHM was measured for 1-keV photons [Kraft et al. 1999], and 1.9 eV FWHM for 70-eV photons [Friedrich et al. [1999]. The response time is determined by the time that quasiparticles remain in the quantum well. Their disappearance results from recombination or diffusion from the region which results in response times of about 3 μs [Friedrich 2006].

Microwave Kinetic Inductance Detectors

In the past ten years a new type of athermal detector has attracted considerable attenuation, particularly in the astrophysical community, because these detectors can be easily fabricated as large imaging arrays with high quantum efficiency for photons with wavelengths in the mid infrared (5 μm) to UV photons (0.1 μm). These detectors are known as Kinetic Inductance Detectors (KIDs) and operate by measuring the change in kinetic inductance caused by absorption of photons in a thin strip of superconducting material. The change in the kinetic inductance caused by the liberation of quasiparticles in the semiconductor by the incident photon is measured as the change in the resonance frequency of a microwave resonator and, hence these detectors are known better as Microwave Kinetic Inductance Detectors (MKIDs).

The seminal paper that began the flurry of interest in these detectors is that by Day et al. [2003], upon which most of the following discussion is based. Recall that in a superconductor a DC supercurrent, carried by Cooper pairs, flows without resistance. A Cooper pair, which is bound together by electron-phonon interactions, has a binding energy $w_q < 1.7\epsilon_{gT_c}$. However, superconductors have a non-zero impedance for AC currents. An electric field applied near the surface of a superconductor accelerates the Cooper pairs and, thereby stores energy in the superconductor in the form of kinetic energy. Because the supercurrent is non-dissipative, the stored energy may be extracted by reversing the electric field. Similarly, energy may be stored in the magnetic field inside the superconductor, which penetrates only a short distance, $\lambda \simeq 50$ nm, from the surface. Consequently, a superconductor has a surface inductance $L_s = \mu_o\lambda$ caused by the reactive energy flow between the superconductor and the electromagnetic field. The surface impedance $Z_s = R_s + j\omega L_s$[35] includes a surface resistance R_s to account for AC losses at angular frequency ω caused by the small fraction of electrons that are not in Cooper pairs, i.e., the quasiparticles. For temperatures $T \ll T_c$ we find that $R_s \ll \omega L_s$, thereby having negligible losses in the resonance circuit [Baselmans 2011].

Photons with energy ($h\nu > 2w_q$) may dissociate one or more Cooper pairs. The absorption of a high-energy photon creates $N_{qp} < \eta h\nu/w_q$ quasiparticles where $\eta < 0.57$ is the efficiency with which the photon energy is converted to quasiparticles. The quasiparticles recombine into Cooper pairs on timescales of $\tau_{qp} = 10^{-3}$ to 10^{-6} s during which they diffuse over a distance $\ell \simeq \sqrt{D\tau_{qp}}$ where D is the diffusion constant for quasiparticles in the superconductor material. Similarly, the absorption of a steady stream of low-energy (millimeter/submillimeter) photons would raise the steady-state quasiparticle density by an amount δn_{qp} above its thermal equilibrium value. MKIDs make use of the dependence of the surface impedance Z_s on the quasiparticle density. Although the changes δZ_s are quite small, very sensitive measurements may be made using a resonant circuit. Changes in L_s and R_s affect the frequency and width of the resonance, respectively. These changes, in turn, alter the amplitude and phase of a microwave signal transmitted through the measurement circuit.

The resonant circuit is often a parallel LC circuit which is capacitively coupled to a coaxial through line. The effect of the surface inductance L_s is to increase the total inductance L, while the effect of the surface resistance R_s is to make the inductor slightly lossy (adding a series resistance). On resonance, the LC circuit loads the through line, producing a dip in its transmission. The quasiparticles produced by the photons increase both L_s and R_s. These changes move the resonance to lower frequency (due to L_s), and make the dip broader and shallower (due to R_s). Both of these effects contribute to changing the amplitude and phase of a microwave probe signal transmitted though the circuit.

The choice of a parallel LC circuit coupled to a through line has high transmission at frequencies away from the resonance and, thus, is very well suited for frequency-domain multiplexing because multiple resonators operating at slightly different frequencies can all be coupled to the same through line. These detectors can count individual photons with no false counts and determine the energy and arrival time of each photon with good quantum efficiency.

Other Athermal Detectors

Superconducting Nanowire Single-Photon Detector A superconducting nanowire single-photon detector (SNSPD) uses an array of superconducting wires cooled to well below T_c and biased with a DC current just below the superconducting critical current. Typically these wires are niobium nitride 5 nm thick and 100 nm wide patterned on a substrate. If a photon is absorbed in a wire dissociating Cooper paired electrons, a small region is created in which the critical current is momentarily reduced below the bias current to form a small non-superconducting region. A detectable voltage pulse of about 1 ns duration indicates the photon

[35] $j = \sqrt{-1}$ is used to avoid confusion with the multiple uses of i.

absorption event [Natarajan et al. 2012]. Advantages of this detector include its high speed (up to 2 GHz count rate) and low dark current. However, SNSPDs provide little information about the photon energy.

Roton Detectors The elementary collective excitations in superfluid ^{4}He are *phonons* and *rotons*.[36] A particle interacting in this fluid can produce rotons. These rotons can be detected bolometrically or by the evaporation of helium atoms [Bandler et al. 1992]. Because ^{4}He is very pure, rotons travel ballistically and are stable and thus a large volume of fluid can be used.

Quasiparticles in Superfluid ^{3}He Below 0.001 K ^{3}He behaves as a *superfluid* in which pairs of atoms are bound as quasiparticles similar to Cooper pairs, ultimately having zero viscosity and flows without kinetic energy losses. The paired atoms have an exceptionally small energy gap of about 100 neV. Thus a detector similar to a STJ could be fabricated [Bradley et al. 1995]. The advantage of such a detector is that a huge number (10^9) of unpaired normal ^{3}He atoms are produced per particle interaction. But this detector is not very practical because it is very difficult to detect the normal ^{3}He atoms and to produce and maintain much superfluid at such low temperatures.

Capabilities of the Two Classes of Cryogenic Detectors

The principal advantage of charge detectors over microcalorimeters is that the former is much faster [Frank et al. 1998]. STJs and MKIDs can produce several thousand counts per second per pixel. By contrast, microcalorimeters are limited to a few tens of counts per second. However, charge detectors, unlike microcalorimeters, are limited to low energy photons because superconductors cannot sustain electric fields to sweep out the charges and charges diffuse little before they recombine. Microcalorimeters, while somewhat more robust in measuring the energy of the radiation quanta, cannot absorb all the energy of very energetic particles, such as a 10-MeV gamma ray, in their typically small absorbers.

19.5 Wavelength-Dispersive Spectroscopy

Ultra-high resolution can be achieved for low energy gamma and x rays with wavelength dispersive spectroscopy (WDS), which can yield x-ray peak resolution better than that of semiconductor or cryogenic detectors. The method utilizes Bragg scattering, in which the Bragg condition for constructive interference must be satisfied, i.e,

$$n\lambda = 2d\sin\theta, \tag{19.88}$$

where n is an integer, d is the spacing between crystalline planes, λ is the wavelength of the photon under inspection, and θ is the angle at which radiation intersects the crystal from the parallel condition as shown in Fig. 19.58.

Because it is difficult to make a portable diffraction system, this instrument is generally attached to an electron microprobe or scanning electron microscope (SEM) [Goldstein et al. 1981]. These instruments accelerate a focused energetic electron beam onto a sample to produce induced radiations such as secondary electrons, backscattered electrons (from the beam), and various x-rays as shown in Fig. 19.59. Different radiation detectors are used with these types of instruments, including gas-filled, scintillation, and semiconductor detectors. For instance, secondary electrons are generally detected by a scintillation detector[37] shrouded by a Faraday cage, all inside the SEM or microprobe chamber. Backscattered electrons have lower energy, and because of their wider spatial dispersement, an annular semiconductor detector around the SEM pole piece is used to detect these electrons. X-ray emissions are often detected with a cryogenically-cooled

[36] Rotons are excitations or quasiparticles with a very short wavelength of about 3Å, which is about the same as the spacing between the helium atoms in the liquid. At temperatures of 1 K and above, it is the rotons which make the main contribution to the specific heat and the thermal energy.

[37] Named a Everhart-Thornley detector after the inventors.

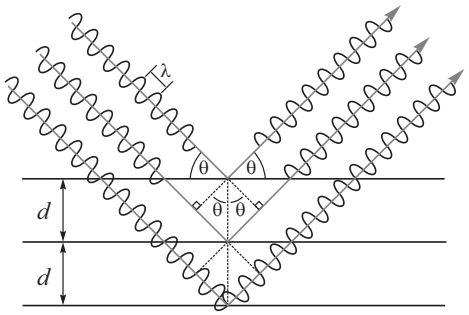

Figure 19.58. Geometry for Bragg diffraction of photons.

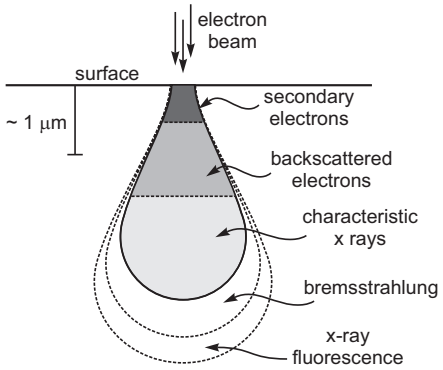

Figure 19.59. Radiations emitted from different parts of the interaction volume probed with an electron microprobe.

Si(Li) detector (see Sec. 16.4.1), which yields excellent spectroscopic energy resolution.[38] However, in some cases, higher x-ray energy resolution is required than that provided by a chilled Si(Li) detector and in such cases WDS can produce the higher energy resolution.

Shown in Fig. 19.60 is a common arrangement for the WDS tool, which allows a sample to be inspected while it is irradiated with an electron beam which produces characteristic x rays from the sample. These x rays intersect a slightly bent diffraction crystal. Those x rays satisfying the Bragg condition diffract into a detector and can be recorded, whereas other x rays are absorbed in the crystal, scatter randomly, or pass through the crystal. Because only the number of counts at a given diffraction angle need be recorded, the detector need not be a high-resolution spectrometer, hence a gas-filled proportional counter is usually used as the x-ray detector. During operation, the crystal and detector are rotated through a Rowland circle, which permits the Bragg condition to be maintained as the arrangement rotates through a continuum of wavelengths.

As a result, the x ray detector records the number of counts as a function of wavelength. The stringent requirement for the Bragg condition results in ultra-high resolution, which can be plotted as a function of photon energy. The important advantage of WDS is the superior identification ability it provides to the user. Comparison spectra between a Si(Li) spectrometer, a microcalorimeter, and a WDS spectrometer are shown in Fig. 19.61. Unfortunately, the system can be used only for photons with sufficiently low energy that Bragg diffraction can occur. Several commercial systems have a rotating rack of different diffraction crystals that extend the sensitive range. WDS systems are laboratory-based, hence are not generally considered portable.

19.6 Čerenkov (Cherenkov) Detectors

A charged particle passing through a dielectric material can cause the molecules along its path of travel to form dipoles, forming a segment of polarization. These molecules promptly return to the relaxed condition by the spontaneous emission of light, forming wavelets of light to propagate through the dielectric. If the particle is passing through the material at velocities below that of light in the same media, these successively released wavelets destructively interfere with each other, resulting in the suppression of luminescence. However, if the particle is traveling faster than the speed of light in the medium, these wavelets add constructively to produce a wavefront of light (depicted in Fig. 19.62, left). This pulse of light is known as Čerenkov

[38] This method is often called EDS, or energy dispersive spectroscopy, but is the same as energy pulse height analysis.

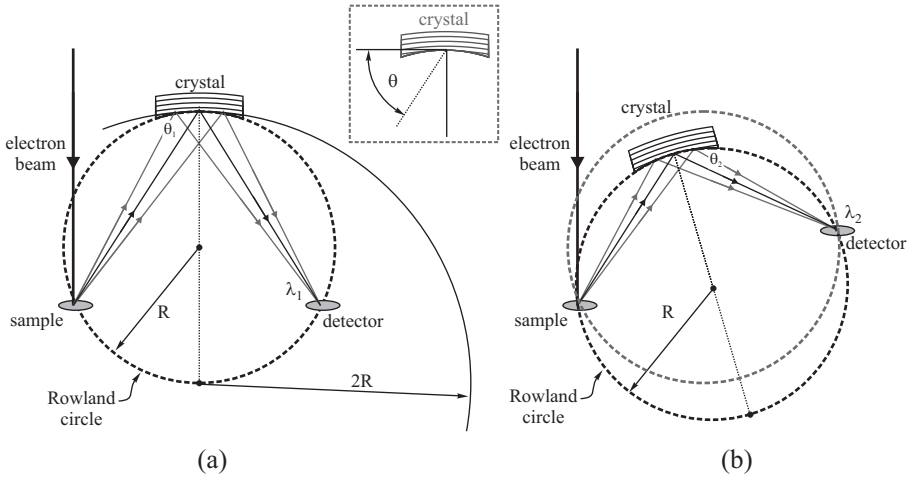

Figure 19.60. A typical WDS diffraction arrangement is aligned on a Rowland circle. The sample location remains stationary. The diffraction crystal is bent with a radius twice that of the Rowland circle radius R, and it is typically ground with radius R. The Bragg condition is maintained for various values of λ by moving both the crystal and detector, with the sample remaining stationary, such that all points remain on the Rowland circle.

(Cherenkov) radiation, after the Russian physicist who first observed the phenomenon in 1934 by noticing blue light emissions from water irradiated with gamma rays [Čerenkov 1934; see also Jelley 1955].[39]

The speed of light c' in a dielectric medium is determined by the index of refraction n of the medium as

$$c' = \frac{c}{n}, \tag{19.89}$$

where c is the speed of light in a vacuum. If the particle speed v is greater than c', then conditions arise that produce Čerenkov radiation.[40] Consider the diagram of Fig. 19.62(right) in which the distance traveled by a particle from point **A** to point **C** is represented by vt. If the speed of the particle $v > c'$, i.e., $v/c \equiv \beta > 1/n$ then the dipoles along its path emit light as the particle slows. The time t for the light wave to travel from point **A** to point **B** is the same as the time needed for the particle to travel from point **A** to point **C**, namely

$$vt\cos\theta = \frac{c}{n}t. \tag{19.90}$$

Rearrangement gives the following condition for Čerenkov radiation emissions

$$\cos\theta = \frac{1}{\beta n}. \tag{19.91}$$

There are some important observations to make from this result. First, the particle speed v greatly affects the light emission angle θ because Čerenkov radiation is emitted anisotropically, i.e., this light is emitted perpendicularly to the surface of a conical shell subtended by an angle 2θ along the particle path. Second, if βn falls to unity, then θ goes to zero and there is no emission angle or light emission. As the particle loses

[39] Pavel Čerenkov, Il'ja Frank, and Igor Tamm were awarded the 1958 Nobel Prize in Physics for the discovery and interpretation of this phenomenon.

[40] Oliver Heaviside had already predicted Čerenkov radiation in two papers published in 1888 and 1889.

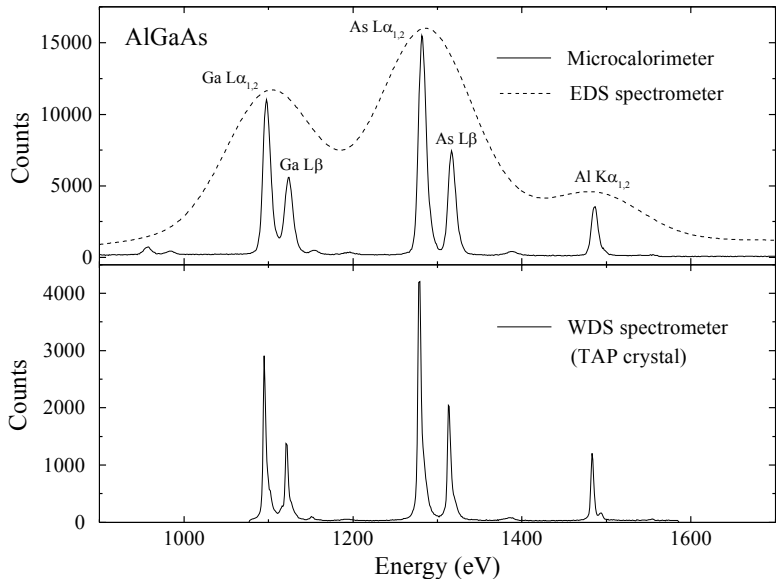

Figure 19.61. Shown are (top) a comparison of EDS spectra from a Si(Li) detector and a microcalorimeter detector and (bottom) an additional comparison to a WDS detector. Reproduced from Wollman et al., *J. Microscopy*, **188**, 196–223, (1997), with the permission of Wiley Publishing.

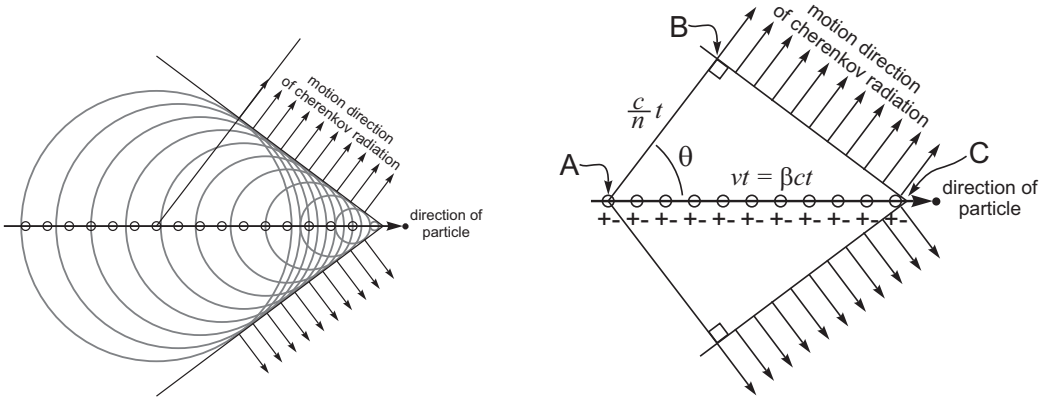

Figure 19.62. (left) A particle moving through a medium faster than the velocity of light produces polar-aligned waves. (right) The angle of light emission is defined by the particle speed and the index of refraction.

energy through light emissions, the conical angle diminishes and eventually becomes zero. The emission anisotropy was photographically documented by Čerenkov by irradiating water and benzene with gamma rays [Čerenkov 1937]. In that experiment, a vial filled with either water or benzene was surrounded by an angled toroidal mirror to reflect the light up into a camera. The resulting images are shown in Fig. 19.63. The general outline of the cone is apparent as two fuzzy bright spots in the photographs. Also apparent is an increase in cone angle with an increase in the index of refraction as predicted by Eq. (19.91).

Frank and Tamm [1937] used Maxwell's equations to obtain the following expression for the number of Čerenkov photons emitted, per unit differential path length of travel for a particle with charge number z,

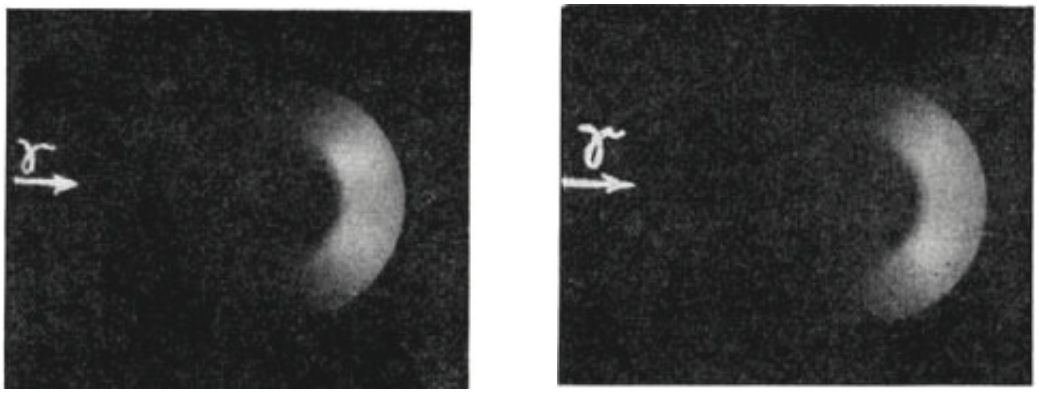

Figure 19.63. Čerenkov radiation from (left) water ($n = 1.337$) and (right) benzene ($n = 1.501$). The semiannular feature is an artifact of the angled toroidal mirror wrapped around the dielectric samples. However, the two fuzzy bright spots in both photographs do show the perimeter of the emission cone. Reproduced from Čerenkov, *Phys. Rev.*, **52**, 378–379, (1937), with the permission of APS Publishing.

per unit wavelength,

$$\frac{d^2N}{dx\,d\lambda} = 2\pi\alpha z^2\left(1 - \frac{1}{\beta^2 n^2}\right)\frac{1}{\lambda^2} = \frac{2\pi\alpha z^2}{137\lambda^2}\left(1 - \cos^2\theta\right) = \frac{2\pi\alpha z^2}{137\lambda^2}\sin^2\theta, \tag{19.92}$$

where λ is the emission wavelength and $\alpha \equiv q^2/(2\epsilon_0 hc) = 1/137.03567$ is the mysterious dimensionless fine-structure constant.[41] From Eq. (19.92), it becomes clear that the light yield increases as λ decreases so that the emission spectrum is greatest in the violet-blue end of the visible spectrum. However, ultraviolet light is readily absorbed in many dielectrics and, thus, reduces that portion of the spectrum. Consequently, Čerenkov radiation usually appears blue in color, although many other visible light wavelengths are emitted but with lower intensities. In the derivation of this expression for Čerenkov radiation, Frank and Tamm assumed that the index of refraction n is constant, i.e., independent of the light wavelength. However, for wavelengths in the x- and gamma-ray portion of the spectrum, n decreases to below unity and Čerenkov emission cannot occur.

The number of Čerenkov photons emitted between λ_1 and $\lambda_2 < \lambda_1$, per unit path length of travel of the charged particle, is

$$\frac{dN}{dx} = \int_{\lambda_2}^{\lambda_1}\frac{d^2N}{dx\,d\lambda}\,d\lambda = \frac{2\pi z^2}{137}\left[\frac{1}{\lambda_2} - \frac{1}{\lambda_1}\right]\sin^2\theta. \tag{19.93}$$

Because the most probable wavelengths are also in the sensitive region of most photomultiplier tubes, Čerenkov radiation can contribute to background for some scintillation detectors, especially organic scintillators. Also, because common glass ($n = 1.5$) can produce Čerenkov radiation, the glass enclosure of a PMT can produce background Čerenkov photons and it is especially problematic if the photocathode or first few dynode stages are illuminated by these photons.

The total threshold particle energy E_{th} for Čerenkov emission occurs when $\beta = 1/n$ and is found to be

$$E_{th} = \frac{m_0c^2}{\sqrt{1-\beta^2}} = m_0c^2\sqrt{\frac{n^2}{n^2-1}}, \tag{19.94}$$

[41] No one knows why $1/\alpha = 137.03567$ or how to calculate it. But if it were to change even slightly, our universe would be very different. For example, if it changed by even 0.4% fusion in stars could not produce carbon and carbon-based life would not be possible.

which includes rest mass energy equivalent m_0c^2. The kinetic energy T_{th} required to first produce Čerenkov radiation is found by subtracting the rest mass energy of the particle from the above total energy to give

$$T_{th} = m_0c^2 \left[\sqrt{\frac{n^2}{n^2-1}} - 1 \right]. \tag{19.95}$$

Compton scattering is the most probable interaction for gamma rays in low Z dielectrics, and the gamma-ray energy E_γ to produce a maximum energy $T_{\max}$ of the recoil electron can be found from Eq. (4.74) with $\theta_s = \pi$ as

$$E_\gamma = \frac{T_{\max} + \sqrt{T_{\max}^2 + 2T_{\max}m_oc^2}}{2}. \tag{19.96}$$

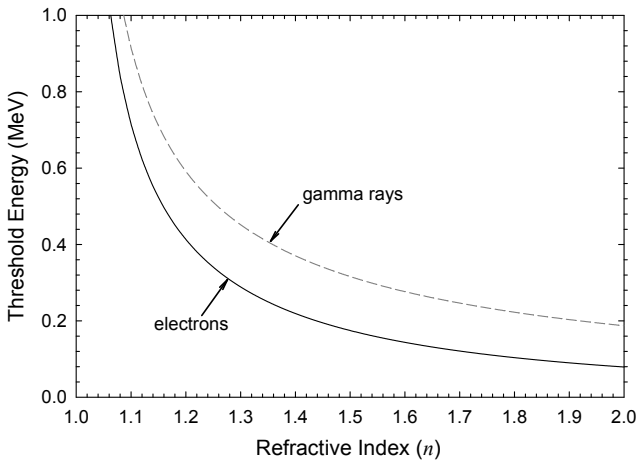

Figure 19.64. Čerenkov threshold energies for electrons and gamma rays as a function of the refractive index. Note that gamma rays can impart only a fraction of energy through Compton scattering, and therefore have higher Čerenkov thresholds than electrons of the same energy.

Substituting T_{th} of Eq. (19.95) for $T_{\max}$ into Eq. (19.96) then gives an expression for the minimum energy of gamma rays to produce recoil electrons that in turn produce Čerenkov radiation in a medium with an index of refraction n. The threshold energies for electrons and gamma rays are plotted in Fig. 19.64.

Čerenkov detectors are used for a number of different applications for the detection of highly energetic particles, which include gamma rays (producing energetic electrons), electrons, β particles, π mesons, neutrinos, and cosmic rays. They usually consist of a transparent interaction medium, such as water or heavy water (D_2O), plastic, or other organic material. Attached to the absorbing medium are light detectors, usually photomultiplier tubes (PMTs). Materials chosen for Čerenkov detectors should not produce scintillation luminescence or phosphorescence. For high n materials, the energy threshold is lower and the Čerenkov cone angle is broader for a given energy. Further, the material should be optically transparent to the Čerenkov emissions. It is also preferred that the absorbing medium be composed of low Z lightweight materials to reduce scattering and extend the path length of the energetic ionizing particles. A short list of materials investigated for Čerenkov radiation detectors includes purified water, heavy water, lucite, silica aerogel, benzene, glass, and various gases (some listed in Table 19.4).

Čerenkov radiation detectors have a fast time response, typically measured in picoseconds. Although the fast response may have discrimination advantages from other forms of luminescence, this fast timing property ultimately is limited by the PMT response. The Čerenkov light flashes are relatively dim compared to those from scintillators consisting of several hundred visible light photons per centimete of particle travel in the medium. Distinguishing this dim light from background light can be a problem.

The light wave direction and cone angle can be used to determine both particle energy and speed. The light ring formed by the cone can be projected upon a surface, a method used in Ring Imaging Čerenkov Counters (RICH) [Seguinot and Ypsilantis 1994; Ypsilantis and Seguinot 1994]. A RICH counter has an interaction medium adjacent to a reflecting mirror that projects Čerenkov light rings upon a light imaging sensor. These measurements can also be conducted by arranging multiple PMTs around (or in) the absorber

Table 19.4. Čerenkov detector properties for pure materials.

Material	Refractive Index (n) $\lambda = 589.29$ nm	Threshold Energy (MeV) (electrons)	Threshold Energy (MeV) (gamma rays)
Air (STP)	1.000277	21.2	21.46

and tracking the PMTs that respond to the Čerenkov cone. The Sudbury Neutrino Observatory (powered off on Nov. 28, 2006) had a 6-m diameter spherical acrylic tank filled with 1102 tons of heavy water, surrounded by 9600 PMTs. The Super-Kamiokande Neutrino Detection Experiment, or Super-K, has 50,000 tons of purified water with over 11,100 PMTs surrounding the tank.[42]

There is an enormous Čerenkov detector array in Antarctica underneath the Amundsen-Scott Pole Station, formerly the Antarctic Muon and Neutrino Detector Array (AMANDA), but now officially a part of the IceCube Neutrino Observatory array. It consists of digital optical modules (DOMs), each containing one photomultiplier tube (PMT), sunk in the Antarctic ice cap at depths between 1500 to 1900 meters. AMANDA was originally composed of 677 optical modules mounted on 19 separate strings spread out in a circle roughly 200 meters in diameter. The newer IceCube array has 60 DOMs per string, with 86 strings deployed ranging in depths from 1450 m to 2450 m. There are 5160 DOMs in operation within the IceCube Neutrino Observatory. Each string was placed in the ice by first drilling holes with a hot water hose, lowering the cable string and attached optical modules into the hole, and then the water was allowed to refreeze around the string.

AMANDA detects neutrinos that pass through the Earth from the northern hemisphere and then react just as they are leaving upwards through the Antarctic ice. A neutrino collides with nuclei of oxygen or hydrogen atoms contained in the surrounding water ice, producing a muon and a hadronic shower. The optical modules detect the Čerenkov radiation produced by these particles, and by analysis of the timing and location of when and where photons strike the PMTs, the direction of the original neutrino can be determined with a spatial resolution of approximately 2 degrees.

[42] On November 12, 2001, the Super-Kamiokande suffered a severe setback when one of the PMTs imploded and caused a shock wave in the water that subsequently led to a chain reaction and implosion of over 7000 of the PMTs. The accident occurred when the water tank was being refilled after routine maintenance. The detector has been rebuilt and is back in operation.

The IceTop detector array, which is a surface array above IceCube arranged to detect neutrino air showers, is composed of an additional 320 optical sensors. The main goal of the IceCube experiment is to detect neutrinos in the energy range from 10^{11} eV to about 10^{21} eV.

An additional array called the Deep Core Low-Energy Extension, part of the IceCube Neutrino Observatory, is located in the overall IceCube array at depths between 1760 m and 2450 m. The array location was chosen for the clarity of the ice at those depths. The Deep Core array is targeted at measuring neutrinos with energy below 100 GeV and is focused on identifying and characterizing extra-solar sources of neutrinos. Compared to other large underground neutrino detectors consisting of large water tanks and hundreds of PMTs, the IceCube is capable of looking at higher energy neutrinos because it is not limited in volume. However, accuracy is compromised because the PMTs are spaced further apart and the conditions of the Antarctic ice are not controllable. Traditional neutrino observatories, such as the former Sudbury Neutrino Observatory or the Super-Kamiokande Neutrino Observatory, were designed to provide greater detail about neutrinos emanating from the Sun or generated in the Earth's atmosphere. However, higher neutrino energies in the spectrum should be dominated by neutrinos from sources external to our solar system.

PROBLEMS

1. Prove the result of Eq. (19.8) from Eq. (19.7).

2. Derive the result of Eq. (19.15) beginning from Eq. (19.13).

3. Both scintillators and TLDs emit photons from radiation absorption, and the phenomenon is used to measure radiation. Explain the basic difference between these two types of detectors. Why are electron traps preferred in TLDs but not in scintillators?

4. Consider an extension to the simple model of single-trap level TLD discussed in Sec. 19.1.1. Assume the traps have a continuous distribution of energies $N_{te}(E_t)$. Derive an expression for the glow curve from such a TLD analogous to that of Eq. (19.10) for multiple discrete trap levels.

5. An OSL has decay constant $\tau = 6$ ms and $\upsilon = 1\ \text{s}^{-1}$. Given a duty cycle of 10%, determine the fraction of measured light from an OSL measurement if (a) $\tau = 30$ ms and (b) if $\tau = 3$ ms. Assume $P_r^*(0) = 0$.

6. Discuss the many advantages and disadvantages of a TLD versus an OSLD.

7. Why is the logarithm of the *transmitted* intensity through photographic film used instead of simply the intensity to characterize the response of film to light?

8. What is the critical angle for a track etch film where $v_T = 2v_G$?

9. Quartz is perpendicularly irradiated with 5.5 MeV alpha particles with average range of 25 microns. The track is then etched in a dilute solution of hydrofluoric acid. Given an etch rate of 50 nanometers per minute for a general undamaged rate, with the damaged rate being 3 times the undamaged rate, what is the diameter of the track etch after 30 minutes? What is the track length?

10. Derive Eq. (19.78) from Eq. (19.76).

11. Consider the simplified cryogenic calorimeter discussed in Sec. 19.4.2. Calculate and plot the output response produced by a series of impulse inputs, i.e., $P_{in}(t) = \sum_{i=1}^{N} E\delta(t - t_i)$ where $t_i = (i-1)\tau_F/2$.

12. What is the minimum electron energy required to produce Čerenkov radiation in flint glass? Compare this energy to the minimum required energy to produce Čerenkov radiation in pure water.

13. Based on Eq. (19.92), show that the number of Čerenkov photons emitted per unit path length of charged-particle travel and per unit frequency is independent of frequency and is given by

$$\frac{d^2N}{dx\,d\nu} = 2\pi\alpha z^2\left(1 - \frac{1}{\beta^2 n^2}\right).$$

Show that integration of this result from frequency ν_1 to $\nu_2 > \nu_1$ (corresponding to wavelengths λ_1 and λ_2) to obtain the number of photons emitted between these two frequencies is the same as that given by Eq. (19.93).

14. Equation (19.92) suggests that as $\lambda \to \infty$ an infinite number of Čerenkov photons which have an infinite amount of energy are emitted. Clearly this cannot be the case. What is the explanation for this false inference?

15. Derive Eq. (19.96) from Eq. (4.74).

16. Gamma rays of various energies irradiate a translucent material and Čerenkov radiation is observed when the gamma rays have an energy greater than 1.6 MeV. What is the index of refraction for the material?

Chapter 20

Radiation Measurements and Spectroscopy

Experimental confirmation of a prediction is merely a measurement.
An experiment disproving a prediction is a discovery.

Enrico Fermi

In this book many detectors have been described that respond not only to the presence of radiation but also have a response that depends upon the energy of the radiation. Unfortunately, the energy response of such spectrometers is generally not directly proportional to the energy of the incident radiation. Consequently, the output from such detectors must first be analyzed or unfolded to obtain information about the true nature of the radiation energy emitted by a source.

By far the most frequently used energy spectrometers are those used to obtain information about x-ray and gamma-ray sources. In this chapter, methods of analyzing gamma-ray spectra obtained from detectors capable of energy discrimination are discussed. However, the methods used for gamma-ray spectroscopy are somewhat general and can also be applied to spectroscopy of other types of radiation. Thus, also included in this chapter are some basic aspects of charged-particle spectroscopy. Not included here are energy spectroscopic methods for neutrons, a topic discussed earlier in Chapter 18 on neutron detectors.

The general objective of spectroscopy is to obtain, at a minimum, the qualitative identification of the source (e.g., source energies or the radionuclides present). However, most spectroscopy applications also seek quantitative information such as the strengths of the sources or the concentrations of the radionuclides in a source. Several different methods for qualitative and quantitative analyses are summarized here and illustrative examples are provided.

20.1 Introduction

Gamma rays and x rays are photons of electromagnetic radiation that are capable of producing ionization through their interactions with ambient atoms. Technically, x rays differ from gamma rays in their source of origin but, for practical purposes, this nuance is irrelevant and photon spectra can be analyzed by the same methods for both x rays or gamma rays. As a practical matter, photons of energy less than about 10 keV are difficult to detect because they are easily absorbed by the detector housing or source material itself. The concepts that are discussed here can be applied, in principle, to spectra from photons of energy less than 10 keV and also to spectra generated by other particles, such as electrons. For instance x-ray photoelectron spectroscopy (XPS) and electron scattering for chemical analysis (ESCA) lead to electron spectra that can be analyzed by the methods discussed here for photons. Thus, it is understood that reference to gamma-ray spectroscopy is an oversimplification and many of the methods discussed here can be applied to spectra generated by x rays, gamma rays, or other types of radiation.

Gamma-ray spectroscopy is a general area of study within which spectra are analyzed in order to determine qualitative and, if possible, quantitative information about a sample under investigation. Spectra generally refer to collections of data for which the independent variable is the channel number (or a related quantity such as momentum, energy, or wavelength) and the dependent variable is a detector response that depends on the independent variable. Spectra are generated in many radiation measurement techniques, such as energy-dispersive x-ray fluorescence (EDXRF), neutron activation analysis (NAA), prompt-capture gamma-ray neutron activation analysis (PGNAA), electron photoelectron spectroscopy (XPS), and general counting of unknown radioactive sources. Often, spectroscopy is directed at the quantitative objective of identifying concentrations of specific elements or isotopes (henceforth the generic term "nuclides" is used) that are present in samples, but it also can be employed in a qualitative manner to identify whether specific gamma-emitting nuclides, such as those in special nuclear materials, are present in samples.

In general, a sample to be analyzed emits photons whose energies are characteristic of the nuclides present in the sample. The emitted photons may arise from excitation from an external energy source or the sample may emit these photons naturally. A careful spectroscopic investigation generally seeks to determine either the energies emitted and their intensities or the nuclides present and their concentrations. In previous chapters on radiation detectors, mainly Chapters 13, 14, and 16–18, examples of radiation measurements with specific detector materials and configurations have been presented, and the reader is directed to those chapters for particular detector applications applied to radiation measurements and spectroscopy. For example, the performance of HPGe detectors is described in Sec. 16.4.2. However, there are measurement and spectroscopy methods that can be generally applied to most spectrometers. In this chapter, attention is given to photon spectra that are generated from samples interrogated by any of a number of means, active or passive, to determine information about the constituents of the sample.

20.2 Basic Concepts

Various photon detectors can provide responses that are proportional to the energy deposited in the detector. These include proportional counters, scintillation detectors, and semiconductor detectors. Regardless of the detector, a voltage pulse is created whose amplitude h, generally called the *pulse height*, is a function of the energy deposited E_d in the detector, i.e.,

$$h = f(E_d), \tag{20.1}$$

where f is some function. For many detectors, f is linear and

$$h = \alpha + \beta E_d, \tag{20.2}$$

where α and β are constants unique to a detector. However, scintillation detectors, in particular, can exhibit non-linearities, especially at low photon energies (see Sec. 13.2.2), and this non-linearity should be taken into account. (Linearity of a detector is often expressed in terms of the pulse height per unit energy as a function of the deposition energy, a quantity which is constant for a linear detector.) In any event, a good spectroscopist should know f, the functional relationship between pulse height and deposited energy, for any spectroscopic detector used.

In gamma-spectroscopy, the pulse height h is measured and the deposited energy E_d is obtained by inversion of Eq. (20.1), namely

$$E_d = f^{-1}(h), \tag{20.3}$$

or, if the spectrometer is linear, then

$$E_d = \frac{h - \alpha}{\beta}. \tag{20.4}$$

Moreover, the pulse heights produced by repeated deposition of energy E_d in a detector are not exactly the same; rather, they are distributed about a mean value $h_0 = f(E_d)$ by some kernel $g(h|E_d)$ such that $g(h|E_d)dh$ is the probability an event that deposits energy E_d in the detector results in a pulse with an amplitude in dh about h. In gamma-ray spectroscopy, this *spreading* kernel has a shape similar to a Gaussian shape although, in practice, it is usually skewed slightly towards lower amplitudes as a consequence of different collection times of charge carriers produced in different regions of the detector and the different amount of recombination and trapping they experience as they are collected. Shallow angle Compton scattering also contributes slightly to this asymmetry. An example of this amplitude kernel for a HPGe detector is shown in Fig. 20.1. In effect, the detector systems that produce the voltage pulses operate on the energy deposited E_d with an energy kernel $z(E_d, E')$ that transforms E_d into a range of "apparent" energies E', which are centered on E_d. The resolution of a spectrometer is determined by the degree to which pulse amplitudes are spread out around h_0 or around E_d and is quantified by the full width at half maximum (FWHM) either as a percent or in energy units.

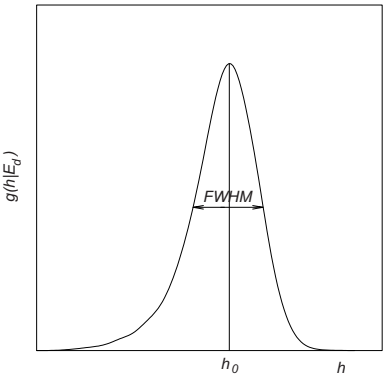

Figure 20.1. A pulse-height spreading kernel for a HPGe detector as measured for the 1173-keV ^{60}Co gamma ray [IEEE-325 1996]. Note the peak is not quite symmetric about the centroid $h_{\max}$.

Often the amplitude spreading kernel is approximated by the Gaussian probability distribution

$$g(h|h_0, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} \exp[-(h - h_0)^2/(2\sigma^2)], \tag{20.5}$$

where h_0 is the mean value or centroid and σ is the standard deviation. The peak value of the Gaussian PDF occurs at the centroid and is given by $g_{max} = 1/(\sqrt{2\pi}\sigma)$. As discussed in Sec. 6.8 the FWHM for a Gaussian is FWHM $= 2\sqrt{2\ln 2}\sigma \simeq 2.355\sigma$.

It is worth noting that the energy resolution of semiconductor detectors is, in general, significantly better than that for scintillation detectors or proportional counters. McGregor [2008] gives a good comparative description of the resolution of various detector types. Each type of detector has its advantages and disadvantages. The chapters in this book on the various detector types provide useful information on the characteristics of each type of detector.

The pulse heights are scaled to be within a finite interval $[h_{min}, h_{max}]$. Typically, these limits are $h_{min} = 0$ and $h_{max} = 10$ V. In any case, the variables E_d and h are continuous variables. Whatever the pulse height limits are, the response of a detector is typically binned into discrete "channels." If n denotes an individual discrete (integral) channel number and N is the total number of channels, then the channel width is

$$\Delta = \frac{h_{max} - h_{min}}{N}.$$

The channel numbers are related to the detected magnitudes of the voltage pulses (pulse heights) by the relations

$$\begin{aligned} n &= 1, \text{ if } h_{min} < h \le h_{min} + \Delta \\ &= 2, \text{ if } h_{min} + \Delta < h \le h_{min} + 2\Delta \\ &\vdots \\ &= N, \text{ if } h_{min} + (N-1)\Delta < h \le h_{min} + N\Delta. \end{aligned} \tag{20.6}$$

Thus, the measured continuous pulse heights are converted into discrete channels and each pulse registers a count in one and only one channel. NIM multichannel analyzer systems confine voltage signals or pulse heights to be within 0–10 volts. Hence, a binary system may be subdivided with 2^N voltage bins over the 10-volt range. For $N = 10$, there are 1024 bins, or *channels*, over the 10 volt range having, in this case, 9.8×10^{-3} volts per channel. Typical spectroscopic systems now often operate with $N = 13$ where $2^{13} = 8,192$ channels, with some having $N = 14$, or 16,384 channels.

Although there are a finite number of discrete channels, corresponding to the pulse-height intervals specified in Eq. (20.6), the peak centroid can occur at any continuous value of h. Thus, it is customary to specify a linear relationship between the continuous values of h and a continuous channel number $\tilde{n}$, given by

$$\tilde{n} = \frac{h - h_{min}}{\Delta}, \tag{20.7}$$

which varies continuously between 0 and N. Henceforth, the term channel number is used to mean either the discrete integer channel number n or the continuous channel number $\tilde{n}$; the context can be used to infer the intent.[1]

20.3 Detector Response Models

Consider a source that emits photons at a rate with some energy distribution $s(E)$ and a spectrometer that detects the photons and produces a pulse-height spectrum. The basic spectroscopic relationship in its continuous form can be written [Dunn and McGregor 2012],

$$r(h) = \frac{dR(h)}{dh} = \int_0^\infty s(E)\mathcal{R}(h|E)dE + b(h), \quad h \in [h_{min}, h_{max}], \tag{20.8}$$

where

- $r(h)$ is the detector response such that $r(h)dh$ is the expected number of counts within dh about h per unit time.
- $s(E)$ is the source strength, in photons per unit time, such that $s(E)dE$ is the number of source photons emitted within dE about E.
- $\mathcal{R}(h|E)$ is the detector response kernel such that $\mathcal{R}(h|E)dh$ gives the probability that a particle of energy E interacting in the detector produces a pulse whose height is within dh about h. Here $\mathcal{R}(h|E) = p(E, E_d)g(h|E_d)$ where $p(E, E_d)dE_d$ is the probability that is a source gamma ray of energy E interacts in the detector and deposits an energy in dE_d about E_d in the detector.
- $b(h)$ is the background count rate such that $b(h)dh$ is the expected number of counts within dh about h, per unit time, that are due to background radiation.

Note that $R(h) = \int_0^h r(h')dh'$ is the cumulative number of counts per unit time due to pulses whose heights are less than h and that $R(h_2) - R(h_1) = \int_{h_1}^{h_2} r(h)dh$ is the total number of counts, per unit time, whose pulse heights are between h_1 and h_2. Note also that $\mathcal{R}(h|E)dh$ accounts for the probability of transport of source photons to and within the detector, deposition of energy E_d in the detector, and spreading of the deposited energy into an apparent energy E' that produces a pulse whose pulse height is within dh about h.

[1] In this book n is also used as a dependent variable that represents a net count rate $n = c - b$ where c and b are the source and background count rates, respectively. Likewise N refers sometimes to the total net counts, the number of spectral channels or the number density of some particle. Again the context should make clear the meaning of n and N.

In general, a source can emit photons at J discrete energies and also over a continuum of energies. For such sources

$$s(E) = \sum_{j=1}^{J} s_j \delta(E - E_j) + s_c(E), \tag{20.9}$$

where s_j is the emission rate of photons of energy E_j from the source, $\delta(E - E_j)$ is the Dirac delta function, and $s_c(E)$ is the source emission rate of the photons with continuum of energies such that $s_c(E)dE$ is the expected number of photons emitted within dE about E per unit time. For a detector that sorts counts into discrete channels, one can substitute Eq. (20.9) into Eq. (20.8), integrate over each channel width, and write the discrete form of the pulse height spectrum in the form

$$c(n) = \sum_{j=1}^{J} s_j \mathcal{R}_n(E_j) + \int_0^\infty s_c(E)\mathcal{R}_n(E)dE + b_n, \quad n = 1, 2, \ldots, N, \tag{20.10}$$

where $c(n)$ is the number of counts recorded in channel n (per unit time), b_n is the expected number of counts recorded in channel n (per unit time) from background radiation, and $\mathcal{R}_n(E)$ is the *detector response function* that is the probability that a particle of initial energy E that is emitted by the source produces a count within the nth channel. Here

$$\mathcal{R}_n(E) = \int_{(n-1)\Delta}^{n\Delta} \mathcal{R}(h|E)\, dh.$$

In general, spectra are accumulated over a counting time T, in order to increase the number of recorded counts and, hence, improve the statistical precision of the measurements. In this chapter, it is assumed that the source strength $S(E)$ is constant in time. If the photon source is from the decay of a radionuclide, then the measurement time T must be much less than the half-life of the radionuclide; otherwise, corrections must be made to correct for the decrease in photon emission rate as was done in the discussion of foil activation in Sec. 17.7.2.

The total counts obtained over counting time T per channel can be obtained by integrating Eq. (20.10) over the counting time. The continuum source term can be due to photons emitted from the source over a continuum of energies and/or to photons emitted at discrete energies from the source that scatter into the detector from material around the detector. Because the primary objective of spectroscopy is to find the E_j and s_j, for $j = 1, 2, \ldots, J$, it is customary to combine the continuum and background terms into a generalized background. Doing so and integrating over the counting time T, one obtains

$$\boxed{C(n) = \sum_{j=1}^{J} S_j \mathcal{R}_n(E_j) + B(n), \quad n = 1, 2, \ldots, N,} \tag{20.11}$$

where $C(n) \equiv C_n = c(n)T$ is the detector response in channel n, $S_j = s_j T$, and

$$B(n) = \left[\int_0^\infty s_c(E)\mathcal{R}_n(E)dE + b(n)\right] T. \tag{20.12}$$

A plot of $C(n)$ versus n is called a *pulse height spectrum*. Summation over any range of channels gives the total counts within those channels.

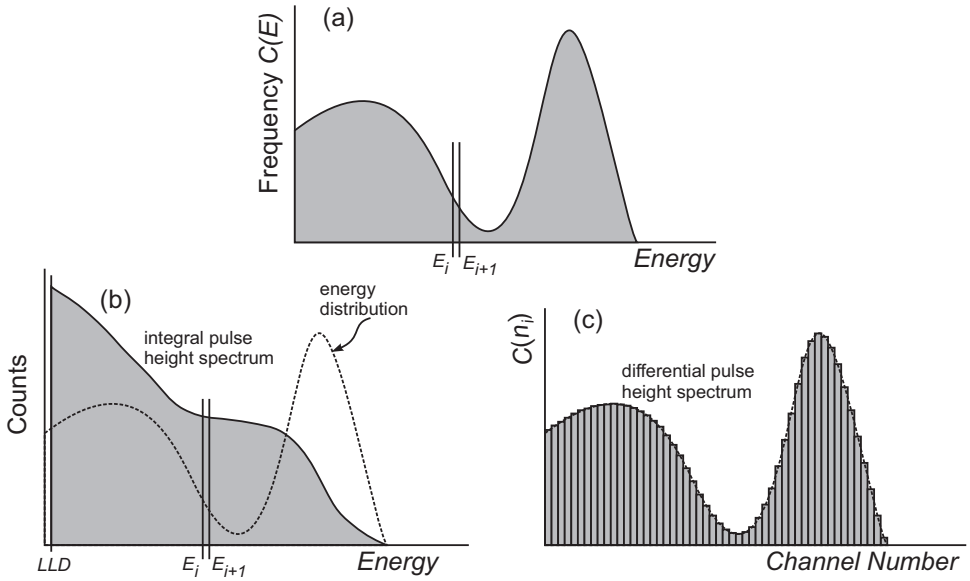

Figure 20.2. Shown in (a) is the continuous energy distribution recorded with a radiation spectrometer. If a counter is connected to the detector, shown in (b) is the resulting count rate as a function of the lower level discriminator setting, called the integral pulse height spectrum, superimposed on the radiation energy distribution. Shown in (c) is the resulting discrete differential pulse height spectrum from (b).

Equation (20.11) describes an inverse problem, in which the specific E_j and $S_j, j = 1, 2, \ldots, J$ are sought given $J \leq N$ measured pulse-height responses $C(n)$. The generalized background B_n is typically not known explicitly and, thus, further complicates the inversion process. There are different methods that can be used to approach this inverse problem and the number M of channels, $M \leq N$, used depends on the method chosen. Because most spectrometers have thousands of channels, most spectroscopy inverse problems are over-determined in the sense that there are considerably more responses available than unknowns.

It is noted that a variant of this inverse problem often is posed in terms of the $k = 1, 2, \ldots, K$ nuclides present in a sample, each of which can emit photons at one or more discrete energies. Rather than look for the J discrete energies and their intensities, one looks for the K nuclides and their concentrations. The form of this inverse problem is similar to the form of Eq. (20.11) and is defined later more precisely by Eq. (20.95).

20.4 Gamma-Ray Spectroscopy

Suppose that the energy deposition in the detector is that shown in Fig. 20.2. A simple counter records events in the detector that produced a signal exceeding the lower level discriminator (LLD). In the hypothetical case with no electronic noise or background, *all* events interacting in the detector within measurement time T are recorded if the LLD is set to zero. As the LLD is increased, those lower energy events in Fig. 20.2(a) are excluded from the count rate, and the total number of recorded counts within time T decreases. This function can be plotted as shown in Fig. 20.2(b), where the total integrated counts above the energy equivalent LLD setting are plotted as a function of LLD setting. This plot is called the *integral pulse height spectrum*. There are notable features in the integral pulse height curve that can be interpreted as follows. Flatter features indicate energy regions where few events appear, usually from valleys in the energy spectrum. Steeper features indicate energy regions where many counts are located and produce a large change in counts as a function of LLD, often caused by energy maxima or peaks in the energy spectrum.

Although an experienced spectroscopist might be able to interpret the data of an integral pulse height spectrum, it is usually the derivative of this spectrum that is used in spectroscopy, mainly because interpretation is more straightforward. Suppose the energy spectrum of Fig. 20.2(b) is divided into n number of channels, each channel having width of ΔE, then the total number of channels describing the spectrum is

$$n = (E_{max} - E_0)/\Delta E, \tag{20.13}$$

where E_{max} is the highest energy recorded as a function of channel number and E_0 is an experimentally determined *zero offset*. Ideally, the value of E_0 is zero, but in practice usually is not. Suppose that each energy bin is defined by the energies between two adjacent boundaries, i.e., by $E_{i+1} - E_i = \Delta E$. Then the number of counts within each boundary, or channel n, is described by

$$C_i = \int_0^{\infty} C(E)dE - \int_0^{E_i} C(E)dE - \int_{E_{i+1}}^{\infty} C(E)dE = \int_{E_i}^{E_{i+1}} C(E)dE. \tag{20.14}$$

This result is the same as that found by taking the difference between the counts at E_i and E_{i+1} in Fig. 20.2(b). If this change in the recorded counts from the integral pulse height spectrum is plotted as a function of the channel number (or energy), then a discrete *differential pulse height spectrum* is produced,

$$C(n_i) = \frac{-(C_{E_{i+1}} - C_{E_i})}{E_{i+1} - E_i} = \frac{-\Delta\text{Counts}}{\Delta E}, \tag{20.15}$$

as depicted in Fig. 20.2(c).

Figure 20.2(c) is a histogram called the *differential pulse height spectrum*, which mimics the energy distribution seen by the detector, i.e., that of Fig. 20.2(a). For a good spectrometer, the measured energy distribution is very similar to the actual distribution of energy deposited in the detector. However, for detectors that have non-linear effects, recombination, or charge carrier trapping problems, the energy deposited in the detector and the output signal are not necessarily proportional. Although a spectrum such as that depicted in Fig. 20.2(c) can be developed with a single channel analyzer (Sec. 2.5.6) by sequentially moving the energy window ΔE from zero up to 10 volts, it is a multichannel analyzer that is generally used to display the energy spectrum (Sec. 2.5.13).

20.4.1 Gamma-Ray and X-Ray Spectral Features

Already discussed in Chapter 4 are the various ways that photons interact in a material and, for the present application, in radiation detectors. The three main mechanisms are the photoelectric interaction, Compton scattering, and pair production. Although Raleigh (coherent) scattering can be significant at low energies, the photoelectric effect dominates (in the same energy region), usually by more than an order of magnitude. Consequently, Rayleigh scattering is usually ignored in practical gamma-ray spectroscopy. Likewise, binding effects become apparent only at low energies and are usually ignored.

Photoelectric Effect Features

Photons of relatively low energy (less than a few hundreds of keV) interact with the ambient medium mostly through photoelectric absorption in which some of the photon energy is transferred to a photoelectron to give it an energy

$$T_{pe} = E_\gamma - E_b, \tag{20.16}$$

where E_b is the binding energy of the electron which depends on its electron shell of origin. The liberated photoelectron moves through the detector medium causing more ionization through Coulombic interactions. Ultimately, an average number of electrons per unit energy is liberated (or excited) in the detector medium.

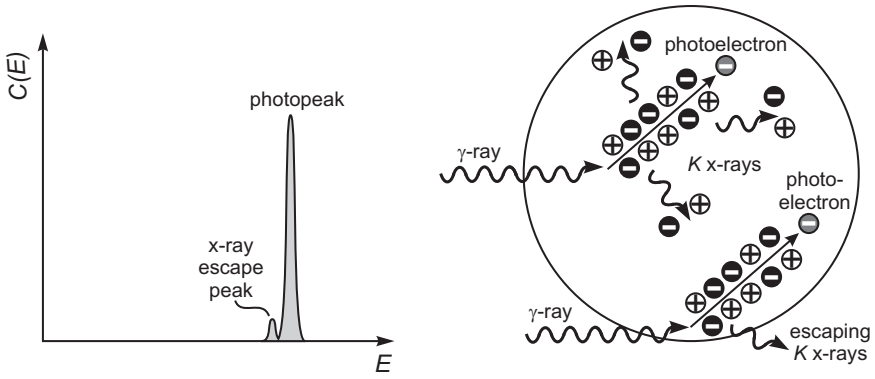

Figure 20.3. A photoelectron absorbs the full gamma-ray energy, minus the binding energy ($h\nu - E_b$). This photoelectron produces free charges in the detector. Through electron deexcitation, the binding energy is recovered by the emission and reabsorption of characteristic x rays. Some x rays emitted near surfaces can escape the detector. The resulting common spectral features are shown.

For scintillators, the important quantity is the average number of excited electrons that produce fluorescent light. For gas detectors the important quantity is the average energy required to produce an electron-ion pair. Similar to gas detectors, in a semiconductor it is the average energy required to produce an electron-hole pair that is important. Ultimately, the number of information carriers is a function of the average energy w required to produce the carriers and the absorbed photon energy. The effect is observed as a *photopeak* in the differential pulse height spectrum (depicted in Fig. 20.3).

The binding energy E_b is recovered as electrons fall into lower energy levels. For instance, an ejected K shell electron leaves an empty state, which can be filled by an electron falling from the L shell into the K shell, producing a characteristic K_α x ray. The energy may also be recovered by the emission of an Auger electron. If the x ray is absorbed by a lower energy bound electron (L or M), it produces more ionization, and the energy is recovered. The same is true for M shell electrons falling into K or L states, producing either K_β or L_α x rays, respectively. If generated near the detector surface, it is possible that these characteristic x rays escape the detector, consequently causing the total deposited energy to be reduced by the characteristic x ray energy. The photopeak under such a circumstance forms at the initial photon energy less the x-ray energy, thereby creating an x ray escape peak as depicted in Fig. 20.3. This escape peak results primarily from K shell x rays escaping and not from the loss of L shell x rays because L shell x rays have much lower energies and are less likely to escape and, if they do escape, the lost energy usually blends with the main photopeak and is less noticeable. These x ray escape peaks are a function of the detector material, and appear mainly when (1) the detector is small so that a large fraction of the characteristic x rays can escape and (2) when the detector is made of high Z material so that the characteristic x rays have larger energies.

Compton Scattering Features

At higher photon energies, ranging between tens of keV up to several MeV, depending on the material, the Compton scattering effect becomes dominant compared to the photoelectric effect. The energy of a Compton scattered electron is

$$T_{cs} = \frac{E_\gamma^2(1 - \cos\theta_s)}{m_e c^2 + E_\gamma(1 - \cos\theta_s)}, \tag{20.17}$$

where θ is the photon scatter angle and $m_e c^2 = 511.0$ keV is the rest-mass energy equivalent of an electron. The scattered gamma rays have a continuum of energies from zero up to the maximum possible energy

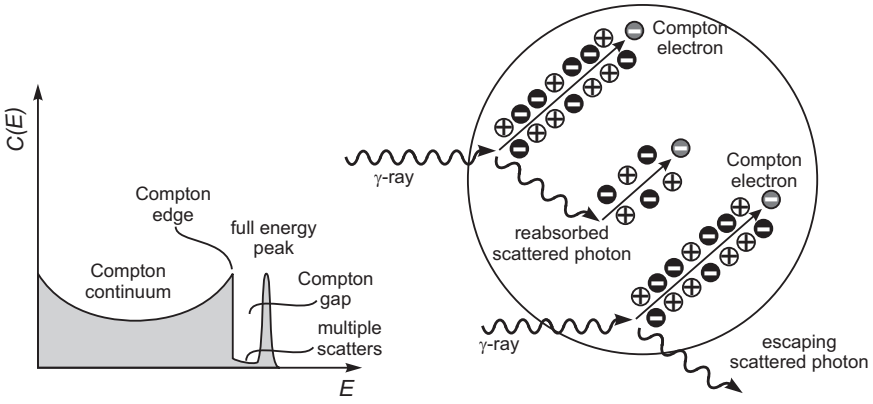

Figure 20.4. Compton scattered electrons produce free charges in the detector up to the maximum allowable energy transfer. If the Compton scattered photon is recaptured and full energy deposited, the energy adds to the full energy peak. If the scattered photon escapes the detector, the energy is added to the Compton continuum.

transfer to a Compton electron (for a single scatter at $\theta_s = \pi$), namely

$$T_{cs} = \frac{2E_\gamma^2}{m_e c^2 + 2E_\gamma}. \tag{20.18}$$

A simple example is the case in which there is a single Compton scatter and the scattered gamma ray escapes the detector. Under such a condition, the energy lost from the detector is given by Eq. (20.17). Consequently, the pulse height spectrum is a continuum of energies from zero up to the energy described by Eq. (20.18), termed the *Compton continuum* and is depicted in Fig. 20.4. The high energy limit of the Compton continuum is called the *Compton edge*. If a considerable fraction of photons are Compton scattered multiple times, ultimately terminating with photoelectric absorption, then the total initial photon energy is represented by the energy peak in the pulse height spectrum. Because more than one type of interaction contributed to the energy absorption, the proper term for this peak is the *full energy peak*. A gap appears between the full energy peak and the Compton edge, termed the *Compton gap*. Multiple Compton scatters that still result in some energy escaping the detector produce a small continuum in the Compton gap. Ultimately, the Compton continuum is more prominent in small detectors than large detectors, mainly because more Compton scattered photons escape the smaller detector.

Compton scattering of source photons in the surroundings and shielding of a detector can result in some of these scattered photons reaching the detector and being absorbed in it. Theoretically, this backscatter spectrum can have energies described by

$$E_{bs} = \frac{E_\gamma m_e c^2}{m_e c^2 + E_\gamma(1 - \cos\theta)}, \tag{20.19}$$

where θ is the scattering angle needed for the scattered photon to reach the detector. The minimum energy of these scattered photons that reach the detector occurs when $\theta = \pi$ and is

$$E_{bs} = \frac{E_\gamma m_e c^2}{m_e c^2 + 2E_\gamma}. \tag{20.20}$$

Recall from Sec. 4.4.2 the discussion on scatter angle probability and photon energy, where forward scattering becomes more probable with increasing gamma-ray energy. Hence, the differential backscatter cross section

actually decreases with higher gamma-ray energies (see Fig. 4.6). However, from Fig. 4.7, photons that scatter with angle greater than about 100° emerge with nearly the same energies.

In practice, for geometrical reasons, it is unlikely that forward scattering in the surroundings or shielding results in a significant number of scattered photons entering the detector. In fact, it is the larger scattering angles that are most likely to return to the detector, so that the backscattering spectrum typically increases at low energies in the pulse height spectrum. The effect is enhanced because low energy photons are more readily absorbed in a detector than are high energy photons. Further, from Fig. 4.7, the energies of backscattered photons are similar. A wide peak appears at the lower limit, called the *backscatter peak*, as depicted in Fig. 20.5. This backscatter peak is actually a continuum with a somewhat discernible maxima. Multiple scatters can cause the appearance of photon energies below the backscatter peak, but in practical spectroscopy, these energy additions are difficult to distinguish from the Compton continuum.

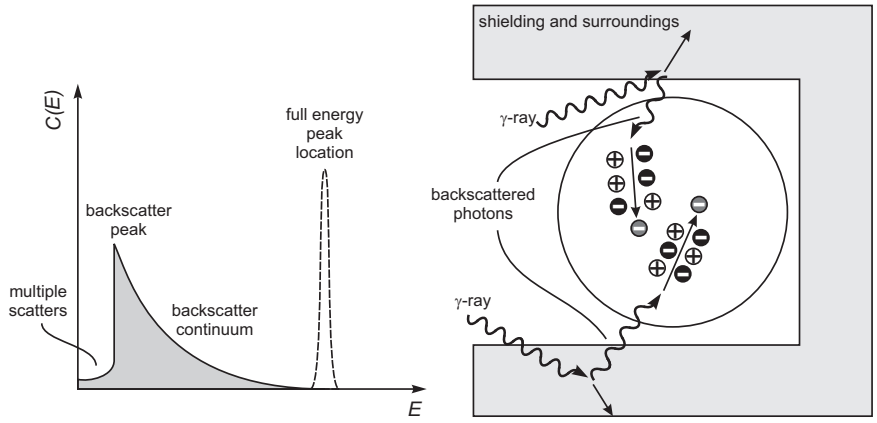

Figure 20.5. Gamma rays that are Compton scattered in the materials surrounding the detector may deposit energy in the detector. Consequently a backscatter spectrum appears.

Pair Production Features

If the gamma-ray energy is greater than 1.022 MeV, then pair production is possible. When this photon interaction occurs in a detector, 1.022 MeV of the photon energy is converted into the masses of the electron-positron pair and the remaining energy shared as kinetic energy between the two particles. The particles produce ionization in the detector just like photoelectrons and Compton electrons. After the electron loses almost all its initial energy, it is absorbed in the material and returns to an allowed state. However, when the positron comes to rest, it combines with an electron and annihilates, producing two 511-keV photons emitted in opposite directions to preserve the zero linear momentum condition. If both of the annihilation photons are reabsorbed in the detector, the initial gamma-ray energy is represented in the full energy peak. If multiple events result in one 511-keV annihilation photon escaping the detector, then an energy peak forms in the pulse height spectrum at $E_\gamma - 511$ keV, named a *single escape peak*. If multiple events result in both 511-keV annihilation photons escaping the detector, then an energy peak forms in the pulse height spectrum at $E_\gamma - 1.022$ MeV, named a *double escape peak*. Single and double escape peaks can be identified by (1) noticing that no Compton edge forms and (2) noting their energy location with respect to the full energy peak. Escape peaks are more prominent in small detectors than large detectors, mainly because a larger fraction of annihilation photons escape the smaller detector.

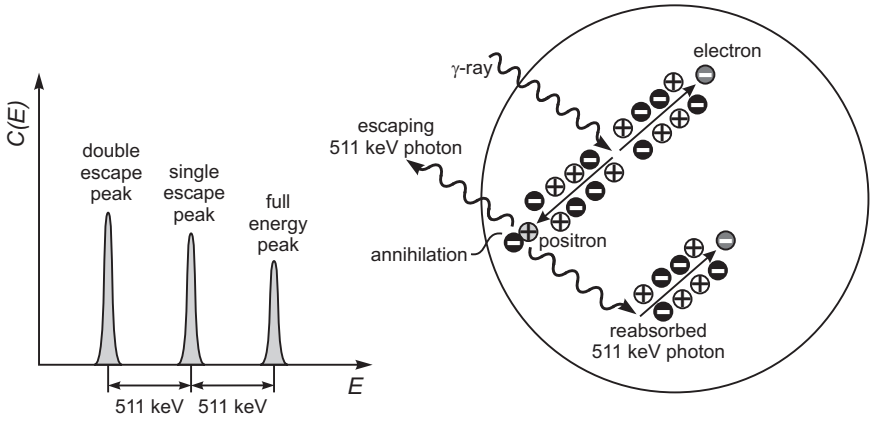

Figure 20.6. Gamma rays that undergo pair production produce energetic electron-positron pairs. These particles produce free charge in the detector. When the positron loses nearly all kinetic energy, it annihilates with an electron and emits two 511-keV photons in opposite directions. Spectral features form accordingly if these annihilation photons are reabsorbed, one escapes the detector, or if both escape the detector.

Pair Production and Fluorescence in the Surroundings

Pair production can also can occur in the shielding and surroundings, causing the emission of 511 keV annihilation photons that can enter the detector and add to the pulse height spectrum (Fig. 20.7). Because of this possibility of contamination, 511 keV annihilation photons are typically not used for efficiency calibration, but can still be used for energy calibration.

The shielding and surrounding material, when irradiated by energetic photons, can also fluoresce by the emission of characteristic x rays. These x rays appear in the pulse height spectrum at low energies, usually below 90 keV. Because lead is a common shielding material, several energy lines ranging from 72.8 keV to 87.3 keV may appear in the low energy portion of the pulse height spectrum. Unless low energy spectroscopy is required, usually these additional lines are of little consequence. However, directional shielding can be applied to reduce the appearance of these lines, usually realized by a layer of copper placed between the detector and lead shielding (as described further in Chapter 21).

Finally, bremsstrahlung fluorescence is generally present with gamma-ray detection. Many gamma-ray emitting radioisotopes also emit beta particles, which in turn emit bremsstrahlung as they slow down in a target material (Sec. 5.3.2). From Eq. (5.6), the energy intensity of bremsstrahlung increases with target Z and the electron energy. A low Z beta-particle filter between the radionuclide source and the detector can soften the bremsstrahlung spectrum. Also, photon interactions in the surroundings produce energetic electrons, and these energetic electrons radiate bremsstrahlung as they slow down. Sample emission distributions in lead are shown in Fig. 5.2. Although much of bremsstrahlung is self-absorbed in the shielding, some of it can still interact in the detector. Because bremsstrahlung is generally featureless, this form of fluorescent contamination increases the background but does not produce energy peaks. Regardless, the addition of bremsstrahlung does increase the total counts in the pulse height spectrum, generally in the lower energy channels, which can cause an overestimation of the gamma-ray flux.

Summary

To summarize, consider a radiation source that emits monoenergetic photons of energy E_o. A source photon that enters the detector may experience any of several outcomes, including the following:

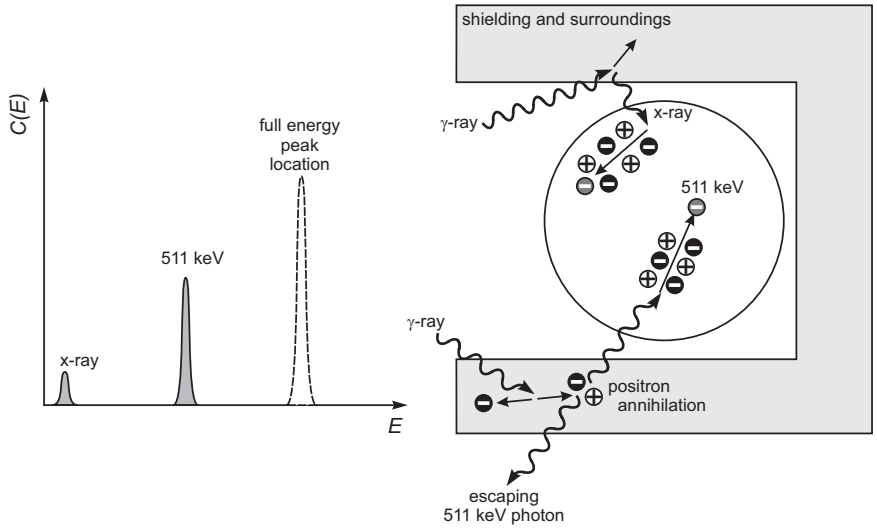

Figure 20.7. Gamma rays can also produce pair production in the surroundings. Consequently, 511 keV annihilation photons can enter the detector from outside sources. Energetic photons can also fluoresce the surroundings and the detector container to produce x-rays that can enter the detector.

1. It may be completely absorbed by photoelectric absorption, in which case the deposited energy is the photon energy, i.e., $E_d = E_o$.

2. It might undergo a sequence of one or more scatters within the detector and then be absorbed within the detector by photoelectric absorption, which again leads to $E_d = E_o$.

3. It might scatter one or more times in the detector and then escape with an energy E_r, which leads to a deposited energy of $E_d = E_o - E_r$.

4. If $E_o > 1.022$ MeV, it might undergo pair production in the detector, producing an electron-positron pair that usually leads to the production of two 0.511-MeV photons by positron annihilation.[2] If both annihilation photons deposit all of their energy in the detector, then $E_d = E_o$. If one of the annihilation photons escapes and the other is absorbed, the energy deposited is $E_d = E_o - 0.511$ MeV. If both annihilation photons escape the detector, the deposited energy is $E_d = E_o - 1.022$ MeV. If either or both annihilation photons scatter within the detector and then escape, an intermediate energy within the range $E_o - 1.022 < E_d < E_o$ is deposited.

5. It might not interact at all in the detector and so $E_d = 0$.

Note that outcomes 1 and 2 both contribute to a "full-energy" peak. Voltage pulses result whose pulse heights are distributed from zero up to a maximum determined by the energy E_d and the energy resolution of the detector. Thus a monoenergetic source produces a pulse-height spectrum that is distributed over the many channels. The features shown in Fig. 20.3 through Fig. 20.6 can be combined to produce the expected features that appear in a gamma-ray pulse height spectrum. Depicted in Fig. 20.8 are differential pulse height spectra for monoenergetic gamma rays with energies below and above 1.022 MeV.

[2]Positron annihilation occasionally takes place at higher than thermal energies. Consequently, annihilation photons of higher energies are (infrequently) produced.

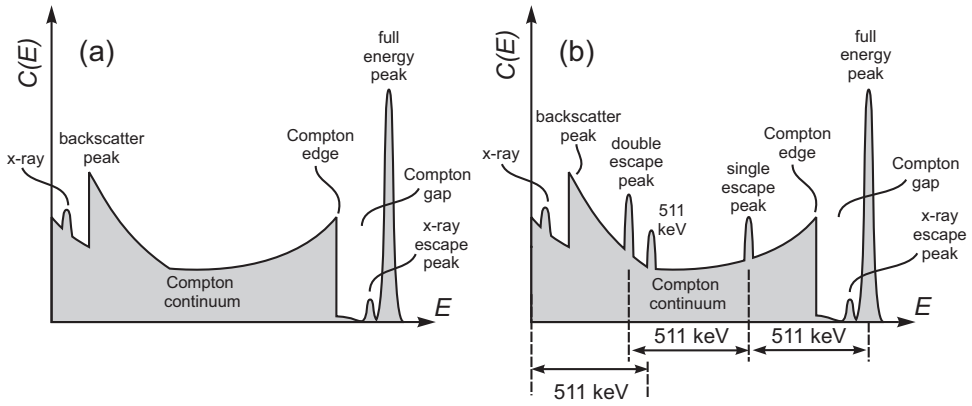

Figure 20.8. Composite pulse height spectra for monoenergetic gamma rays formed from the features shown in Fig. 20.3 - Fig. 20.6, with (a) $E_\gamma < 1.022$ MeV, and (b) with $E_\gamma > 1.022$ MeV.

An example pulse height spectrum obtained from a scintillation spectrometer exposed to the photons from a ^{22}Na source, which emits 1.28-MeV photons and 0.511-MeV annihilation photons, is shown in Fig. 20.9. The features in the spectrum, from right to left, include a full-energy peak centered about the channel corresponding to $E_1 = 1.28$ MeV, a Compton edge and a continuum extending from about channel 1250 downward, a full-energy peak due to 0.511-MeV annihilation photons, a Compton edge and Compton continuum for the annihilation photons, and a backscatter peak. The maximum amount of energy that a photon can give up in a Compton scatter occurs in a "backscatter" through an angle of π radians, and so the Compton edge occurs over those channels that represent Compton scatters in the detector through angles near π. Photons that are emitted by the source and backscatter (within either the source or the material behind the source) have energies that are near the energy given by Compton scatter through π radians. The backscatter peak in the spectrum of Fig. 20.9 is caused by source gamma rays that scatter, in or near the sample, through angles close to π and then deposit full energy in the detector. This peak typically has a FWHM that is larger than the FWHM of a full-energy peak for monoenergetic photons. The larger FWHM occurs because source photons can backscatter in or near the source over a range of angles near π radians and thus these scattered photons that reach the detector do not all have the same energy.

Summation Peaks

Other features that may appear in the pulse height spectrum are *sum peaks*, which are artifacts from two or more photons interacting nearly simultaneously (i.e., within the resolving time) in the detector. Sum peaks appear to be valid energies because they have many of the aforementioned features including Compton edges and Compton gaps. Unknown energy peaks appearing in a pulse height spectrum can be checked to determine if combinations of known energy emissions from the source sum to the unknown energy.

Given a source with multiple independent gamma-ray energy emissions E_i, each having intrinsic full energy peak absorption efficiency of ϵ_{pi}, the probability of N coincident photons leading to a full energy absorption is represented by

$$P_N = KW(0^\circ) \prod_i^N \Omega_{fi} \epsilon_{pi} B_i \tag{20.21}$$

where Ω_{fi} is the fractional solid angle for the source energy, B_i is the branching ratio (or frequency) of the emission, and K is a geometric correction for parallax and detector shape, and $W(0^\circ)$ is a factor included to account for the angular correlation between the coincident gamma rays [Heath 1964; Rose 1953]. Gamma-ray sources with multiple emissions per decay, such as ^{60}Co and ^{133}Ba, can be expected to develop sum peaks

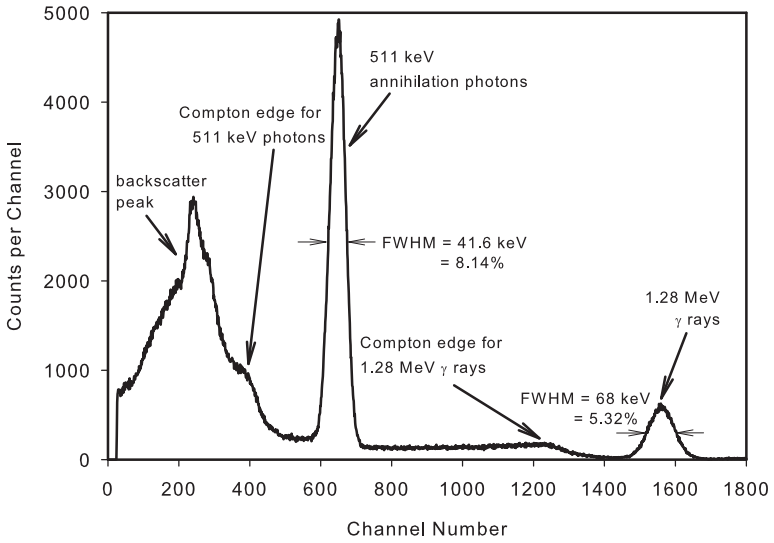

Figure 20.9. The pulse height spectrum obtained by a NaI:Tl scintillation detector exposed to a ^{22}Na source. The source emits photons at 0.511 MeV, as a result of positron annihilations, and at 1.28 MeV, emitted as the product ^{22}Na transitions from the excited state to the ground state [McGregor 2008].

in the pulse height spectrum. Events of this type, in which two or more photons are released from a single decay and are coincident in the detector, are often called *true coincidences*. The expected number of counts in the sum peak are determined by multiplying the total source emission At by P_N, where A is the source activity and t is the counting time.

For geometries with a single point source and detector, the value of Ω_{fi} is the same for all E_i. Consider those cases in which there are only two simultaneous gamma-ray emissions such as occurs, for instance, with ^{60}Co. Then for a point source and single detector Eq. (20.21) becomes

$$P_2 = KW(0^\circ)\Omega_f^2\epsilon_1\epsilon_2 B_1 B_2. \tag{20.22}$$

The parallax correction factor K approaches unity as the source-to-detector becomes large. Also, it is often assumed that the emission directions of the different photons are uncorrelated so that $W(0^\circ) = 1$.[3] Under these conditions the true coincidence sum rate for two simultaneous emissions reduces to the often used expression

$$R_{\text{true}} = A\Omega_f^2\epsilon_1\epsilon_2 B_1 B_2. \tag{20.23}$$

From Eqs. (20.21) and (20.23) it is clear that decreasing the fractional solid angle Ω_f reduces the formation of sum peaks more effectively than reducing counts in the real energy peaks because coincidences are a function of Ω_f^N while true energy peaks are proportional only to Ω_f.

Sum peaks can also appear for high count rates, when two gamma rays from independent radioactive decays are coincident within the processing time of the detection system. Recall from the discussion on dead time coincidences in Sec. 7.3.2 that a random sequence of incoming pulses with average interaction rate $\overline{r}$. The average number of interactions within time t is simply $\overline{r}t$. The Poisson distribution of Eq. (7.26) describes the probability of multiple interactions in the detector within some time period t from a single

[3]This assumption of course does not pertain to positron annihilation photons, which are emitted in opposite directions.

radiation source, namely,

$$\mathcal{P}(n|\mu) = \frac{(\overline{r}t)^n}{n!}e^{-\overline{r}t}, \tag{20.24}$$

where n is the number of interactions. If t_r represents the pulse resolving time of the detector system, and should these emissions enter a single detector within the pulse processing time, then they can produce a coincidence sum peak. These events are sometimes referred to as *accidental coincidences*, mainly because of the stochastic nature of radioactive decay allows such events to randomly occur by accident from unrelated radioactive disintegrations. For a monoenergetic source, where the efficiencies, branching ratios, and solid angles are the same, from Eq. (7.26) the probability that *only one* gamma ray interacts within the resolving time of the same detector t_r reduces to

$$P = \mathcal{P}(1|\mu) = \overline{r}t_r e^{-\overline{r}t_r}. \tag{20.25}$$

For small $\overline{r}t \ll 1$, Eq. (20.25) reduces to

$$P = \overline{r}t_r e^{-\overline{r}t_r} \simeq \overline{r}t_r(1 - \overline{r}t_r) \simeq \overline{r}t_r = \mu, \tag{20.26}$$

which is also the average number of photons interacting in the detector within time t_r. Suppose that an initial gamma ray event occurs in the detector at $t = 0$, from gamma rays interacting at an average rate of $\overline{r}$. The rate of accidental coincidences, therefore, is the product of the average interaction rate $\overline{r}$ and the average number of photons interacting within time t_r

$$R_{acc} = (\overline{r})(\mu) = \overline{r}^2 t_r. \tag{20.27}$$

Equation 20.27 is the widely used expression for accidental coincidences from a monoenergetic source [Vincent 1973].

There is a (smaller) possibility that two or more photons interact within the resolving time, which would also reduce counts in the ideal spectrum without coincident effects. The probability that at least one event occurs in time t_r is given by

$$P = 1 - \mathcal{P}(0|\mu) = 1 - e^{-\overline{r}t_r}, \tag{20.28}$$

which yields a total accidental coincidence rate of

$$R_{acc} = \overline{r}(1 - e^{-\overline{r}t_r}). \tag{20.29}$$

By adjusting (reducing) either $\overline{r}$ or t_r, the rate of accidental coincidences can be reduced.

Shown in Fig. 20.10 is a spectrum of ^{60}Co emissions taken with an HPGe detector. The features include a true coincidence sum peak from the two gamma-ray emissions along with two chance coincidence sum peaks of the two emissions. Note that the counts in the 1173.2 keV + 1332.5 keV sum peak may be from both true and chance coincidences, which are difficult to discern without some added analysis (e.g., with measurements taken at different distances). Also shown in Fig. 20.10 are other features discussed in the previous sections, including two Compton continua along with the coincidence sum Compton continua, single and double escape peaks, 511-keV annihilation photons from the surroundings, Pb x rays, background from ^{40}K, and a backscatter peak.

A consequence of summation peaks is their ultimate reduction in the counts represented in the actual full energy peaks. Consider the sum peaks of Fig. 20.10. For each count in the sum peak formed from 1173.2 keV + 1332.5 keV gamma rays, one gamma ray each is removed from their corresponding real full energy peaks. Also, the accidental sum peaks remove two gamma rays each from their corresponding full energy peaks. One might correct the problem by simply adding the counts tallied in the sum peaks to the appropriate full

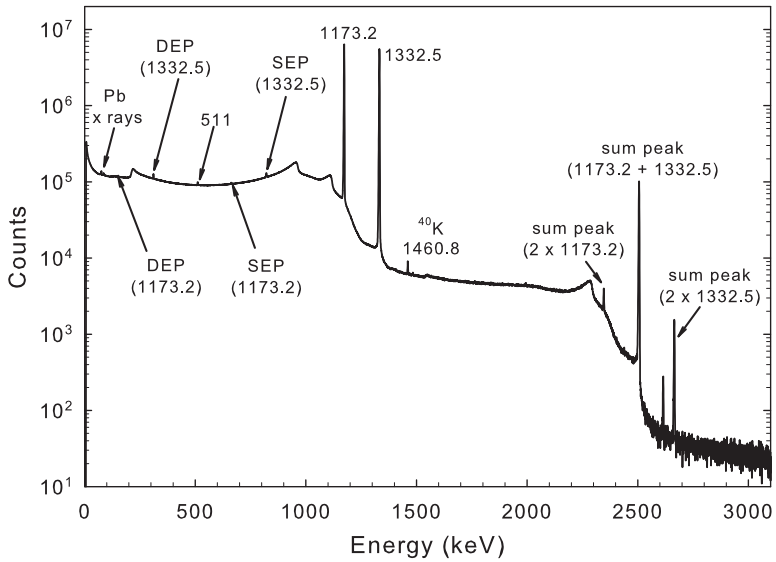

Figure 20.10. A gamma-ray spectrum of ^{60}Co taken with an HPGe detector. Included in the features are three sum peaks from true and chance coincident absorptions of the 1173 and 1332 keV gamma rays. Courtesy of Nathaniel Edwards, KSU.

energy peak, yet this alone does not account for all coincident losses. The coincident absorptions where at least one photon is Compton scattered produces a coincidence Compton spectrum below the sum peak(s). Any coincidence of one photon with full energy deposition of a second photon alters the number of counts in full energy peaks. For instance, a full energy absorption of one energy (say, E_1) coincident with a Compton scatter from another photon (E_2) still removes a count from the full energy peak of E_1. Unfortunately, these events fall into the coincidence Compton spectrum, and the original photon energies are difficult to determine. Consequently, proper correction to the full energy peaks becomes difficult.

The total counts observed C_{oi} in the full energy peak for E_i is related to the total counts C_i that should appear in the peak by

$$C_{oi} = C_i - (\text{real coincident counts} + \text{accidental coincident counts}), \tag{20.30}$$

where the full energy of E_i is deposited in the detector for each coincidence. For conceptual simplicity, consider a source with only two gamma ray emissions per decay, such as a ^{60}Co source. The observed counts in the full energy peak for the gamma rays of energy E_1 are represented by

$$C_{o1} \simeq At\left[\Omega_{f1}\epsilon_{p1}B_1(1 - K\Omega_{f2}\epsilon_{I2}B_2 - Att_r(\Omega_{f1}\epsilon_{I1}B_1) - Att_r(\Omega_{f2}\epsilon_{I2}B_2))\right], \tag{20.31}$$

where ϵ_{I2} is the total intrinsic counting efficiency of the second photon of energy E_2. For a single point source and detector, the solid angle is the same, and the counts for E_1 become

$$C_{o1} \simeq At\Omega_f\epsilon_{p1}B_1\left[(1 - \Omega_f(K\epsilon_{I2}B_2 + Att_r(\epsilon_{I1}B_1 + \epsilon_{I2}B_2))\right]. \tag{20.32}$$

A similar expression can be found for the full energy peak of E_2. For decay schemes with more than two gamma-ray emissions per decay, then the multiple coincident possibilities must be considered. These expressions can become quite complicated as shown by Vincent [1975] and Smith [1978]. Byun et al. [2004] describe a Monte Carlo method to obtain coincidence correction factors for multiple coincidences and detectors.

20.4.2 Spectral Response Function

A spectrum such as that in Fig. 20.9, normalized to unit concentration, is called the *spectral response function* for a given radionuclide. Each nuclide has a characteristic spectral response function which is different for each spectrometer for a specified source-detector geometry. Let the subscript k denote a specific nuclide. Then the detector response function u_{nk} is the expected response (number of counts) of the spectrometer in channel n per unit concentration of nuclide k.

Spectral response functions also can be associated with monoenergetic photons. If a source of monoenergetic photons of energy E_j, in some specific source-detector geometry, irradiates a detector then the detector response function u_{nj} gives the expected response in channel n per source particle of energy E_j emitted from the source. In either case, it is not the full energy peaks that are of only interest; the entire spectrum contains information about the source. Ways to exploit this dependence are considered later.

20.4.3 Qualitative Analysis

For some purposes, it is necessary to identify only whether or not a sample emits photons at certain discrete energies E_j. This may be the case, for instance, if one wants to know if a sample contains a particular radionuclide. Alternatively, a procedure such as EDXRF, NAA, or PGNAA can be used to excite characteristic photons from a sample under investigation. If the element of interest is present, the characteristic photons emitted from the sample should create full-energy peaks in a pulse-height spectrum collected from the sample.

Photons of energy E_j that are emitted by the source produce full-energy pulses whose magnitudes are distributed about a mean value of

$$h_j = f^{-1}(E_j). \tag{20.33}$$

A pulse of magnitude h_j produces a count in discrete channel n_j if

$$h_{min} + (n_j - 1)\Delta < h_j \leq h_{min} + n_j\Delta.$$

For purposes of energy determination, it is useful to consider the continuous, non-integer, channel number n_j corresponding to the pulse-height h_j of the full-energy peak. Then the gamma-ray energy can be estimated by determining the continuous or fractional channel number $\tilde{n}_j$ centroid of each peak.

It is then straightforward to obtain the corresponding h_j from

$$h_j = h_{min} + \tilde{n}_j\Delta. \tag{20.34}$$

For the usual case, where $h_{min} = 0$ and $h_{max} = 10$ V, this reduces to

$$h_j = \frac{10}{N}\tilde{n}_j. \tag{20.35}$$

The expected source energy is then easily obtained from

$$E_j = f^{-1}(h_j). \tag{20.36}$$

For a linear detector whose response is given by Eq. (20.2), then Eq. (20.36) is simply

$$E_j = \frac{h_j - \alpha}{\beta}. \tag{20.37}$$

If a nuclide emits several characteristic-energy photons, then one can gain confidence in the conclusion that the element is present if peaks occur at all energies for which the photon abundance and the detection efficiency would lead one to suspect that a peak should occur.

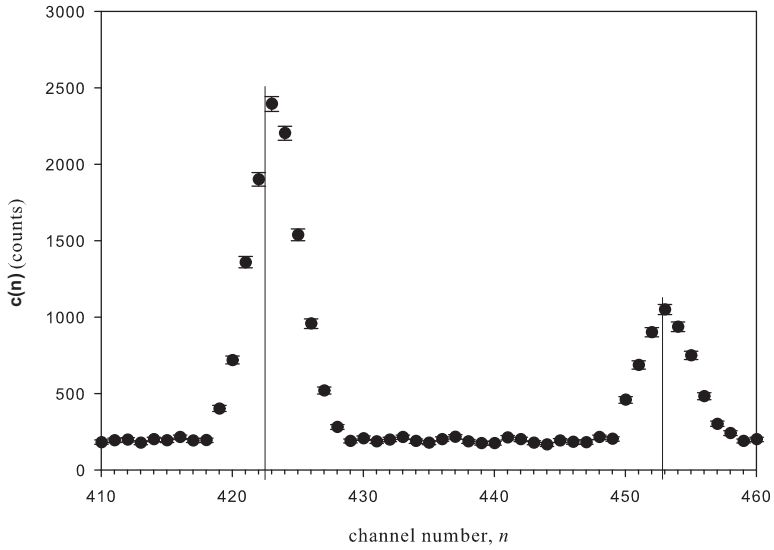

Figure 20.11. An example of visual inspection to yield the channel numbers corresponding to the centroids of two peaks in a spectrum. The vertical lines are used to connect the apparent peaks to their centroid fractional channel numbers.

The simplest way to estimate the channel corresponding to the peak is by inspection of the plotted spectrum. This technique often is adequate. One merely estimates the continuous channel number n_j that corresponds to the apparent centroid of the full-energy peak due to photons of energy E_j. For instance, in the spectrum shown in Fig. 20.11, one can obtain estimates of the fractional channel numbers of the centroids of the two peaks shown.[4] It should be apparent that this procedure is subjective (different researchers may estimate slightly different centroids) and, thus, has limited accuracy. Nevertheless this procedure may suffice for some applications.

When estimation of the centroid by inspection is deemed insufficient, other methods must be employed. The wavelet transform has been used in various spectroscopic applications, including nuclear magnetic resonance [Barache et al. 1997] and Raman spectroscopy [Xu et al. 1994]. However, this approach is not commonly employed in gamma-ray spectroscopy and, thus, is not further considered here. Rather, it is common that the centroids of the peaks present are identified as part of a fitting process that can determine quantitative information about both the characteristic energies E_j and their relative abundances. Alternatively, such methods may seek to identify particular radionuclides and their concentrations in a sample. Such methods are discussed in the next sections.

20.4.4 Quantitative Analysis

The model of Eq. (20.11) identifies a general inverse problem in which many channels contain information about the source distribution. One typically seeks to determine not only the characteristic energies E_j emitted by the source but also the individual source strengths s_j from the measured responses. Alternatively, one may use the spectral responses to identify the nuclide k and its concentration ξ_k in a sample. Quanti-

[4] In this example, the analyst is inexperienced because the maximum of a symmetric Gaussian distribution must lie between the midpoint of the channel with the most counts and the channel boundary adjacent to the boundary with the second most counts. Thus, both vertical lines should be moved slightly to the right.

tative analysis refers to the determination of quantities such as s_j and ξ_k. There are several approaches to quantitative analysis in spectroscopy, including the following:

1. Area under isolated peaks
2. Model fitting
3. Spectrum stripping
4. Library least-squares
5. Symbolic Monte Carlo

Summaries of how these methods are typically implemented are given in the following sections. In general, one seeks to obtain both the $E_j, j = 1, 2, \ldots, J$, and the net areas under each of the J peaks. For spectra that are linearly related to the source strengths, the net area A_j under the jth full-energy peak is related to S_j, the number of gamma rays emitted by the source during the counting time T, by

$$S_j = \frac{A_j}{\eta_j},$$

where η_j is the detector efficiency, presumed known, at energy E_j,

$$A_j = \sum_{n_1}^{n_2} [C(n) - B(n)], \tag{20.38}$$

and n_1 and n_2 are channel numbers over which the peak is spread. Similarly, in linear systems, the concentration ξ_k of nuclide k is directly related to the net peak area.

A gamma-ray spectrum, generally, consists of a series of peaks atop a continuum produced by sources emitting a continuum of energies and Compton plateaus from scattered photons. Ideally such a spectrum can be described by a sum of K Gaussian peaks plus a continuum as

$$y(n) = \sum_{k=1}^{K} g_k(n, \mu_k, \sigma_k) + B(n), \tag{20.39}$$

where

$$g_k(\tilde{n}, \mu_k, \sigma_k) = \frac{A_k}{\sqrt{2\pi}\sigma_k} \exp[-(\tilde{n} - \mu_k)^2/(2\sigma_k^2)], = B_k \exp[-((\tilde{n} - \mu_k)/\tau_k)^2]. \tag{20.40}$$

Here $A_k = \sqrt{\pi}\tau_k B_k$ is the number of counts in peak k and $\sigma_k = \tau_k/\sqrt{2}$ is the standard deviation of the peak. Usually, the continuum is represented by a (piecewise) polynomial of $\tilde{n}$ of low order. The principal purpose of quantitative analysis of the spectrum is to determine values of A_k and μ_k from which radioisotope identification and concentrations can be determined. Also in calibrated MCA spectrometer systems, the continuous channel number $\tilde{n}$ is replaced by the photon energy E and the channel number n by the energy E_n at the channel midpoint.

20.4.5 Area Under an Isolated Peak

For isolated peaks, i.e., those that do not overlap with other peaks, a simple approach can be used to estimate the net peak area. Generally, the peak is superimposed on a generalized background, as shown, for an ideal

case, in Fig. 20.12. To obtain the net area A, one identifies the channel numbers, n_1 and n_2, at which the peak disappears into the background. Then, the net peak area is estimated as

$$A = \sum_{n=n_1}^{n_2} \left[C(n) - (n_2 - n_1)\frac{C(n_1) + C(n_2)}{2} \right]. \tag{20.41}$$

The net area is the total number of counts between channels n_1 and n_2 minus the area under an (assumed) linear background between $C(n_1)$ and $C(n_2)$. For instance, for the spectrum shown in Fig. 20.12, one might choose $n_1 = 833$ and $n_2 = 861$. The total area between these channels is the sum of the counts in each channel and the background is the area under the straight line connecting $C(833)$ and $C(861)$; thus, the net area A is the area beneath the peak and above the background line in the figure.

This simple procedure cannot be applied to overlapping peaks and gives only approximate net areas because the background may not be linear under the peak and identifying the channels n_1 and n_2 is subjective, especially when the standard deviations of the responses, $\sigma(C(n_1))$ and $\sigma(C(n_2))$, are large relative to the values $C(n_1)$ and $C(n_2)$.

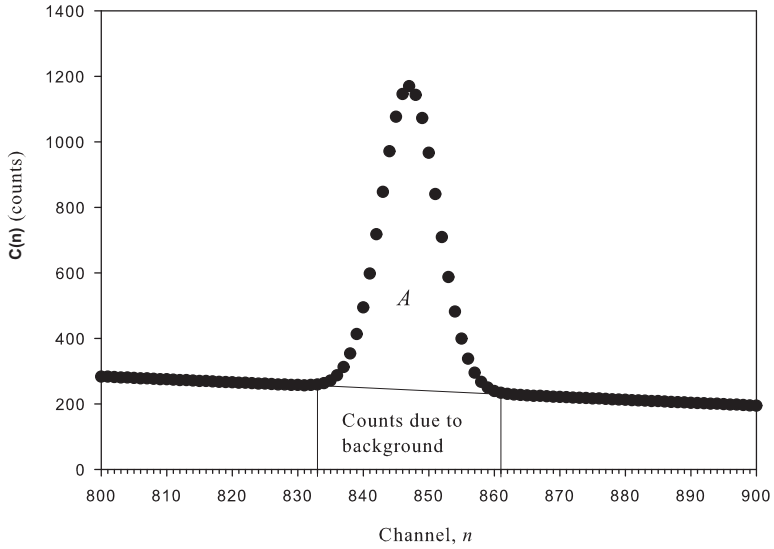

Figure 20.12. The net area A under the peak but above background.

20.4.6 Linear Least Squares Method for a Straight Line

Before methods to identify energy peaks and their corresponding energies, a review of the least squares method to fit models to data is appropriate. The least squares method presented here and in subsequent sections draws heavily on the discussion by Price et al. [2002].

Begin by considering the problem of fitting N data points (x_i, y_i) to a straight-line model

$$y(x) \equiv y(x|a, b) = a + bx. \tag{20.42}$$

This problem is often called *linear regression* by social scientists who invented the phrase a long time ago. Here it is assumed that the standard deviation σ_i for the measurements y_i are known and that the values of

x_i are known exactly. To quantify how well this linear model agrees with the data, the chi-square statistic is often used, which in this case is

$$\chi^2(a,b) = \sum_{i=1}^{N} \left(\frac{y_i - a - bx_i}{\sigma_i} \right)^2, \tag{20.43}$$

where σ_i is the standard deviation of y_i and is assumed to be known. If the σ_i are not known, then simply set $\sigma_i = 1$. If the measurement errors are normally distributed, as in counting data, then minimizing χ^2 with respect to a and b gives the maximum likelihood estimators of a and b [Press et al. 1992]. Even if the errors are not normally distributed the following approach is still useful.

At the minimum of Eq. (20.43) its derivatives with respect to a and b vanish, i.e.,

$$\begin{aligned} 0 = \frac{\partial \chi^2}{\partial a} &= -2 \sum_{i=1}^{N} \frac{y_i - a - bx_i}{\sigma_i^2} \\ 0 = \frac{\partial \chi^2}{\partial b} &= -2 \sum_{i=1}^{N} \frac{x_i (y_i - a - bx_i)}{\sigma_i^2} \end{aligned} \tag{20.44}$$

The equations can be rewritten more conveniently by first defining the following summations:

$$S \equiv \sum_{i=1}^{N} \frac{1}{\sigma_i^2}, \quad S_x \equiv \sum_{i=1}^{N} \frac{x_i}{\sigma_i^2}, \quad S_y \equiv \sum_{i=1}^{N} \frac{y_i}{\sigma_i^2}, \quad S_{xx} \equiv \sum_{i=1}^{N} \frac{x_i^2}{\sigma_i^2}, \text{ and } S_{xy} \equiv \sum_{i=1}^{N} \frac{x_i y_i}{\sigma_i^2}. \tag{20.45}$$

With these definitions, Eqs. (20.44) become

$$aS + bS_x = S_y \qquad \text{and} \qquad aS_x + bS_{xx} = S_{xy}. \tag{20.46}$$

The solution of these two equations for a and b is

$$a = \frac{S_{xx} S_y - S_x S_{xy}}{\Delta} \quad \text{and} \quad b = \frac{S S_{xy} - S_x S_y}{\Delta}, \tag{20.47}$$

where $\Delta \equiv S S_{xx} - (S_x)^2$.

This is not the end of the problem. The uncertainties in a and b must still be estimated because the uncertainties in the measurements makes the above estimates of a and b also somewhat uncertain. Recall from Sec. 6.9 that the variance in some function f of the y_i is, for independent y_i,

$$\sigma_f^2 = \sum_{i=1}^{N} \sigma_i^2 \left(\frac{\partial f}{\partial y_i} \right)^2. \tag{20.48}$$

For the straight line the derivatives of a and b with respect to the y_i are found from Eqs. (20.47)

$$\frac{\partial a}{\partial y_i} = \frac{S_{xx} - S_x x_i}{\sigma_i^2 \Delta} \qquad \text{and} \qquad \frac{\partial b}{\partial y_i} = \frac{S x_i - S_x}{\sigma_i^2 \Delta}. \tag{20.49}$$

Sum over the points as in Eq. (20.48) to obtain

$$\sigma_a^2 = S_{xx}/\Delta \qquad \text{and} \qquad \sigma_b^2 = S/\Delta. \tag{20.50}$$

Finally, the covariance of a and b is $\text{covar}(a,b) = -S_x/\Delta$ from which the coefficient of correlation between the uncertainty in a and b is

$$\rho_{ab} = \frac{-S_x}{\sqrt{SS_xx}}, \tag{20.51}$$

which is a number between -1 and 1. A positive value of r_{ab} indicates that the errors in a and b are likely to have the same sign, while a negative value indicates the errors are anti-correlated, i.e., the errors are likely to have opposite signs.

Numerical Considerations

The formulas of Eqs. (20.47) are notoriously susceptible to roundoff error [Press et al. 1992]. To avoid roundoff problems, define

$$t_i = \frac{1}{\sigma_i}\left(x_i - \frac{S_x}{S}\right), \quad i = 1, 2, ..., N \qquad \text{and} \qquad S_{tt} \equiv \sum_{i=1}^{N} t_i^2. \tag{20.52}$$

Then, as can be verified by direct substitution into Eqs. (20.47)–(20.51),

$$a = \frac{1}{S_{tt}} \sum_{i=1}^{N} \frac{t_i y_i}{\sigma_i} \qquad \text{and} \qquad b = \frac{S_y - S_x b}{S}, \tag{20.53}$$

$$\sigma_a^2 = \frac{1}{S}\left(1 + \frac{S_x^2}{SS_{tt}}\right) \qquad \text{and} \qquad \sigma_b^2 = \frac{1}{S_{tt}}, \tag{20.54}$$

$$\text{cov}(a,b) = -\frac{S_x}{SS_{tt}} \qquad \text{and} \qquad r_{ab} = \text{cov}(a,b)\sigma_a\sigma_b. \tag{20.55}$$

Application to Power and Exponential Functions

The linear least squares curve fit method can be used on power and exponential functions with appropriate substitutions. For example, the function $y(x) = \alpha x^\beta$ can be curve fit by substituting $Y = \ln(y)$, $X = \ln(x)$, $a = \ln(\alpha)$, and $b = \beta$. Likewise an exponential function $y(x) = \alpha e^{\beta x}$ can be fit to a straight line with substitutions $Y = \ln(y)$, $X = x$, $a = \ln(\alpha)$ and $b = \beta$. These substitutions can then be used to fit the linear model

$$a + bX = Y \tag{20.56}$$

to the observed data $y(x_i)$ and x_i, $i = 1, \ldots, N$. The use of such a transformation to make a non-linear model into a linear one is illustrated in Example 20.1.

Application to Unweighted Least Squares Fitting

Sometimes the uncertainties σ_i of the data points are unknown (such as in Example 20.1). In this case, an unweighted straight line can be fit to the data by setting all the $\sigma_i = 1$. The values of a and b obtained from Eq. (20.50) are then used to evaluate $\chi^2(a,b)$ from Eq. (20.43). The variances in the fit parameters are then estimated by multiplying the values obtained from Eq. (20.54) (with $\sigma_i = 1$) by $\sqrt{\chi^2/(N-2)}$ [Price et al. 1992].

Example 20.1: An experiment is conducted with a set of lead absorbers of different thicknesses with a ^{137}Cs gamma-ray source which emits a 661.7-keV gamma ray. A spectrometer is used to measure the number of counts per measurement acquired in the gamma-ray full energy peak as a function of absorber thickness. Each measurement has the same counting time. Determine the linear and mass attenuation coefficients for Pb for the gamma-ray energy emitted from ^{137}Cs.

Solution:
The data are best described by an exponential function,

$$y = \alpha e^{-\beta x} = \alpha e^{-(\beta/\rho)(\rho x)},$$

where β is the linear attenuation coefficient in units of cm^{-1} and β/ρ is the mass attenuation coefficient in units of $\text{cm}^2\ \text{g}^{-1}$. The absorbers were calibrated according to mass thickness ρx with units of g cm^{-2}. The measured data are listed the following table.

Data for attenuation of ^{137}Cs gamma rays through lead.

Mass Thickness (g cm^{-2}) $x_i = X_i$	X_i^2	Counts in Peak y_i	$Y_i = \ln y_i$	$X_i Y_i$
0	0	10136	9.22385	0
0.9253	0.85618	8990	9.10387	8.4238
1.8213	3.31713	8290	9.02281	16.4332
2.6507	7.02621	7683	8.94677	23.7152
4.4936	20.19244	6184	8.72972	39.2279
7.1408	50.99102	4727	8.46105	60.4187
$S_x = 17.032$	$S_{xx} = 82.3830$		$S_y = 53.4881$	$S_{xy} = 148.219$

With $S = N = 6$ and all $\sigma_i = 1$, the set of linear fitting equations Eqs. (20.47) becomes

$$6a + 17.0322b = 53.4881 \qquad \text{and} \qquad 17.0322a + 82.3830b = 148.219,$$

which are easily solved to give

$$a = 9.2127 \qquad \text{and} \qquad b = -0.10560$$

With these values, the $\chi^2(a, b)$ of Eq. (20.43), with all $\sigma_i = 1$, is found to be $\chi^2 = 8.516 \times 10^{-4}$. The standard deviations of a and b are then estimated (as explained above) by multiplying the values obtained from Eqs. (20.50), with all $\sigma_i = 1$, by $\sqrt{\chi^2/(N-2)}$. The results are

$$\sigma_a = 0.00927 \qquad \text{and} \qquad \sigma_b = 0.00257.$$

Converting back to an exponential $\alpha = e^a = 10024$ and $\beta = b/\rho = -0.1056 \pm 0.0026$ so the best expected fit to the data is

$$y = \alpha e^{-\beta x} = 10,024(\text{cts}) \exp[-0.1056(\text{cm}^2\ \text{g}^{-1})\rho x(\text{g cm}^{-2})].$$

Hence, the mass attenuation coefficient at 661.7 keV is $0.1056 \pm 0.00257\ \text{cm}^2\text{g}^{-1}$. Multiplication by the mass density of lead of $\rho = 11.34\ \text{g cm}^{-3}$, the linear attenuation coefficient at 661.7 keV is estimated to be $1.198 \pm 0.029\ \text{cm}^{-1}$.

20.4.7 General Linear Least-Squares Model Fitting

Here is considered the problem of fitting a linear combination of M *basis functions* $X_k(x)$ to a set of data points (x_i, y_i), i.e.,

$$y(x|a_1, ..., a_M) \equiv y(x|\mathbf{a}) = \sum_{m=1}^{M} a_m X_m(x), \tag{20.57}$$

where $X_m(x)$ can be highly non-linear in x. The term "linear" refers to the linear dependence of the model on the parameters a_m. This problem is a more general problem of fitting a straight line to a set of data in which $X_1(x) = 1$ and $X_2(x) = x$. As before, one seeks values of the parameters a_m that minimize the merit function

$$\chi^2 = \sum_{i=1}^{N} \left[\frac{y_i - \sum_{m=1}^{M} a_m X_m(x_i)}{\sigma_i} \right]^2. \tag{20.58}$$

First define an $N \times M$ *design* matrix $\mathbf{A}$ with elements

$$A_{ij} = \frac{X_j(x_i)}{\sigma_i}. \tag{20.59}$$

In general $N \geq M$ because there must be at least as many data points as there are model parameters. Also define a vector $\mathbf{b}$ with components

$$b_i = \frac{y_i}{\sigma_i}, \quad i = 1, \ldots, N \tag{20.60}$$

and a vector $\mathbf{a}$ whose components are the parameters $a_m,\ m = 1, \ldots, M$.

The minimum of χ^2 occurs when $\partial\chi^2/\partial a_m = 0$ or when

$$0 = \sum_{i=1}^{N} \frac{1}{\sigma_i^2} \left[y_i - \sum_{j=1}^{M} a_j X_j(x_i) \right] X_m(x_i), \quad m = 1, \ldots, M. \tag{20.61}$$

This is a set of M linear algebraic equations in the M unknown a_m. These so-called *normal equations* can be written compactly as

$$\sum_{j=1}^{M} \alpha_{mj} a_j = \beta_m, \quad m = 1, \ldots, M, \tag{20.62}$$

where

$$\alpha_{mj} = \sum_{i=1}^{N} \frac{X_j(x_i) X_m(x_i)}{\sigma_i^2} \qquad \text{or equivalently} \qquad \boldsymbol{\alpha} = \mathbf{A}^T \cdot \mathbf{A} \tag{20.63}$$

and

$$\beta_m = \sum_{i=1}^{N} \frac{y_i X_m(x_i)}{\sigma_i^2} \qquad \text{or equivalently} \qquad \boldsymbol{\beta} = \mathbf{A}^T \cdot \mathbf{b}. \tag{20.64}$$

Equations (20.62) can be solved by any standard linear equation solver such as Gauss-Jordan or Cholesky decomposition techniques. However, these normal equations are susceptible to roundoff errors and often these simple solution methods fail and more sophisticated methods such as the *singular value decomposition* technique should be used. Formally, the solution of Eq. (20.62) can be written as

$$a_j = \sum_{m=1}^{M} [\boldsymbol{\alpha}^{-1}]_{jm} \beta_m = \sum_{m=1}^{M} C_{jm} \left[\sum_{i=1}^{N} \frac{y_i X_m(x_i)}{\sigma_i^2} \right], \tag{20.65}$$

where $\mathbf{C} = \boldsymbol{\alpha}^{-1}$.

However, finding the model parameters is not the end of the data fitting problem. The standard errors for the estimated parameters must also be estimated. With the usual formula for the propagation of errors (see Eq. (6.75)) the variance of a fit parameter is estimated as

$$\sigma^2(a_j) = \sum_{i=1}^{N} \sigma_i^2 \left(\frac{\partial a_j}{\partial y_i} \right)^2. \tag{20.66}$$

Because C_{jm} is independent of y_i differentiation of Eq. (20.65) with respect to y_i gives

$$\frac{\partial a_j}{\partial y_i} = \sum_{m=1}^{M} C_{jm} X_m(x_i)/\sigma_i^2 \tag{20.67}$$

so that

$$\left(\frac{\partial a_j}{\partial y_i}\right)^2 = \frac{1}{\sigma_i^2} \sum_{m=1}^{M} \sum_{k=1}^{M} C_{jm} C_{jk} \left[\sum_{i=1}^{N} X_m(x_i) X_k(x_i)\right]. \tag{20.68}$$

Substitution of Eq. (20.68) into Eq. (20.66) produces

$$\sigma^2(a_j) = \sum_{m=1}^{M} C_{jm} \sum_{k=1}^{M} C_{jk} \left[\sum_{i=1}^{N} \frac{X_m(x_i) X_k(x_i)}{\sigma_i^2}\right] = C_{jj}. \tag{20.69}$$

The last simplification in this result arises because the term in square brackets is α_{km} (see Eq. (20.63)) and, because $\boldsymbol{\alpha}^{-1} = \mathbf{C}$, one has

$$\sum_{k=1}^{M} C_{jk} \left[\sum_{i=1}^{N} \frac{X_m(x_i) X_k(x_i)}{\sigma_i^2}\right] = \sum_{k=1}^{M} C_{jk} C_{km}^{-1} = [\mathbf{C} \cdot \mathbf{C}^{-1}]_{jm} = \delta_{jm}. \tag{20.70}$$

Hence the diagonal elements of the $\mathbf{C}$ matrix are the variances of the estimated parameters. Not surprisingly, the off-diagonal elements of $\mathbf{C}$ are the covariances covar(a_j, a_m).

Computer programs and subroutines for performing linear least squares fits are provided by Press et al. [1992], Bevington [1969] and Moré et al. [1980]. An application of this fitting procedure for an isolated peak is given in the following example.

Example 20.2:

Consider a full-energy peak produced in a HPGe spectrometer from 350-keV gamma rays emitted by the naturally occurring ^{214}Pb radionuclide. The measured data in the spectrum around this peak are listed in Table 20.1. Fit the data to a Gaussian distribution and determine the area of the peak.

Table 20.1. A portion of a spectrum around the 351.93-keV ^{214}Pb full-energy peak in the background spectrum shown in Fig. 21.7.

i	E_i (keV)	y_i cnts	i	E_i (keV)	y_i cnts	i	E_i (keV)	y_i cnts	i	E_i (keV)	y_i cnts

Solution:

From Fig. 20.13 the data appears to consist of a single Gaussian on top of an almost linear background. Thus, the general model of Eq. (20.39) reduces to

$$y(E, E_o, \sigma) = \frac{A}{\sqrt{2\pi}\sigma} \exp[-(E - E_o)^2/(2\sigma^2)] + a_1 + a_2 E. \tag{20.71}$$

It is this model that is to be fitted to the data in Table 20.1. However, to use the general linear least-squares fitting method described in this section, the peak energy E_o and its standard deviation σ must be known *a priori* so that the fitting function depends only linearly on A, a_1 and a_2.

Because the radioisotope is given as ^{214}Pb, then the energy of the decay gamma ray shown in Table 20.1 is $E_o = 351.9$ keV (see Appendix C), which, for this example is rounded to 520 keV. The variances of the counts is taken as the number of counts, i.e., $\sigma_i^2 = y_i$. From past experience with the spectrometer used to obtain the data of Table 20.1, the value of $\sigma \simeq 0.47$ keV. Thus, it is decided to look at two cases, one in which $\sigma = 0.45$ keV and another in which $\sigma = 0.50$ keV. The results of the fits for the two choices of σ are shown in Fig. 20.13. Clearly, $\sigma = 0.50$ kev is a better choice.

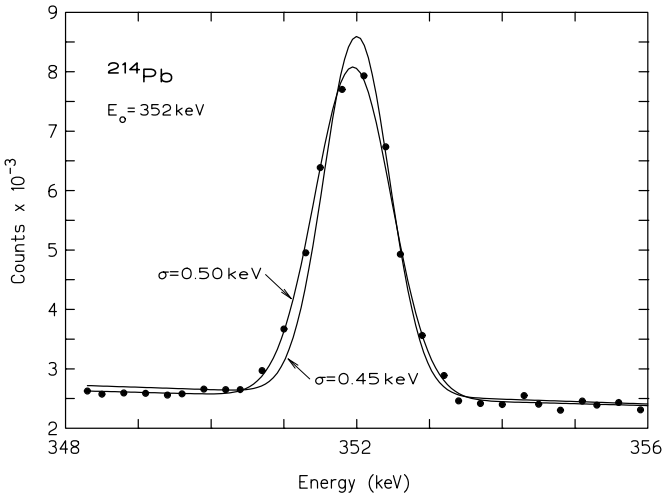

Figure 20.13. Two linear least-squares fit of Eq. (20.71) to the data of Table 20.1 for two assumed values of σ.

To determine the number of counts in the peak, the method described in Sec. 20.4.5 could be used. By inspection $n_1 = 9$ and $n_2 = 20$. Then the area is

$$\begin{aligned} \text{area}_1 &= \sum_{n=9}^{20} c(n) - \text{ trapezoid area} \\ &= 56,833 - \frac{1}{2}[c(9) + c(20)][11] = 28,717. \end{aligned}$$

From the linear least squares fit (with $E_o = 352$ keV and $\sigma = 0.50$) it is found that $A = 7161.79 \pm 62.19$ keV, $a_1 = 15819 \pm 1316$, and $a_2 = -37.75 \pm 3.73$ keV^{-1}. The energy width per channel is

$$\Delta E = \frac{E(31) - E(1)}{31 - 1} = 0.2700 \text{ keV/ch}.$$

Thus, the least-squares area of the Gaussian peak is estimated as

$$\text{area}_2 = [A \pm \sigma(A)]/\Delta E = \frac{7161.79 \pm 62.188 \text{ keV}}{0.2700 \text{ keV}} = 26,525 \pm 230.$$

20.4.8 Non-Linear Least-Squares Model Fitting

Often the model $y(x|\mathbf{a})$ to be fitted to the data $y_i,\ i = 1, ..., N$ depends both linearly on some of the parameters in $\mathbf{a}$ and non-linearly on the remaining M parameters. As before, in the least squares method, values of the parameters are determined by choosing parameter values that minimize the merit function

$$\chi^2(\mathbf{a}) = \sum_{i=1}^{N} \left[\frac{y_i - y(x_i|\mathbf{a})}{\sigma_i} \right]^2. \tag{20.72}$$

The normal equations (similar to Eq. (20.61)) are no longer linear in the parameters $\mathbf{a}$ and so cannot be solved directly. Rather, iterative techniques must be used to find the minimum of $\chi^2(\mathbf{a})$.

Equation (20.72) describes a hypersurface in the M-dimensional hyperspace whose axes are the M parameters in $\mathbf{a}$. One must incrementally traverse this hypersurface in some methodical fashion to find its minimum. Such searches range from brute-force grid searches, in which one moves incrementally along each axis to find a local minimum before searching along another axis, to more sophisticated searches, in which each incremental step is taken in a direction opposite to the gradient of $\chi^2(\mathbf{a})$. However, the hypersurface often has many local minima in which an incremental search can become trapped and, thus miss the sought-for global minimum. Moreover, these searches can often venture into regions of the hyperspace with physically unrealistic parameter values, such as those producing negative Gaussian distributions. Such a problem is frequently encountered if a search is begun far from the global minimum. Consequently, it is often necessary to do a constrained search to prevent the search path from entering unrealistic regions of the hyperspace.

In the analysis of gamma-ray spectroscopic data (x_i, y_i), x_i is either the channel number n or the channel midpoint energy E_n and y_i is the measured number of counts in a channel. Typically, data in a gamma-ray spectrum, or more often, a portion of the spectrum are fit to a sum of Gaussian peaks plus a polynomial to represent the continuum upon which the peaks sit. For this case, the fitting model is

$$y(x|\mathbf{a}) = \sum_{k=1}^{K} B_k \exp\left[-\left(\frac{x - E_k}{\tau_k} \right)^2 \right] + a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n. \tag{20.73}$$

The model parameters $B_1,\ E_1,\ \tau_1, ..., B_K,\ E_K,\ \tau_K,\ a_0,\ a1, ..., a_n$ are the components of $\mathbf{a}$. However, other models are easily treated with the non-linear least squares technique described below.

Non-Linear Least-Squares Search

There are several ways to search the M dimensional hyperspace to find $\mathbf{a}_{\min}$ that minimizes $\chi^2(\mathbf{a})$ of Eq. (20.72). Here the Leverberg-Marquardt (LM) method is presented and follows closely that presented by Press et al. [1992]. Near the minimum of $\chi^2(\mathbf{a})$ the hypersurface should be well approximated by a hyperparaboloid of the form

$$\chi^2(\mathbf{a}) \simeq \gamma - \mathbf{d} \cdot \mathbf{a} + \frac{1}{2} \mathbf{a} \cdot \mathbf{D} \cdot \mathbf{a}, \tag{20.74}$$

where γ is a constant, $\mathbf{d}$ is an M component vector, and $\mathbf{D}$ is an $M \times M$ matrix. Take the gradient of this expression and rearrange to obtain

$$\mathbf{a} = \mathbf{D}^{-1} \cdot \mathbf{d} - \mathbf{D}^{-1} \cdot \boldsymbol{\nabla} \chi^2(\mathbf{a}). \tag{20.75}$$

At the minimum $\boldsymbol{\nabla} \chi^2(\mathbf{a}_{\min}) = 0$, so $\mathbf{a}_{\min} = \mathbf{D}^{-1} \cdot \mathbf{d}$. Substitute this result into Eq. (20.75) to see that $\mathbf{a}_{\min}$ can be reached from the current position in hyperspace $\mathbf{a}_{\text{cur}}$ in a single step as

$$\mathbf{a}_{\min} = \mathbf{a}_{\text{cur}} + \mathbf{D}^{-1} \cdot \boldsymbol{\nabla} \chi^2(\mathbf{a}_{\text{cur}}). \tag{20.76}$$

However, if Eq. (20.74) is a poor approximation, then the best that can be done is to step down the gradient, i.e.,

$$\mathbf{a}_{\text{next}} = \mathbf{a}_{\text{cur}} - \text{constant} \times \boldsymbol{\nabla}\chi^2(\mathbf{a}_{\text{cur}}) \tag{20.77}$$

where the constant is sufficiently small to avoid overshooting the minimum. To use either Eq. (20.76) or Eq. (20.77) of the above stepping procedures the gradient of $\chi^2(\mathbf{a})$ must be known for any $\mathbf{a}$ and to use Eq. (20.76) one must also know $\mathbf{D}$, the so-called *Hessian* matrix, whose components are the second derivatives of $\chi^2(\mathbf{a})$.

The gradient of $\chi^2(\mathbf{a})$ with respect to the parameters $\mathbf{a}$, which equals zero at the minimum of $\chi^2(\mathbf{a})$, is

$$\frac{\partial\chi^2}{\partial a_m} = -2\sum_{i=1}^{N}\frac{[y_i - y(x_i|\mathbf{a})]}{\sigma_i^2}\frac{\partial y(x_i|\mathbf{a})}{\partial a_m}. \tag{20.78}$$

Then differentiate this result to obtain the second derivatives, namely

$$\frac{\partial^2\chi^2}{\partial a_m \partial a_l} = 2\sum_{i=1}^{N}\frac{1}{\sigma_i^2}\left[\frac{\partial y(x_i|\mathbf{a})}{\partial a_m}\frac{\partial y(x_i|\mathbf{a})}{\partial a_l} - [y_i - y(x_i|\mathbf{a})]\frac{\partial^2 y(x_i|\mathbf{a})}{\partial a_l \partial a_m}\right]. \tag{20.79}$$

Now define a vector $\boldsymbol{\beta}$ and matrix $\boldsymbol{\alpha}$ as[5]

$$\beta_m \equiv -\frac{1}{2}\frac{\partial\chi^2}{\partial a_m} \qquad \text{and} \qquad \alpha_{ml} \equiv \frac{1}{2}\frac{\partial^2\chi^2}{\partial a_m \partial a_l}. \tag{20.80}$$

Let $\delta\mathbf{a} = \mathbf{a}_{\text{cur}} - \mathbf{a}_{\text{next}}$, which is the next step in the search through hyperspace to find the minimum of $\chi^2(\mathbf{a})$. If the iterative search is based on Eq. (20.76) with $\mathbf{a}_{\min}$ replaced by $\mathbf{a}_{\text{next}}$ then manipulation of Eq. (20.76) gives

$$\mathbf{D}\,\delta\mathbf{a} = \boldsymbol{\nabla}\chi^2(\mathbf{a}) \qquad \text{or} \qquad \boldsymbol{\alpha}\,\delta\mathbf{a} = \boldsymbol{\beta}, \tag{20.81}$$

which can be rewritten as a set of linear algebraic equations

$$\sum_{l=1}^{M}\alpha_{ml}\delta a_l = \beta_m. \tag{20.82}$$

If, on the other hand, one wishes to use the steepest descent formula of Eq. (20.77) then

$$\delta a_l = \text{constant} \times \beta_l. \tag{20.83}$$

The Hessian matrix of Eq. (20.79), in general, contains the second derivatives $\partial^2 y(x_i|\mathbf{a})/\partial a_l \partial a_m$. These terms can be ignored if they are zero (as in a linear model) or if they are small compared to the other terms. Because the second derivatives are multiplied by $[y_i - y(x_i|\mathbf{a})]$ a quantity that, for a good fitting model, is the random measurement error. These errors can have either sign and should tend to cancel out when averaged over all i. Further, the second derivatives can destabilize the iterative search for the minimum if the spectrum is contaminated by outlier points. For these reasons, the second derivative terms in Eq. (20.79) are almost always neglected. Additionally, their neglect makes the search somewhat simpler and, although altering the matrix $\boldsymbol{\alpha}$ changes the path taken in hyperspace to reach the minimum of $\chi^2(\mathbf{a})$, the values of the parameters at the minimum are unaltered. Henceforth the elements of the $\boldsymbol{\alpha}$ are taken as

$$\alpha_{ml} = \sum_{i=1}^{N}\frac{1}{\sigma_i^2}\left[\frac{\partial y(x_i|\mathbf{a})}{\partial \alpha_m}\frac{\partial y(x_i|\mathbf{a})}{\partial \alpha_l}\right]. \tag{20.84}$$

[5]The $\boldsymbol{\alpha}$, which equals one-half of the Hessian matrix, is often called the *curvature* matrix.

The Levenberg-Marquardt Search

The Levenberg-Marquardt (LM) method is widely used for non-linear least-squares analyses. It varies smoothly between the inverse-Hessian method of Eq. (20.82) when close to the minimum and the steepest descent method of Eq. (20.83) when far from the minimum. The LM method is based on two key insights made by Levenberg and Marquardt.

The first insight concerns the constant in Eq. (20.83). It is not dimensionless as is $\chi^2(\mathbf{a})$; but because β_m has dimensions of those of $1/a_m$, which may be different for each m. Thus the constant of proportionality between β_m and δa_m must have dimensions of a_m^2. In the matrix $\boldsymbol{\alpha}$ the only element with this dimension is $1/\alpha_{mm}$, which defines the scale of the constant. However, this scale may produce too large a step size. To reduce the step size, a factor $\lambda \gg 1$ is introduced so that Eq. (20.83) can be written as

$$\delta a_l = \frac{1}{\lambda \alpha_{ll}} \beta_l \qquad \text{or} \qquad \lambda \alpha_{ll} \delta a_l = \beta_l \tag{20.85}$$

Clearly α_{ll} must be positive as is guaranteed by its definition in Eq. (20.84).

The second important key observation made by Marquardt is that Eqs. (20.85) and (20.82) can be combined by defining a new matrix $\boldsymbol{\alpha'}$ as

$$\alpha'_{jj} \equiv \alpha_{jj}(1 + \lambda) \qquad \text{and} \qquad \alpha'_{jm} \equiv \alpha_{jm}, \ j \neq k, \tag{20.86}$$

so Eqs. (20.85) and (20.82) can be replaced by the single equation

$$\sum_{l=1}^{N} \alpha'_{ml} \delta a_l = \beta_m. \tag{20.87}$$

Notice that when λ is very large, $\boldsymbol{\alpha'}$ becomes diagonally dominant and Eq. (20.87) becomes Eq. (20.85). But as λ becomes very small, Eq. (20.87) converges to Eq. (20.82).

Given an initial guess for the parameters $\mathbf{a}$, the algorithm for the LM search for the minimum of $\chi^2(\mathbf{a})$ proceeds as follows:

1. Compute $\chi^2(\mathbf{a})$.
2. Pick a modest value for λ, say $\lambda = 0.001$.
3. Solve Eqs. (20.87) for $\delta\mathbf{a}$ and evaluate $\chi^2(\mathbf{a} + \delta\mathbf{a})$.
4. If $\chi^2(\mathbf{a} + \delta\mathbf{a}) \geq \chi^2(\mathbf{a})$, increase λ by a factor of 10 or other substantial amount. Then go to step 3.
5. If $\chi^2(\mathbf{a} + \delta\mathbf{a}) < \chi^2(\mathbf{a})$, decrease λ by a factor of 10 and go back to step 3.

Continue this incremental walk through hyperspace until $\chi^2(\mathbf{a})$ decreases by a small amount such as 0.001 or some small fractional amount such as 0.001. Once an acceptable minimum has been found, the covariance matrix

$$\mathbf{C} = \boldsymbol{\alpha}^{-1} \tag{20.88}$$

is computed (after setting $\lambda = 1$). The diagonal elements of this matrix give estimates of the variances of the corresponding parameters.

In the examples below, the LM method is applied to the case of an isolated peak considered in Example 20.2 and to a case in which two peaks overlap. In both cases, the calculations use the LM computer subroutines given by Press et al. [1992].

Isolated Peaks

To assure that the entire isolated peak is completely fit, it is suggested that the portion of the spectrum extend to at least $\pm 3\sigma$ above and below the centroid channel. These limits are chosen because the area under a Gaussian over the range $\mu \pm 3\sigma$ is 0.997 of the total area under the Gaussian and thus the parameter A or B in Eqs. (20.39) and (20.40) is a very good approximation to the total area under the Gaussian.

For the portion of the spectrum containing an isolated peak, the appropriate fitting model $y(x|\mathbf{a})$ is that of Eq. (20.39) with $K = 1$ and a polynomial of low order n to describe the background upon which the peak sits. The merit function to be minimized in this case is

$$\chi^2(\mathbf{a}) = \sum_{i=1}^{N} \left[\frac{y_i - y(x_i|\mathbf{a})}{\sigma_i} \right]^2 = \sum_{i=1}^{N} \frac{1}{\sigma_i^2} \left[y_i - \left\{ B \exp\left[-\left(\frac{x_i - \mu}{\tau} \right)^2 \right] + \sum_{m=0}^{n} a_m x_i^m \right\} \right]^2, \tag{20.89}$$

where the components of the parameter vector $\mathbf{a}$ are $B,\ \mu,\ \tau,\ a_0, ..., a_n$. To use the LM method, the derivatives of $y(x|\mathbf{a})$ with respect to each parameter are needed. Here one has

$$\frac{dy(x|\mathbf{a})}{dB} = f(x, \mu, \tau), \qquad \frac{dy(x|\mathbf{a})}{d\mu} = B f(x, \mu, \tau) \frac{2(x - \mu)}{\tau^2},$$
$$\frac{dy(x|\mathbf{a})}{d\tau} = f(x, \mu, \tau) \frac{2(x - \mu)^2}{\tau^3}, \qquad \text{and} \qquad \frac{dy(x|\mathbf{a})}{da_j} = x^j, \quad j = 0, 1, ..., n. \tag{20.90}$$

To illustrate this analysis approach, the data of Table 20.1 for a ^{214}Pb peak are fit to a Gaussian plus a linear function ($n = 1$) in Example 20.3.

Example 20.3:

For the portion of a spectrum containing an isolated peak, as given by the data in Table 20.1, the fitting model $y(x|\mathbf{a})$ is given by Eq. (20.73) with $K = 1$ and a linear background function so $n = 1$ in Eq. (20.73). This is the same model used in Example 20.2, but now estimate the centroid of the peak and its standard deviation by including them in the fitting parameters.

Solution:

The merit function to be minimized is that of Eq. (20.89) with $n = 1$. The initial guess of the parameter values was

$$B = 3000 \text{ MeV}, \quad \mu = 0.350 \text{ MeV}, \quad \tau = 0.002 \text{ MeV}, \quad a_0 = 1000, \quad a_1 = -200 \text{ MeV}^{-1}.$$

After 23 LM steps through 5-dimensional parameter hyperspace, the $\chi^2(\mathbf{a})$ was reduced from an initial value of 16,653 to 72.55, the minimum of $\chi^2(\mathbf{a})$. The best fit parameters at the $\chi^2(\mathbf{a})$ minimum were

$$B = 5583.6 \pm 58.4, \quad \mu = 351.960 \ \pm \ 0.0051 \text{ keV}, \quad \tau = 0.74146 \pm 0.00744 \text{ keV},$$
$$a_0 = 14062 \pm 1331 \quad \text{and} \quad a_1 = -32823 \pm 3776 \text{ MeV}^{-1}$$

The normalization of the Gaussian is $A = \sqrt{\pi}\tau B = 7338.0 \pm 70.64$ keV counts/channel, which, upon dividing by the energy width per channel of 0.2700 keV/channel, gives the total counts in the peak as

$$A_3 = 27,178 \pm 262.$$

This result is midway between the two estimates $A_1 = 28,717$ and $A_2 = 26,525 \pm 230$ obtained in Example 20.2. Finally, the standard deviation of the peak is $\sigma = \tau/\sqrt{2} = 0.52429 \pm 0.00526$ keV. The resulting model fit and its two components are shown in Fig. 20.14. Of note is the estimated gamma-ray energy of 351.960 keV for this peak. This value compares very favorably to the accepted NUDAT value of 351.9321

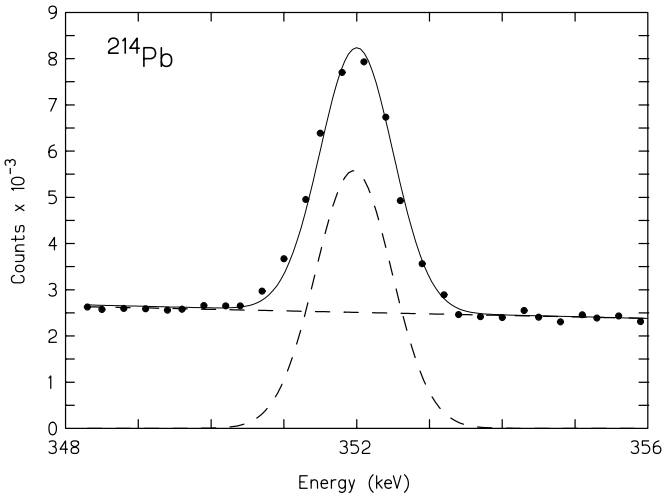

Figure 20.14. The LM fit to the data of Table 20.1. Also shown by dashed lines are the Gaussian peak component and the linear background.

(18) keV. The small difference is easily accounted for by inevitable small errors in the energy calibration of the channels of the spectrometer system.

Overlapping Peaks

Sometimes two or more peaks overlap. In situations where a peak is asymmetric or has a FWHM larger than expected, one can try to fit multiple peaks to the data locally. In such cases, one might try a fitting model of the form (see Eq. (20.39))

$$y(x|\mathbf{a}) = \sum_{j=1}^{K} B_j g_j(x, \mu_j, \tau_j) + a_0 + a_1 x + a_2 x^2, \quad \text{where} \quad g(x, \mu_j, \tau_j) = \exp\left[-\left(\frac{x - \mu_j}{\tau_j} \right)^2 \right] \tag{20.91}$$

and K is the number of peaks one suspects might be overlapping.

Values of the model parameters $\mathbf{a} = (B_1, \mu_1, \tau_1, \ldots, B_K, \mu_K, \tau_K, a_0, a_1, a_2)$ are found as those values that minimize the merit function

$$\chi^2(\mathbf{a}) = \sum_{i=1}^{N} \left[\frac{y_i - y(x_i|\mathbf{a})}{\sigma_i} \right]^2 = \sum_{i=1}^{N} \frac{1}{\sigma_i^2} \left[y_i - \left\{ \sum_{k=1}^{K} B_k \exp\left[-\left(\frac{x_i - \mu_k}{\tau_k} \right)^2 \right] + \sum_{j=0}^{2} a_j x_i^j \right\} \right]^2 . \tag{20.92}$$

As a practical matter, you might try $K = 2$ first and see if you obtain reasonable results. If not, try larger values of K. Of course this model introduces new non-linear model parameters for each additional peak. The fitting of multiple overlapping peaks, with asymmetric peak models, to XPS spectra is considered in detail by Dunn and Dunn [1982].

Generally, the y_i are either gross counts C_i in channel i or, for background-subtracted spectra, net counts N_i in channel i. (Note that background subtraction removes only part of the generalized background, the B_n of Eq. (20.12).) If the $C(i)$ are gross counts, then one presumes that Poisson statistics apply and $\sigma^2(y_i)) \equiv \sigma_i^2 = C(i)$. If the spectrum is background-subtracted, then $\sigma^2(y_i) = C(i) + B_i$. If the $C(i)$ result

from some other process, then one should use the appropriate variances in Eq. (20.92). For the non-linear least-squares approach followed here, values of the model parameters **a** are chosen that minimize the merit function $\chi^2(\mathbf{a})$. To use the LM minimization method, partial derivatives of $\chi^2(\mathbf{a})$ with respect to each parameter are needed and for the above model are given by Eqs. (20.90).

An example of fitting two overlapping peaks is given in Example 20.4. In this example, and in many non-linear least-squares fitting analyses, the incremental path through the $\chi^2(\mathbf{a})$ hypersurface may often lead to physically unrealistic values of some of the parameters. This is particularly true for overlapping peaks. Unless one starts the minimizing search with very good guesses for the μ_k for each peak, often a broad positive Gaussian ($B_1 > 0$) with a negative Gaussian ($B_2 < 0$) results. Such is the case for Example 20.4. One way to avoid these unrealistic parameter values is to start the search very near the minimum of $\chi^2(\mathbf{a})$, which is seldom known *a priori*, or to perform a *constrained* search along the hypersurface. In such a constrained search, the current values of the parameters are examined after each step and, if outside some preset range, an offending parameter is reset to the nearest range limit.

Example 20.4: Fit the model of Eq. (20.91) with $K = 2$ to the count data given in the table below.

Table 20.2. A portion of a spectrum giving channels and gross counts. The data points (x_i, y_i) to be fit are $x_i = i$ the channel number and $y_i = c(i)$ the counts in channel i.

i	$C(i)$	i	$C(i)$	i	$C(i)$	i	$C(i)$
117	2210	127	4756	137	45568	147	3827
118	2253	128	6176	138	36698	148	3416
119	2333	129	9761	139	23773	149	3156
120	2487	130	17016	140	14669	150	2896
121	2763	131	26462	141	10054	151	2713
122	2869	132	30846	142	7666	152	2448
123	2984	133	28392	143	6284	153	2335
124	3312	134	26822	144	5387	154	2119
125	3629	135	32667	145	4792	155	1957
126	4077	136	42618	146	4224	156	1754

Solution:
The LM method was used to find values of the best fit parameters. The derivatives needed for this method are

$$\frac{dy(x|\mathbf{a})}{dB_i} = f(x,\mu_i,\tau_i), \quad i=1,2 \qquad \frac{dy(x|\mathbf{a})}{d\mu_i} = Bf(x,\mu_i,\tau_i)\frac{2(x-\mu_i)}{\tau_i^2}, \quad i=1,2$$

$$\frac{dy(x|\mathbf{a})}{d\tau_i} = f(x,\mu_i,\tau_i)\frac{2(x-\mu_i)^2}{\tau_i^3}, \quad i=1,2 \qquad \frac{dy(x|\mathbf{a})}{da_j} = x^j, \quad j=0,1,2. \tag{20.93}$$

The search for the minimum of $+\chi^2(\mathbf{a})$ began with the following dimensionless starting values.

$$\mu_1 = 130. \quad \sigma_1 = 2.200 \quad B_1 = 22,000. \qquad \mu_1 = 140. \quad \sigma_2 = 2.800 \quad B_2 = 38,000.$$
$$a_0 = -177000. \quad a_2 = 2680 \quad a_2 = -9.8400$$

After 15 steps, the initial value of $\chi^2(\mathbf{a})$ was reduced from 80,978. to 2034.92. Further iterations did not change $\chi^2(\mathbf{a})$. Values of the best fit parameters are

$$\mu_1 = 131.664 \pm 0.015 \qquad \sigma_1 = 2.1298 \pm 0.0157 \qquad B_1 = 23,403.4 \pm 137.7$$

$$\mu_2 = 136.734 \pm 0.0120 \qquad \sigma_2 = 2.8700 \pm 0.0138 \qquad B_2 = 38538.5 \pm 129.0$$
$$a_0 = -166321. \pm 1970. \qquad a_1 = 2517.03 \pm 29.22 \qquad a_2 = -9.2409 \pm 0.10771$$

The areas of the two Gaussians are

$$A_1 = \sqrt{\pi}\tau_1 B_1 = 88348.1 \pm 552.78 \qquad A_2 = \sqrt{\pi}\tau_2 B_2 = 196039. \pm 761.10$$

and the standard deviations of the peak are

$$\sigma_1 = \tau_1/\sqrt{2} = 1.5060 \pm 0.01108 \qquad \sigma_1 = \tau_1/\sqrt{2} = 2.0295 \pm 0.009724.$$

The fit function is shown in Fig. 20.15.

It is seen that the model fits the data quite well. One would expect that a good model would be within the error intervals for about 68% of the data points and this seems to be the case here. The uncertainty in each of the model parameters is small, relative to the parameter value, which also indicates a good fit. It is noted that the values of $i_1 = 117$ and $i_2 = 156$ are well beyond the 3σ range for the σ_1 and σ_2 obtained. Thus, the A_1 and A_2 values should be good estimates of the net areas under the two peaks.

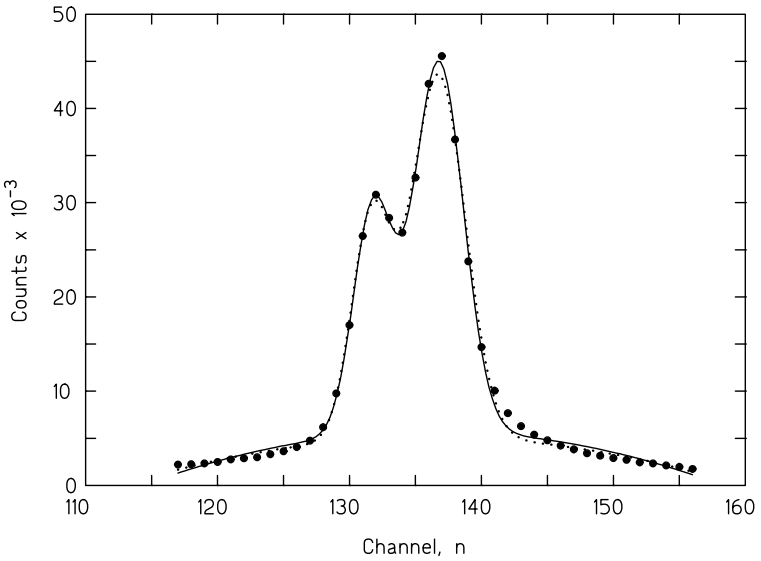

Figure 20.15. A fit of two overlapping peaks with a quadratic background. The solid line is a weighted least-squares fit with $\sigma_i = \sqrt{c(i)}$ and the dotted line is an unweighted least-squares fit with $\sigma_i = 1$.

20.4.9 Spectrum Stripping

If response functions can be collected or generated for all the sources (or radionuclides) that are expected to be present in an unknown sample, and if the dependence of the response model is linearly related to the source strengths or radionuclide concentrations, then the method of spectrum stripping can be applied. This procedure is as follows:

- Collect a spectrum from the unknown sample.

- Identify the highest-energy peak in the spectrum.
- Subtract the response function for that energy peak, weighted by a constant, such that the peak is effectively removed.
- Proceed down the spectrum while subtracting other weighted response functions until all peaks are removed.

If the residuals are randomly distributed about zero or about some smooth background, then the specific response functions stripped from the spectrum for the unknown identify the radionuclides present and the weighting constants estimate the source strength or concentration of each radionuclide.

20.4.10 Library Least-Squares

Because a detector produces a spectrum, even for a monoenergetic input one can try to utilize the entire spectral response, or at least a significant part of it, rather than just the response values near each peak or set of overlapping peaks. The library least-squares approach, originally introduced by Marshall and Zumberge [1989], asks the following question. Why focus on only the peaks since other parts of the spectrum also contain information related to the abundances of the radionuclides that produce the peaks? One approach for using all of the information in a spectrum is the library least-squares (LLS) method, as implemented, for instance, by Gardner and Sood [2004] and Gardner and Xu [2009]. The LLS method is based on a library that contains detector response functions for all radionuclides that might possibly be present in the sample whose spectrum is to be analyzed in order to determine the abundances of specific radionuclides. Then some fitting technique, such as least-squares or weighted least-squares, is used to fit the library spectra to the spectrum from a sample whose radionuclide abundances are sought.

This approach was not possible many years ago because one could not experimentally measure good spectra from all candidate radionuclides or a sufficient number of monoenergetic gamma rays. However, Monte Carlo modeling has become sufficiently robust that detector response functions can be calculated for almost any radionuclide. When Monte Carlo is used to generate detector response functions, the method often is referred to as Monte Carlo library least-squares or MCLLS. In this method, one calculates monoenergetic detector response functions $\mathcal{R}_n(E)$ for a wide range of discrete energies that can be emitted by sources of interest. Examples of such MC calculated detector response functions are shown in Fig. 20.16 and were calculated by special MC software and empirical resolution functions [Gardner and Sood 2004]. The response function $\mathcal{R}_n(E)$ is the probability that a photon of energy E emitted by the source produces a count in channel n. This response function, as before, includes the probability a source photon reaches the detector, a probability which depends on the specific source-detector geometry but it, generally, does not include photons scattered into the detector by material around the detector, i.e., so-called *roomshine*.

To determine the concentrations of various radioisotopes present in a sample, response functions, per unit activity concentration, for each possible radioisotope likely to be in the sample must first be constructed. A library of such radioisotopic response functions $\mathcal{R}_n^k$ can be constructed from the monoenergetic response functions $\mathcal{R}_n(E)$, for a given source-detector geometry, as

$$\mathcal{R}_n^k = \sum_{i=1}^{I} f_i^k \mathcal{R}_n(E_i^k)\hat{\xi}^k, \tag{20.94}$$

where f_i^k is the frequency a photon of energy E_i^k, $i = 1, ..., I$ is emitted per decay of radionuclide k and $\hat{\xi}^k$ is the decay rate of a unit activity concentration of the radionuclide.

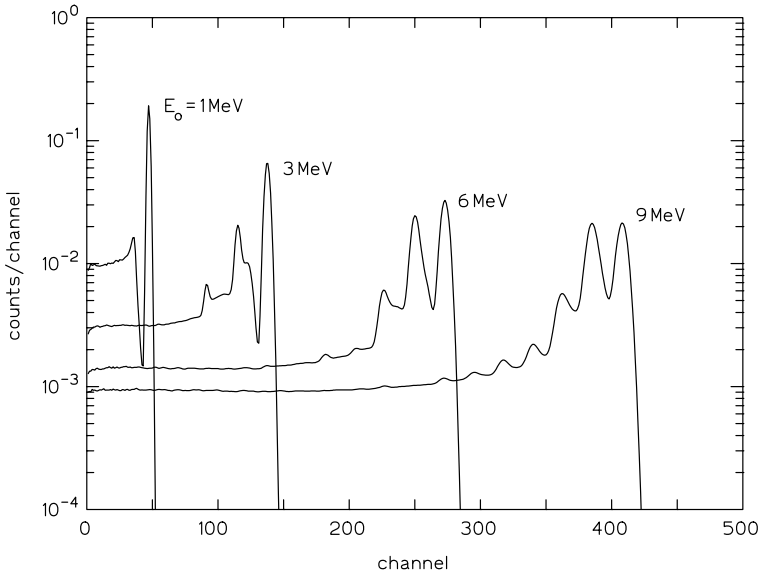

Figure 20.16. Examples of library response functions $\mathcal{R}_n(E)$ for a 6 in $\times$ 6 in cylindrical NaI detector for monoenergetic photons normally and uniformly incident on the circular end of the crystal. No contribution from scattering in material around the detector is included as indicated by the absence of backscatter and annihilation peaks although several annihilation escape peaks from the crystal are evident. These response functions are a small part of the library for a 512-channel spectrum over the photon range 0–11.38 MeV. Courtesy of Robin Gardner, NCSU.

Then the expected number of counts $y(n)$ recorded in channel n in a measurement time T produced by a sample of K possible radioisotopes is

$$y(n|\xi) = T \sum_{k=1}^{K} \mathcal{R}_n^k \xi_k, \qquad n = 1, ..., N, \tag{20.95}$$

where ξ_k are the radioisotopic activity concentrations being sought. Again it is assumed all the activity concentrations remain constant over the measurement time T. If $C(n)$ are the observed number of counts in channel n from the sample, then the vector $\boldsymbol{\xi}$, whose components are the concentrations ξ_k, can be determined as those values that minimize the merit function

$$\chi^2(\boldsymbol{\xi}) = \sum_{n=1}^{N} W_n [c(n) - y(n, |\boldsymbol{\xi})]^2, \tag{20.96}$$

where W_n is a weight factor, often taken as $W_n = 1/\sigma^2(C(n)) = C(n)$. Because the response functions do not include background and roomshine, the counts $C(n)$ must first be corrected for these contributions. If a fitted ξ_k value is negative or near zero for one or more k, then the corresponding radionuclides might not be present in the sample. In this case, it is a good practice to remove the detector response functions for these radionuclides and repeat the analysis to see if a good fit is obtained.

The process just described assumes the response model is linear in the radionuclide concentrations and, thus, can be referred to as the *linear LLS* approach. This approach is very similar to the previous linear

weighted least-squares process used to fit Gaussian distributions to spectral peaks. But here more features of the spectrum other than just the full-energy peaks are used. There are instances, however, in which the model is not linear in the radionuclide concentrations. Such cases arise in prompt gamma-ray neutron activation analysis (PGNAA) and energy dispersive x-ray fluorescence spectroscopy (EDXRF).

Non-Linear Spectra

Generally, the samples used in a neutron activation analysis (NAA) are small and their mass can be accurately measured and, because one is usually seeking concentrations of trace elements, a NAA analysis is well approximated as a linear process and application of linear LS technique is appropriate. However, for bulk samples, a prompt-gamma neutron activation analysis (PGNAA) is non-linear, primarily for the following reasons:

- Sample mass, which often is not known, affects the flux density and the macroscopic capture cross section of the sample.
- The composition of the sample, which is unknown in advance, affects the spectrum. In particular, moisture content strongly affects the thermal-neutron flux density, which is what gives rise to the prompt gamma rays. Also, neutron absorbers affect the thermal flux density.

Thus, non-linear models are needed for a PGNAA. Such models are iterative in nature and require the need to calculate spectral responses. Usually, Monte Carlo methods are used for such calculations. The general Monte Carlo Library Least-Squares (MCLLS) approach in the non-linear case proceeds as follows.

1. Assume values for the concentrations and use Monte Carlo to generate a complete spectrum for a sample of this assumed composition.
2. Keep track of the individual spectral responses for each element within the Monte Carlo code, so as to provide library spectra u_{nk} for each radionuclide.
3. Use linear LLS to estimate the radionuclide concentrations $\xi_k,\ k = 1, 2, \ldots, K$ from the sample spectrum.
4. If the calculated $\xi_k,\ k = 1, 2, \ldots, K$ match the assumed composition closely enough, you are done. If not, pick a new composition, based on the calculated concentrations, and repeat the process.
5. Iterate until you converge to the actual composition, to within a desired tolerance.

Results of this general procedure are given, for instance, by Gardner and Xu [2009].

20.4.11 Symbolic Monte Carlo

In X-ray fluorescence, the responses are due to the *elements* present, but each element is composed of radionuclides and the convention was introduced earlier to refer only to radionuclides. Hence in the discussion below, elemental concentrations are called nuclide concentrations. Non-linear matrix effects lead to absorption and enhancement in EDXRF. For instance, the characteristic x rays of nuclide a can be absorbed by elements with lower atomic numbers, which reduces the signal from nuclide a and enhances the signals for the lower atomic number nuclides. This effect means that the models in EDXRF also are not linear in the nuclide concentrations. Another implementation of Monte Carlo has been used in the EDXRF case. The method, originally called Inverse Monte Carlo (IMC) [Dunn 1981], was applied to EDXRF by Yacout and Dunn [1987] for primary and secondary x rays. Mickael [1991] extended the work to include tertiary fluorescence.

The term IMC has been used for other purposes, e.g. to solve inverse problems by iterative Monte Carlo simulations in which the unknown parameters are varied until simulated and measured results agree sufficiently. The acronym IMC also has been used for "implicit Monte Carlo" [Gentile 2001]. Thus, Dunn and Shultis [2009] recently proposed renaming the version of IMC that is non-iterative in the Monte Carlo simulations *symbolic Monte Carlo* (SMC) because the method proceeds by using symbols in the Monte Carlo scores for the unknown parameters.

SMC is a specialized technique in which the inverse problem of estimating the k and ξ_k is solved by a system of algebraic equations generated by a single Monte Carlo simulation. For purposes of illustration, a ternary system (one that contains three elemental nuclides) is considered. In essence, SMC creates models, with symbols for the unknown concentrations ξ_k, for the areas under all of the various x-ray peaks (e.g., K_α and K_β) in a single simulation. The models depend on the detector efficiency as a function of energy, the nuclide concentrations, the primary, secondary, and tertiary fluorescence produced in the sample, and the background. For a ternary system, three equations result. The equations are rather complex (see Yacout and Dunn [1987] and Mickael [1991]) but can be developed using only a single Monte Carlo simulation. The advantage of this approach is that there is no need to iteratively run full Monte Carlo simulations as the assumed concentrations are varied. The disadvantage is that development of the model is involved and the algebraic equations are quite complex. Nevertheless, the method has been shown to work well in x-ray spectroscopy and can, in principle, be applied to other spectroscopic applications, such as PGNAA, in which the responses are non-linear functions of the concentrations.

20.5 Radiation Spectroscopy Measurements

The purpose of radiation spectroscopy is to identify energetic emissions from radioactive materials. Such emissions are reported with several metrics, mainly the confidence in the identified energy or the *energy resolution* and the source activity (a function of the detector efficiency). The choice of detector is determined by the application and required spectroscopic performance. Detectors needed for field applications with sufficient spectroscopic performance to identify common isotopes may be best performed with lower resolution scintillation detectors. Measurements requiring high resolution spectroscopy generally require more expensive semiconductor spectrometers. No matter the type of spectrometer, it must undergo an energy calibration before any measurements can be made.

20.5.1 Channel Calibration

Calibration of the spectrometer channels in energy units is relatively simple, particularly if a linear energy/channel response is assumed. Typically two particle energies are chosen with relatively wide separation. For instance, ^{60}Co and ^{57}Co might be chosen. The peak channel $\tilde{n}_H$ for the higher energy E_H and the peak channel $\tilde{n}_L$ for the lower energy E_L are observed and a simple linear fit between these two channels provides a channel energy calibration, i.e.,

$$E(\tilde{n}) = \tilde{n}\left(\frac{E_H - E_L}{\tilde{n}_H - \tilde{n}_L}\right) + E_0, \tag{20.97}$$

where E_0 is the energy offset at channel $\tilde{n} = 0.0$, which is found from

$$E_0 = E_H - \tilde{n}_H\left(\frac{E_H - E_L}{\tilde{n}_H - \tilde{n}_L}\right). \tag{20.98}$$

For simplicity, the continuous $\tilde{n}$ is often taken as the channel number n which equals $\tilde{n}$ at the midpoint of a channel. The term in parentheses in the above equations is the energy width per channel ΔE and is

an important spectrometer parameter because it defines the minimum energy resolution possible with the spectrometer.

Semiconductor materials usually show good signal linearity with energy deposition, but there are many scintillators that exhibit a non-linear output with energy, especially at lower energies (see Sec. 13.2.2). Example scintillators include NaI:Tl and CsI:Tl in the energy region below 500 keV. For such non-linear detectors, several energies in the non-linear region should be used to fit a polynomial function to the channel energy calibration.

20.5.2 Quality Metrics

Several quality metrics have been established, some official and others less so, that depend on the system and type of detector. These metrics are used to give the user an idea of the expected detector performance under different measurement conditions. Metrics include measurements of detection efficiency, energy resolution, channel width corrections, figure of merit, noise resolution, energy rate limit, and peak-to-Compton ratio. Many of these metrics are described in the IEEE Std 325-1996 document for HPGe detectors, outlined in this section.

Detection Efficiency

There are multiple methods for defining and measuring the efficiency of a gamma-ray spectrometer. The efficiencies of most interest and utility are the absolute efficiency, the intrinsic efficiency, and the escape peak efficiency. In Sec. 7.1 a general description of detector efficiencies was given. Here efficiencies for a full energy peak from a gamma-ray spectrometer are defined.

Total Intrinsic Detection Efficiency The total intrinsic detection efficiency is defined by

$$\epsilon_{\mathrm{I}} = \sum_{i}^{N} \frac{A_{\mathrm{sp}}}{A\Omega_f t B_i} \tag{20.99}$$

where A_{sp} are the recorded counts from the entire detector spectrum, t is the live time of the counts, A is the source activity, Ω_f is the fractional solid angle subtended by the detector, and B_i are the branching ratios of the radiation emissions. For instance, ^{60}Co emits two gamma rays per decay ($B = 2$), while only 85% of decays from ^{137}Cs result in the emission of a 661.7 keV gamma ray ($B = 0.85$). This metric ϵ_{I} yields some information about the overall detector counting efficiency, but does not give information on the energy resolution performance. Further, this particular metric is subject to changes with the LLD setting, and background contamination can skew the results.

Intrinsic Peak Efficiency The intrinsic full energy peak efficiency, described in Sec. 7.1 and repeated here for convenience, is defined by

$$\epsilon_{\mathrm{peak}} = \frac{A_p}{A\Omega_f B t} \tag{20.100}$$

where A_p are the recorded counts from the detector in the full energy peak, t is the live time of the counts, A is the source activity, Ω_f is the fractional solid angle subtended by the detector, and B is the branching ratio of the emission under investigation. The intrinsic peak efficiency is similar to the intrinsic detection efficiency, except the A_p pertains only to those counts located in the background subtracted full energy peak. It is notable that the intrinsic peak efficiency may be difficult to determine accurately for several detector types. For instance, the size and shape of an HPGe detector may be difficult to assess because the actual crystal is much smaller than the apparent cryogenic packaging (see Fig. 16.34). A similar situation exists with scintillation counters whose crystal is hermetically packed in a light-tight reflecting cannister. The practical outcome of the intrinsic peak efficiency is a function of the packing cannister, the absorbing

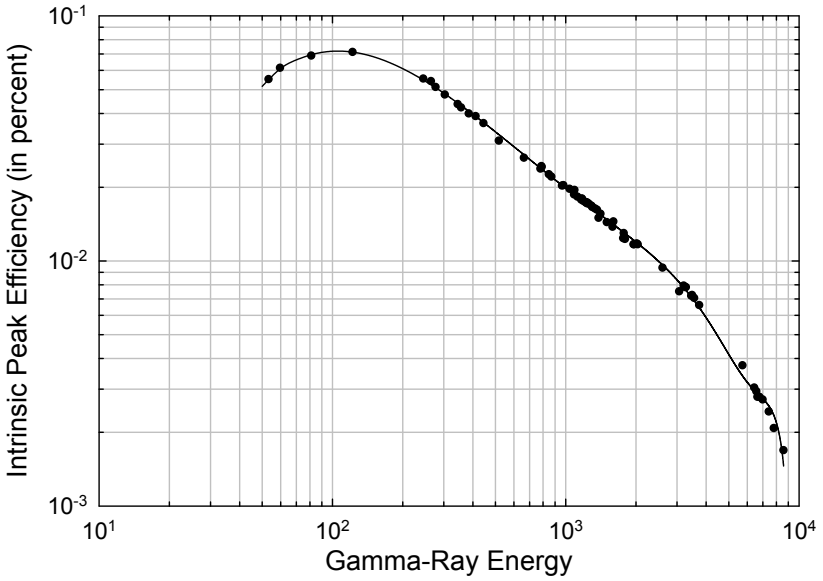

Figure 20.17. Measured intrinsic peak efficiency for a 25% relative efficient n-type HPGe detector. The sources used for the calibration were ^{241}Am, ^{133}Ba, ^{152}Eu, ^{137}Cs, ^{60}Co, ^{188}Ta, ^{56}Co, ^{49}Ti, and ^{36}Cl. Data acquired from Kis et al. [1998].

material (NaI:Tl, HPGe, CdTe, etc.), the type of electrical contacts, the detector size, and the detector shape. Energy absorption in the detector encapsulation and contact dead layer affect the low energy efficiency, while the atomic number and volume of the detector determine the high energy efficiency (see Fig. 16.35). An example of the efficiency variation is shown in Fig. 20.17 for a 25% relative efficient, bulletized coaxial n-type HPGe detector [Kis et al. 1998].

A variety of gamma-ray sources can be used to measure the intrinsic peak efficiency over the energy region of interest. Afterwards, a curve fit can be used as a predictive measure of efficiencies at other energies within the measured span [Kis et al. 1998]. Although there are several curve fitting functions offered in the literature, many examples listed in Kis et al. [1998], modern commercial curve fitting computer programs are available that can provide high fit r^2 values (> 0.999).

Escape Peak Efficiency The escape-peak efficiency, mainly the single and double escape peaks from pair production, is a measure of the detector's ability to effectively recapture 511-keV annihilation photons. Larger escape peaks are indicative of larger losses. Although there are multiple definitions of this metric in the literature, a generally accepted definition for the intrinsic escape peak efficiency is that described by Cline [1968] and Nafee [2011],

$$\epsilon_{es} = \frac{A_{\text{ep}}}{A\Omega_f Bt}, \tag{20.101}$$

where A_{ep} pertains to the number of counts in either the single escape peak or the double escape peak. To determine the number of counts in either escape peak, the subtraction method of Eq. (20.41) is employed. Equation 20.101 can be rewritten as

$$\epsilon_{es} = \epsilon_{\text{peak}} \frac{A_{\text{ep}}}{A_p}, \tag{20.102}$$

where the escape peak under investigation is for the corresponding full energy peak.

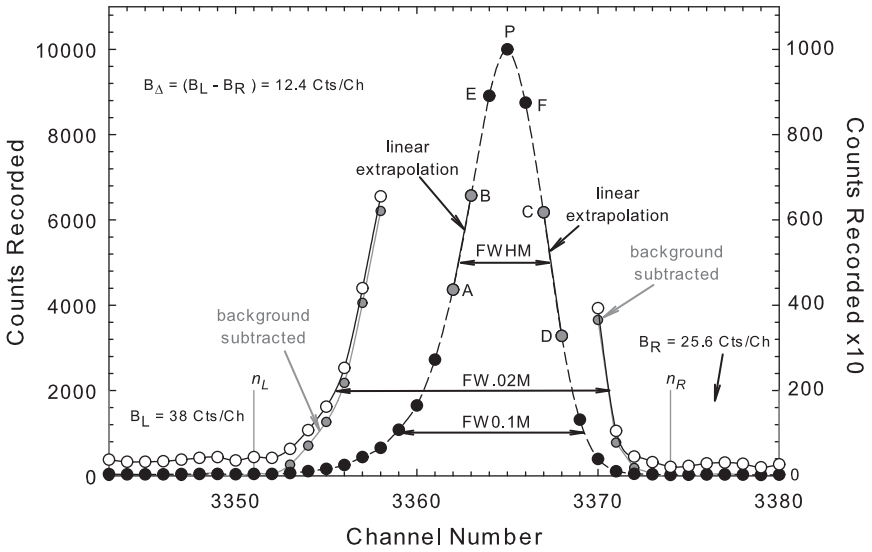

Figure 20.18. Spectral calibration and features for the ^{60}Co 1332.5-keV full energy peak taken with a HPGe detector. The left axis is for the full energy peak and the right axis is for the tails and the background subtracted data on either side of the peak. The open circles are measured counts $C(n)$ and the solid circles are counts corrected for background, i.e., $N(n) = C(n) - B(n)$. Adopted from IEEE 325-1996.

It is notable that escape peaks can be used to identify the initial gamma-ray energies. Escape peaks do not have a Compton gap or Compton edge, and the apparent lack of these features can assist with their identification. Although gamma rays equal to or greater than 1.022 MeV can be absorbed through pair production, escape peaks usually do not become apparent for gamma-ray energies below approximately 1.5 MeV.

Energy Resolution

A method to determine the energy resolution of a gamma-ray spectrometer is prescribed by the IEEE Std 325-1996 and was developed for a HPGe detector and a ^{60}Co check source. The method, which appears to be used by few if any researchers, makes no use of statistical uncertainties in the spectral count data (unlike the weighted least squares fitting methods used earlier). Rather it depends on a very high number of counts in the full energy peak so statistical uncertainties are of little consequence. The one unique feature of this standard, however, is that the method makes no Gaussian symmetry assumption about the shape of the full energy peak and it is capable of treating asymmetric peaks that are wider at energies below the peak energy than above—a feature observed in many spectrometers. In essence, the method relies solely on manipulations of the observed channel counts $C(n) \equiv C_n$ to estimate the FWHM.

The IEEE Std 325-1996 recommends a 8192 (2^{13}) channel multichannel analyzer with the 1332.5-keV ^{60}Co full energy-peak scaled to appear in channel 4032. The reason for the location is to ensure that at least 5 channels are included within the FWHM of the energy peak. If the detector under test has worse resolution than normally expected from a HPGe detector, a lower channel can be used provided that the 5 channel criteria is maintained (see Fig. 20.18). At least 10,000 counts must appear in peak maximum channel, and the spectrum and live time are to be recorded. If a pulse generator is used to measure electronic noise, the pulser peak is to be set between the ^{60}Co energy peaks (1173.2 keV and 1332.5 keV), and as close as possible to the 1332.5-keV full energy peak without interfering with the recorded counts. The method does allow for other gamma-ray sources, but the requirement that at least 5 channels be included in the FWHM remains.

Begin by identifying the first channel n_L to the left of the peak which shows no contribution from the peak and consists solely of background events. Likewise identify n_R the first channel above the peak that shows no peak contribution. Then average the 6-8 channels below n_L and above n_R to find the average background B_L immediately below the peak and B_R above the peak. Use a linear equation between (n_L, B_L) and (n_R, B_R) to represent the background under the full peak, i.e.,

$$B(n) = B_L - (n - n_L)\frac{B_L - B_R}{n_R - n_L}, \quad n_L \le n \le n_R. \tag{20.103}$$

The net peak counts corrected for background are then $N(n) = C(n) - B(n)$.

As shown in Fig. 20.18 the channels containing the seven highest counts are identified with the letters A, B, C, D, E, F, and P and the counts in these channels are used to characterize the peak. The peak may not be exactly at the centroid of channel n_P, which occurs only if $N_E = N_F$, and may be slightly shifted to $\tilde{n}_{\max}$ where the peak has the true maximum $N_{\max}$. To determine the true maximum fit, the three highest counts to the parabola

$$N(\tilde{n}) = \alpha\tilde{n}^2 + \beta\tilde{n} + \gamma. \tag{20.104}$$

The maximum count $N_{\max}$ occurs when $dN(\tilde{n})/d\tilde{n} = 0$ or at $\tilde{n}_{\max} = -\beta/(2\alpha)$. The maximum is found to occur at

$$\tilde{n}_{\max} = n_P + \frac{(N_E - N_F)/2}{N_E + N_F - 2N_P}, \tag{20.105}$$

where $N_E \equiv N(n_E)$ and so on for the other peak channels. The maximum number of counts is

$$N_{\max} = N_P - \frac{(N_E - N_F)^2}{8(N_E + N_F - 2N_P)}. \tag{20.106}$$

The FWHM maximum can be measured by producing linear extrapolations for the data points that straddle the FWHM location at a height $N_{\max}/2$. This procedure is performed after the background has been subtracted. For example from Fig. 20.18, these extrapolations would be applied to data points at positions A and B and also at positions C and D. Note $n_B - n_A = n_C - n_D = 1$. Thus, the location $\tilde{n}_l$ between A and B of the left end of the horizontal FWHM line is found to be

$$\tilde{n}_l = n_A + \frac{N_{\max}/2 - N_A}{N_B - N_A}. \tag{20.107}$$

Similarly the right end $\tilde{n}_r$ between C and D is

$$\tilde{n}_r = n_C - \frac{N_{\max}/2 - N_C}{N_C - N_D}. \tag{20.108}$$

The difference between these two limits then gives the FWHM in channels, namely

$$\mathrm{FWHM}_{\mathrm{ch}} = \tilde{n}_r - \tilde{n}_l = (n_C - n_A) + \frac{N_C - N_{\max}/2}{N_C - N_D} - \frac{N_{\max}/2 - N_A}{N_B - N_A}. \tag{20.109}$$

The energy resolution in energy units and as a percent are

$$\mathrm{FWHM}_{\mathrm{energy}} = \Delta E\ \mathrm{FWHM}_{\mathrm{ch}} \quad \text{and} \quad \mathrm{FWHM}_{\%} = 100\frac{\Delta E}{E_\gamma}\mathrm{FWHM}_{\mathrm{ch}}, \tag{20.110}$$

where ΔE is the channel width in energy units (typically keV) and E_γ is the energy of the gamma ray.

The same method can be used to find the full width at $(1/m)C_{\max}$. Shown in Fig. 20.18 are the FW.1M ($m = 10$) and FW.02M ($m = 50$). These metrics are used to quantify the asymmetry of the full energy peak with a *skewness factor* defined as

$$S_R(m) = \frac{\text{FW}(1/m)\text{M}}{\text{FWHM}}\sqrt{\frac{\ln 2}{\ln m}}. \tag{20.111}$$

For a symmetric Gaussian peak $S_R(m) = 1$ for all m but for asymmetric peaks the skewness factors are greater than unity. That full-energy peaks in a HPGe detector are asymmetric arises from the longer collection times for charges created in low electric field regions of the detector compared to that for charges created in normal regions. This longer collection time produces some signal attenuation when passing through an amplifier's linear pulse shaping network.[6] Also Compton scattering decreases the signal in some pulses. The overall result is an increase in the FW$(1/m)$M compared to the FWHM.

Example 20.5: Determine the corrected peak channel and counts for the peak shown in Fig. 20.18. The peak is located between channels $n_L = 3351$ and $n_R = 3374$ and the observed three highest gross counts are: $G_P = 10,000$ at channel 3365 and $G_E = 8910$ and $G_F = 8748$.

Solution:

First find the background corrections. From Eq. (20.103)

$$B(n) = B_L - (n - n_R)\frac{B_L - B_L}{n_R - n_L} = 38 - (n - 3351)\frac{38 - 25.6}{3374 - 3351} = 38 - (n - 3351)(0.5391),$$

from which $B_E = 30.99$, $B_P = 30.45$, and $B_F = 29.91$. Then $N(n) = G(n) - B(n)$ so that

$$N_E = 8879.01 \qquad N_P = 9969.55 \qquad N_F = 8718.09.$$

From Eq. (20.105) the continuous channel for the maximum counts is

$$\tilde{n}_{\max} = n_p + \frac{(N_E - N_F)/2}{N_E + N_F - 2N_P} = 3365 + \frac{80.46}{-2342} = 3364.96.$$

Finally from Eq. (20.106) the true maximum number of counts is

$$N_{\max} = N_P - \frac{(N_E - N_F)^2}{8(N_E + N_F - 2N_P)} = 9969.55 - \frac{(-160.92)^2}{-2342.00} = 9980.61.$$

In this case the peak correction is very small because N_E is very close to N_F. In fact if $N_E = N_F$ there would be zero correction to N_P. The largest correction would occur when $N_P = N_E$ or $N_P = N_F$.

Peak-to-Compton Ratio

Another metric specified for HPGe radiation spectrometers is the peak-to-Compton ratio (PCR). As described in the ANSI/IEEE standard 325-1996, the measurement of the PCR is performed with the 1332.5 keV gamma-ray energy from ^{60}Co. The PCR is defined as

$$\text{PCR} = \frac{C_{\max}}{\overline{N}}, \tag{20.112}$$

[6] Gated-integrating pulse processing is less prone to this attenuation.

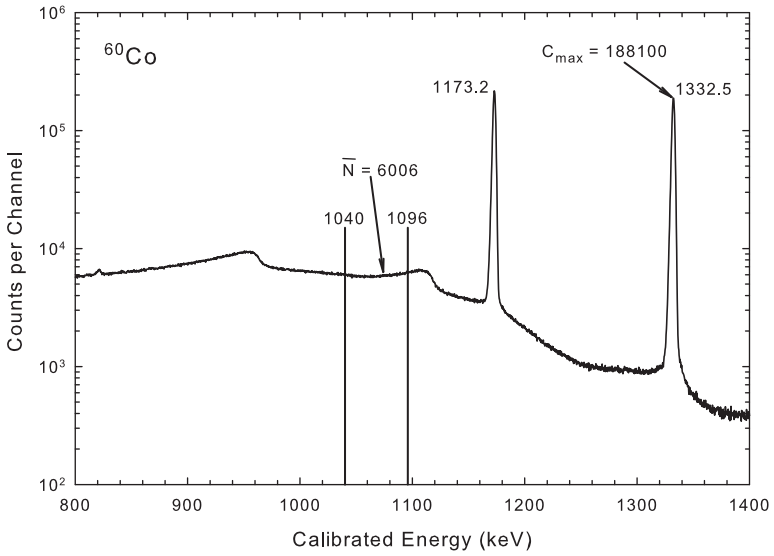

Figure 20.19. The peak-to-Compton ratio (PCR) is calculated by dividing $C_{\max}$ by $\overline{N}$. In this example for a 20% η_{rel} HPGe coaxial detector the measured PCR is 31.3. Courtesy of Nathaniel Edwards, KSU.

where $C_{\max} = C_P$ is the number of counts in the peak channel for the 1332.5-keV gamma ray and $\overline{N}$ is the average number of counts per channel between the channels represented by 1040 keV and 1096 keV. The energy range between 1040 keV and 1096 keV appears in the Compton gap of the 1173.2-keV gamma ray of ^{60}Co; therefore, is almost entirely associated with the Compton continuum of the 1332.5-keV peak (see Fig. 20.19). The environmental background B should be subtracted from the measurements before calculating the PCR. The PCR metric is analogous to a sort of signal-to-noise ratio because the PCR is a measure of the spectrometer's ability to discern lower energy and lower count rate gamma-ray peaks in the presence of higher energy gamma-rays and their corresponding spectral features.

As the energy resolution of a HPGe detector improves, the number of counts in the 1332.5-keV peak channel increases. Also, as the size of the HPGe detector increases, so do counts in the 1332.5-keV peak channel because fewer scattered gamma rays can escape the detector. Hence, improved energy resolution and improved efficiency both tend to increase the PCR. PCR values can range from 30:1 for smaller HPGe detectors up to over 90:1 for relatively large detectors [Gilmore 2008].

It is notable that prior versions of the IEEE ANSI standard 325 also included a PCR for ^{137}Cs in which the maximum counts for the peak channel at 661.7 keV is divided by the average counts per channel in those channels between 358 keV to 382 keV. Although the ^{137}Cs based PCR is generally not used to characterize HPGe detectors, it still has utility as a benchmark for comparing PCR values for much smaller semiconductor spectrometers, such as those with CdZnTe or HgI_2 detectors whose peak efficiency at 1332.5 keV can be small compared to that of a HPGe detector. However, this particular definition does not appear in the most recent version ANSI 325-1996.

Peak-to-Valley Ratio

Another, less official, metric is the peak-to-valley ratio (PVR), which is measured with a ^{137}Cs source. This metric is defined as the number of counts in the peak channel divided by the number of counts in the middle of the Compton gap at 569 keV. This metric is seldom used for HPGe detectors; rather, it is more often used for compound semiconductor detectors and (rarely) used for experimental scintillation detectors. This

metric provides a measure of the detector efficiency, energy resolution, and for semiconductors, a measure of the charge carrier trapping effects.

Peak-to-Total Ratio

The peak-to-total ratio (PTR) is the ratio of the total counts in a full energy peak to the number of counts in the entire spectrum. The metric is useful with monoenergetic gamma-ray sources, such as ^{137}Cs and ^{54}Mn, but is not well defined or interpreted for polyenergetic gamma-ray sources. The peak-to-total ratio is proportional to the intrinsic full energy peak efficiency ϵ_{peak} because

$$\epsilon_{\text{peak}} = \epsilon_{\text{I}} \left(\frac{\text{peak counts}}{\text{total counts}} \right) = \epsilon_{\text{I}} \text{PTR}, \tag{20.113}$$

where ϵ_{I} is the total intrinsic counting efficiency. By carefully selecting monoenergetic gamma-ray sources, the detector intrinsic peak efficiency can be calibrating over a broad energy range [Heath et al. 1967]. Unfortunately, there are a limited few practical monoenergetic gamma-ray sources to conduct such a measurement.

Another method to accomplish this same task is to use two detectors in coincidence, with the detector under investigation receiving the scattered gamma ray. The method entails capturing a Compton scattered gamma ray that escapes from a high energy resolution primary (first) detector. The residual energy deposited in the second detector is determined by subtracting the energy deposited in the first detector from the known emission energy. Collimation and pulse height discrimination can be used to select and allow only scattered gamma rays of a specific energy, thereby producing a pulse height spectrum, at the energy under investigation, from the second detector.

20.5.3 Detection and Spectroscopy with Scintillators

The properties and advantages of scintillators are described in Chapter 13. Added here are some specific details on spectroscopic measurements and performance pertinent to scintillators. The quality metrics used to assess the photon spectroscopy performance of scintillation detectors include the energy resolution, the peak-to-total ratio (PTR), the intrinsic peak efficiency (ϵ_{I}), and the escape peak efficiency (ϵ_{es}) [Heath 1964]. Usually performance comparisons between different scintillation materials and detectors are conducted with 661.7-keV gamma rays from ^{137}Cs.

Recall from Chapter 4 that the photon interactions important to gamma-ray counting and spectroscopy are photoelectric, Compton scattering, and with sufficient energy, pair production. The combined intrinsic gamma-ray interaction efficiencies that any one of these interactions occurs are plotted in Chapter 13, Figs. 13.13, 13.14, 13.15, 13.17, 13.19, and 13.20 as a function of photon energy for several scintillation materials. An often used method to predict gamma-ray detection performance is to couple the solid angle calculations (from Chapter 7) with the interaction efficiencies, a method repeated in many textbooks on radiation detection and measurements. These complicated calculations often include parallax effects as well. Although useful in determining the probability of an interaction occurring, and perhaps assisting with the overall determination of counting efficiency, these methods do not yield information on the energy deposited nor the expected spectral features. Monte Carlo techniques can instead be used to calculate the photon energy deposition and the resulting spectroscopic features and respective intensities with increased accuracy above that of previously used graphical and empirical methods.

Detector Geometries

Commercial scintillators can be acquired in a variety of geometries and configurations, ranging from individual crystals to integrated packages with light collection device, voltage divider, and preamplifier. Many of the alkali metal and halogen based scintillators, such as NaI:Tl, LiI:Eu, CLYC:Ce, SrI_2:Eu, $LaBr_3$:Ce and $CeBr_3$ are highly hygroscopic. Hence, commercial material is usually obtained already packed in a hermetically sealed reflective cannister that can be attached to a light collection device of choice. Large devices are

usually configured as right circular cylinders, while smaller devices can be obtained as either cylinders or cuboids. The cylindrical shape is convenient for coupling to common circular PMTs, while the small cuboid shapes are convenient for coupling to SiPMs. Proper selection of a scintillation crystal requires that the response function of the chosen light collector match the scintillator emission spectrum (see Sec. 13.2.2 and Fig. 13.3). Also, to avoid space charge distortion in a PMT, the response speed of the PMT should be fast enough to follow the light emissions. This requirement is especially important for bright and fast scintillators such as $LaBr_3$:Ce, $LaCl_3$:Ce, and $CeBr_3$. If a proper response speed is not selected, current crowding and space charge buildup result in a non-linear output (see discussions in Sections 13.2.3, 14.1.7, and 14.1.8). For high-energy gamma rays interacting in bright scintillators, similar problems occur with SiPMs in which the probability of coincident light photons interact in the SPADs (see Sec. 14.2.4).

Although commercial vendors may provide just the scintillator for custom work, it is far more common that scintillators are obtained already coupled to the light collection device. Hence, the total package is usually already optimized with the proper coupling compound, shielding, glass envelope, spectral response and electronic output. Commercial vendors quote the optimum operating conditions, including recommended voltage and count rate limitations. Specification sheets usually list the performance metrics mentioned above.

NaI:Tl, discovered by Hofstadter in 1948, remains the most commonly used scintillator for general gamma-radiation spectroscopy applications. The reasons for this widespread usage include its relatively low cost, the fact that large crystals can be produced, and the gamma-ray interaction efficiency is adequately large (because of the iodine component). The general application of NaI:Tl to radiation spectroscopy is reviewed by Smith and Kearfott [2018]. It is the 3 in $\times$ 3 in right circular cylinder of NaI:Tl that is quoted most often in performance comparisons to other spectrometers (scintillators and semiconductors), although a wide variety of NaI:TL sizes are available. Some of these alternative shapes include large plates for Anger cameras, pixelated arrays, well detectors, long bars, cuboids, spheroids, annuli for Compton suppression, and curved crystals.

Right Circular Cylinder Detectors The right circular cylinder is the most common geometry for scintillation detectors, mainly because the flat circular face conveniently couples well to cylindrical PMTs. The nomenclature for detector size is the diameter $\times$ length. For example, a 2 in $\times$ 3 in size describes a 2 in diameter by 3 in long detector. Common commercial sizes are 1 in $\times$ 1 in, 2 in $\times$ 2 in, 3 in $\times$ 3 in, and 5 in $\times$ 5 in, although some companies can provide custom sizes for an added charge. The common use of $m \times n$ dimensions where $m = n$ is with purpose, mainly, the light is distributed more uniformly over the photocathode of the PMT. This uniformity produces the best energy resolution, and deviations from this ratio have a poorer resolution. Solid angle corrections for cylindrical geometry are described in Sec. 7.4, and spectroscopic performance for NaI:Tl detectors are well documented by several authors [see for example Heath 1964; Crouthamel 1970].

Well and Annular Detectors Some scintillation detectors, called *well* detectors, are available as a cylinder with a blind hole or well drilled in them. These detectors are designed to perform, nearly, as a 4π detector, where the sample under investigation is placed at the bottom of the well. The probability that an isotropically emitted gamma ray enters the crystal is

$$P \approx .5 \left[1 + \frac{d}{\sqrt{d^2 + a^2}} \right], \tag{20.114}$$

where d is the well depth and a is the well radius. However, because of different attenuation lengths through the crystal, especially at corners, the probability of interacting in the detector changes with the gamma-ray trajectory. Further, as explained previously, the interaction efficiency (actually the interaction probability) does not describe the efficiency of total energy deposition. Hence, well detectors may increase the total

counting efficiency, but the intrinsic peak efficiency may suffer from added Compton losses at the extended boundary, especially as the gamma-ray energy increases.

If, instead, a smaller detector (small scintillator or semiconductor) is located inside the well, the well detector can be used as a Compton suppression coincidence detector (reviewed later in this chapter). Annular detectors are also used for Compton suppression, where the scintillation detector is a larger ring that surrounds a relatively large detector such as an HPGe detector. The annular detector may be a single annulus, or may be composed of annular segments that form the ring.

Position Sensitive Detectors A long bar of scintillator with a light detector at each end can be used as a position sensitive gamma-ray detector. Light radiates from the ionizing path of the particle, be it a photoelectron, Compton electron, or charges produced by pair production. This light generally decreases exponentially in magnitude as it propagates through the crystal. Consider the configuration of Fig. 20.20 where an ionizing event produces light originating at position x along a scintillator bar of length L. For isotropic generation of scintillation photons and with the same notation used in Sec. 13.2.2, PMT A produces an induced charge signal

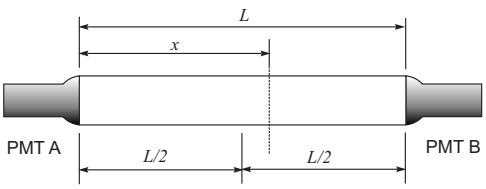

Figure 20.20. Depiction of a scintillator bar detector used for position sensitive measurements.

$$Q_A = f_A q_e M N_e E_n F_n C_{np} U_A e^{-\alpha x} \simeq K_A E_n e^{-\alpha x}, \qquad (20.115)$$

where E_n is the ionizing particle energy, q_e is the unit charge, F_n is the fraction of energy deposited in the detector, C_{np} is the average light conversion efficiency (light yield), N_e is the charge released from the photocathode, M is the PMT gain, f_A is the fraction of photons that propagate generally in the direction of PMT A, and U_A accounts for nonuniformities in light collection from geometrical effects, and α is the attenuation coefficient. The induced charge from PMT B is, therefore,

$$Q_B = f_B q_e M N_e E_n F_n C_{np} U_B e^{-\alpha(L-x)} \equiv K_B E_n e^{-\alpha(L-x)} \qquad (20.116)$$

The ratio of the PMT signals is

$$\frac{S_A}{S_B} \equiv \frac{Q_A}{Q_B} = \frac{K_A E_n e^{-\alpha x}}{K_B E_n e^{-\alpha(L-x)}} = C_1 e^{-2\alpha x + L} \qquad (20.117)$$

By adjusting the gain M of either PMT, the value of K_A can be made equal to K_B, hence C_1 becomes equal to unity. Carter et al. [1982] define $x' = x - (L/2)$ so that Eq. (20.117) yields

$$\frac{S_A}{S_B} = e^{-2\alpha x'}. \qquad (20.118)$$

Hence, taking the natural log of Eq. (20.118) yields a relationship for the interaction position

$$x' = \frac{1}{2\alpha} \ln\left(\frac{S_B}{S_A}\right) \qquad (20.119)$$

The corresponding standard error is

$$\sigma_{x'} = \frac{e^{\alpha L/4}}{2\alpha\sqrt{E_n}} \left(\frac{e^{\alpha x'}}{K_A} + \frac{e^{-\alpha x'}}{K_B}\right)^{1/2}. \qquad (20.120)$$

If $K_A = K_B = K$, then Eq. (20.120) becomes

$$\sigma_{x'} = \frac{e^{\alpha L/4}}{2\alpha}\left(\frac{e^{\alpha x'} + e^{-\alpha x'}}{E_n K}\right)^{1/2}. \tag{20.121}$$

Substituting Eq. (20.119) into Eq. (20.118) yields the interaction position

$$x = \frac{1}{2\alpha}\ln\left(\frac{S_B}{S_A}\right) + \frac{L}{2}. \tag{20.122}$$

and

$$\sigma_x = \frac{e^{\alpha L/4}}{2\alpha}\left(\frac{e^{\alpha(x-L/2)} + e^{-\alpha(x-L/2)}}{E_n K}\right)^{1/2}. \tag{20.123}$$

Finally, to find the initial gamma-ray energy E_n multiply Eqs. (20.115) and (20.116) to obtain

$$Q_A Q_B = K_A K_B E_n^2 e^{-\alpha L} = K^2 E_n^2 e^{-\alpha L}. \tag{20.124}$$

Then solving this result for E_n gives

$$E_n = \sqrt{\frac{Q_A Q_B}{K^2}}e^{\alpha L/2} = C_2\sqrt{S_A S_B}e^{\alpha L/2}, \tag{20.125}$$

where the constant C_2 accounts for signal conversion from the induced charges. From the results of Eqs. (20.119) and (20.124), it is shown that the linear position and energy of an event can be measured with the relatively simple arrangement of Fig. 20.20. For a NaI:Tl bar with dimensions of 5 cm × 5 cm × 50 cm long, Carter et al. [1982] report a position resolution for 661.7-keV gamma rays of 10 mm ± 10% at the center and approximately 12 mm ± 12% at the ends.

Pixelated scintillation detectors are banks of scintillator rectangular prisms fastened together with thin Lambertian layers called "separators". These separators range in thickness from 0.5 mm down to 0.04 mm depending on type, and differ in relative reflectivity, with powders of TiO_2 and MgO_2 being amongst the highest in both reflectivity and thickness. The light emissions from these segmented crystals are isolated; hence, by attaching the array to a position sensitive PMT or SiPM, the xy spatial location of an event can be determined [Saint Gobain, 2019b]. To increase light collection, a Lambertian reflector is applied over the array surface opposing the light detector. There are several types of commercial arrays of prismatic crystals, including CsI:Tl, BGO, LYSO, and $CdWO_4$. The prism sizes are constrained by material limitations, but are generally on the order of 0.3 to 0.8 mm long with side dimensions on the order of 0.3 to 1 mm.

These pixelated arrays are designed for radiation imaging such as computed tomography or other radiation imaging techniques. In principle, the same method described for linear position sensing can be used to determine the z spatial component, making the device a volumetric position sensitive device. However, because of the small prism sizes, Compton escapes into adjacent crystals are relatively probable. To ameliorate this effect, the output can be summed to assist with energy identification and to increase the overall intrinsic peak efficiency. The energy resolution, however, is decreased because of the variation in energy lost in the insensitive separator layers.

An alternative approach has been to grow columnar structures of CsI:Tl, each crystal column being on the order of a micron in diameter and typically are less than 600 microns long, but apparently special units up to 1.5 mm can be obtained [Bugby et al. 2016]. The columns perform as optical light guides that direct light to the column ends. Due to the small thickness, this imaging scintillator is best used for x-ray energies.

The columnar crystal structure is attached to a photon imaging device, which delivers the xy spatial position. A reflective coating can be used to help collect light that transports, initially, in the opposite direction of the position sensitive light detector. Plates on the order of 440 mm × 440 mm are commercially available [Hamamatsu 2016].

Ruggedized Units Many scintillators are extremely fragile, and mishandling can lead to catastrophic fractures induced by mechanical shock that can permanently damage the crystal. However, there are certain ruggedized designs that resist this problem. For instance, polycrystalline NaI:Tl compressed under high temperature conditions can eliminate differences in the index of refraction at the grain boundaries. Hence, light transports through the device in the same fashion as a single crystal. However, fractures induced in a single crystal grain are confined to that grain and do not propagate across the device. These ruggedized units have been developed for the oil well logging industry to meet the stringent demands on instrumentation for in situ measurements, including heat resistant seals and electronics.[7]

Low Background and Low Energy Detectors For low-level radiation measurements, special units composed of scintillators and supporting electronics with relatively low background levels are commercially available. Much of the low-level background contamination comes directly from ^{40}K in the PMT glass envelope. The problem is greatly mitigated by using purified quartz as the PMT envelope, or at least as the main coupling window. Also, the metal housing is made with purified low background stainless steel or copper. The scintillator itself may be contaminated with a background source.[8] Hence, careful selection of purified scintillators without radioactive constituents is preferred.

Low energy gamma- and x-ray applications require special crystal thicknesses that are adequately efficient only at low energies, with higher energy photons either passing through without interaction or depositing only a fraction of their energy. Also, the thickness and material of the entrance window must be altered to allow the efficient passage of low-energy photons. Common choices are beryllium and aluminum, with the former having an energy range between 3 to 100 keV with the latter having an energy range between 10 to 200 keV. Note that NaI:Tl is often selected for low-energy low-background scintillation detectors. The relative light yield at low energy increases (see Fig. 13.4), improving the crystal performance at energies below approximately 100 keV. The phoswich detector, presented later in this chapter, is another detector configuration specifically designed for low-energy gamma-ray measurements. Anti-coincidence methods can reduce the number of Compton scattering events, thereby enhancing the appearance of the gamma-ray full energy peaks.

Energy Resolution

The energy resolution describes the spectroscopic performance of a scintillation. For scintillators this particular metric is traditionally reported as a percent FWHM of the peak energy

$$\text{FWHM}_{\%} = 100\frac{\Delta E}{E_\gamma}, \tag{20.126}$$

where ΔE is the FWHM in units of energy. It is common to quote energy resolution for scintillation detectors at 661.7 keV for gamma rays from ^{137}Cs. Typical energy resolution ranges from approximately 3% FWHM at 661.7 keV for some of the high-performance scintillators ($LaBr_3$:Ce, $CeBr_3$, CLLB:Ce), while traditional scintillators such as NaI:Tl have energy resolution on the order of 7% FWHM at 661.7 keV, or approximately 47 keV FWHM. The energy resolution affects the ability to distinguish neighboring gamma-ray energies. Hence, gamma-ray peaks closer than 47 keV apart significantly overlap.

[7] For instance, the Polyscin® NaI:Tl detector developed by Saint Gobain Crystals is designed to withstand shock and vibration for temperatures between 55°C and 205°C.

[8] Such as ^{138}La and ^{227}Ac in $LaCl_3$ and $LaBr_3$.

The energy resolution of a scintillator is a function of multiple processes, which include the light conversion efficiency, the relative light yield linearity, light collection efficiency, and conversion gain and linearity of the light detector. Given an average photon yield per energy deposited, the percent energy resolution can be generally described by Eq. 13.36, rewritten here as

$$\text{FWHM}_{\%} \approx 235.5\sqrt{\frac{1.1}{\overline{N}}}, \tag{20.127}$$

where $\overline{N}$ is the average number of photons released for the energy under investigation. Assume that the value of $\overline{N}$ is a linear function of the gamma-ray energy, where

$$\overline{N} = C_{np}E_{\gamma} \tag{20.128}$$

and C_{np} is average light yield per MeV. Then

$$R = \text{FWHM}_{\%} \approx 235.5\sqrt{\frac{1.1}{C_{np}E_{\gamma}}} = C_1 E_{\gamma}^{-1/2}, \tag{20.129}$$

where C_1 is a constant. Beattie and Bryne [1972] show that Eq. (20.129) can be described as a linear equation

$$\ln(R) = \ln(C_1) - \frac{1}{2}\ln(E_{\gamma}) \tag{20.130}$$

as plotted in Fig. 20.21 for several gamma ray energies recorded with a NaI:Tl detector.

As a general rule, bright scintillators are sought because the increased photon yield should increase the value of $\overline{N}$, and from Eq. (20.127) should also improve the energy resolution. However recall from Sec. 13.2.2 that linearity of the relative light yield also has a significant effect. For example, from Table 13.1, NaI:Tl has a light yield of 43000/MeV, while $LaBr_3$:Ce has a light yield of 63000/MeV. Hence, it would be expected that $LaBr_3$:Ce would have approximately 1.21 times improved energy resolution over similar sized NaI:Tl detectors. However, energy resolution also depends on spectral matching to the light collection device and the linearity of the relative light yield. From Fig. 13.3, NaI:Tl matches better to common PMTs than does $LaBr_3$:Ce, yet comparing Figs. 13.4 and 13.5, $LaBr_3$:Ce has a superior linear response at low energies. Consequently, the energy resolution of $LaBr_3$:Ce is far superior to that of NaI:Tl than might be surmised from Eq. (20.127), as can be observed by the spectral comparisons in Fig. 20.22. Overall, energy resolution generally improves with scintillator brightness and relative light yield linearity.

Peak-to-Total Ratio

Shown in Fig. 20.23 are PTR values for several NaI:Tl detector sizes, source distances, and gamma-ray energies. Intuitively, the PTR decreases with increasing gamma-ray energy and increases with detector size [Leutz et al. 1966], being best for a collimated gamma-ray beam striking the detector. From Fig. 20.23, it is also notable that the PTR is nearly the same for similar detector sizes regardless of source distance and collimation. The PTR increases, generally, with the effective Z and mass density of the scintillation material. Shown in Fig. 20.24 are calculated PTR values as a function of energy for several different commercial scintillator materials. Clearly the materials with higher Z components have the highest peak-to-total ratios, while the lightest material shown (CaF_2) has the lowest.

Intrinsic peak efficiency

Because the PTR is the ratio of $\epsilon_{\text{peak}}/\epsilon_{\text{I}}$ (see Eq. (20.113)), it is also noted that the full energy peak efficiency increases with PTR. When counting efficiency is most important, for instance in medical imaging applications, then often materials with high Z, and ultimately a high PTR, are attractive choices. Materials that

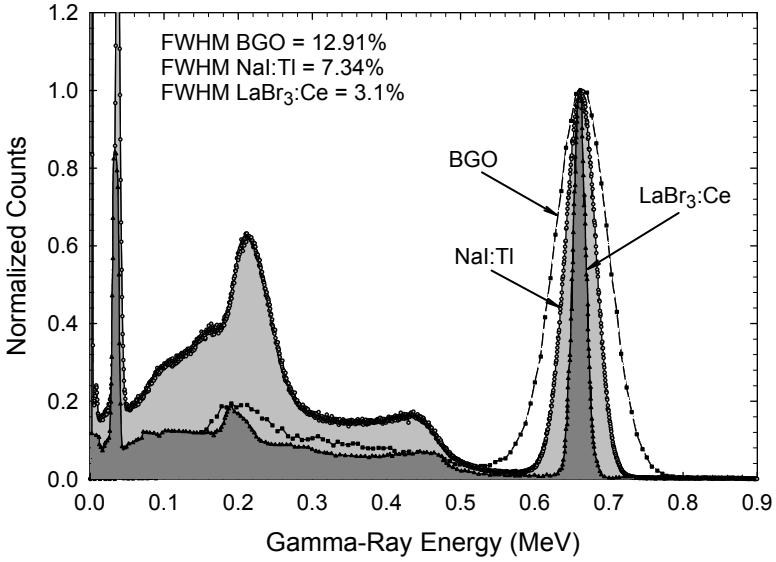

Figure 20.22. Comparison of normalized spectral performance for a 2×2 NaI:Tl detector, a 2×2 $LaBr_3$:Ce detector, and a BGO detector of similar size for 662 keV gamma rays from ^{137}Cs. BGO data from Vincke et al. [2002] and $LaBr_3$:Ce data from Quarati et al. [2007]. NaI:Tl data courtesy of Taylor Ochs, KSU.

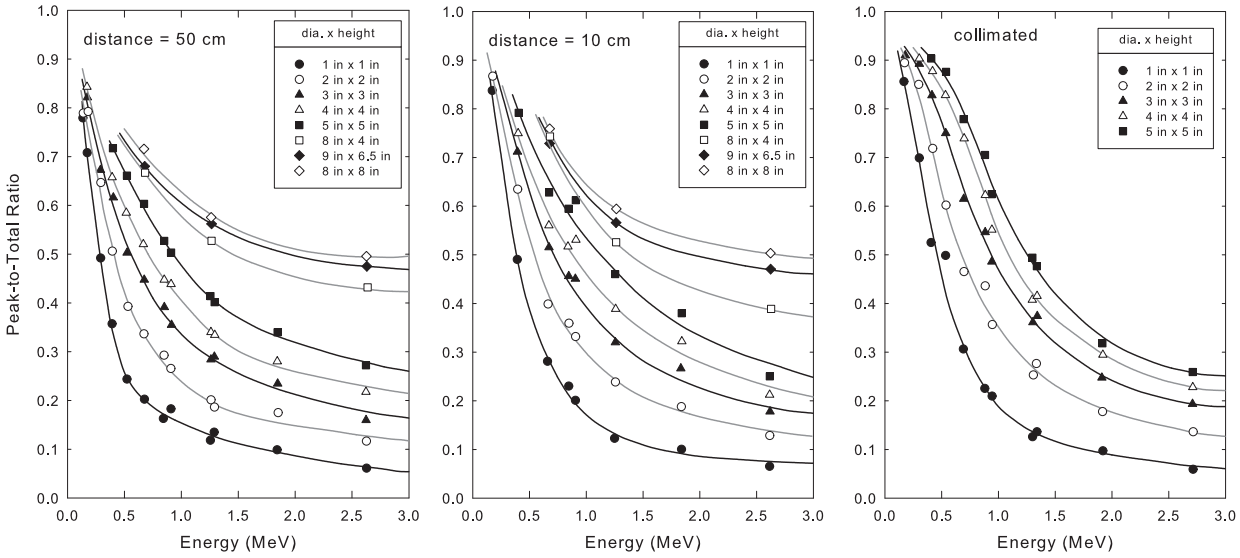

Figure 20.23. Peak-to-total ratios for NaI:Tl detector of different sizes for different gamma ray energies, showing from left to right the results of a point source located 50 cm from the face center, 10 cm from the face center, and a collimated beam 0.7 cm diameter. Data from Leutz et al. [1966].

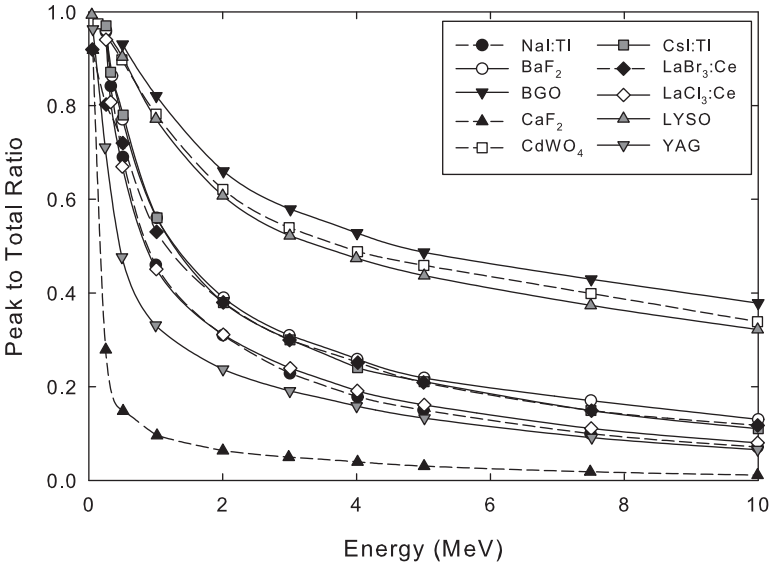

Figure 20.24. Monte Carlo calculated comparisons of peak-to-total ratios for a collimated beam of gamma rays for several commercial scintillators. The data is for 3 in $\times$ 3 in right circular cylinders. Data from Saint Gobain [2016].

generally have high Z elements typically have better intrinsic peak efficiencies than those composed of low Z materials. For instance, the plot in Fig. 20.24 indicates that BGO should have a relatively higher intrinsic peak efficiency than $LaBr_3$:Ce, which should have higher peak efficiency than NaI:Tl. This correlation can be observed from the normalized spectra shown in Fig. 20.22, where clearly BGO has the highest ϵ_{peak} value while NaI:Tl has the lowest ϵ_{peak} value of the three scintillators in the example. Note also that the Compton continuum has relatively more counts for the NaI:Tl detector than either the BGO or $LaBr_3$:Ce detector, an indication that the NaI:Tl detector has more scattered photon losses. Overall, the plots like Fig. 20.24 can also yield some indication of the expected intrinsic peak efficiencies.

Summary

The primary disadvantages of scintillator spectrometers are (1) that a photon detector such as a PMT must be incorporated into the device and (2) that the energy resolution is inferior to that of a semiconductor spectrometer. Historically, scintillation crystals were coupled to PMTs so that the spectrometers were fragile and bulky. A special μ-metal is also needed to shield the PMT from magnetic fields. Modest success was realized with the coupling of scintillators to semiconductor photodiodes, yet the energy resolution was inferior to that obtainable with a PMT. The introduction of the silicon photomultiplier (SiPM) has greatly reduced the problem of fragility of PMTs and their bulkiness while nearly preserving the energy resolution achieved with PMTs. Scintillator spectrometers of many varieties coupled to SiPMs are now commercially available as rugged and compact devices unaffected by magnetic fields and provide nearly the same energy resolution as their PMT-coupled counterparts. Regardless of these new benefits, the spectroscopic performance of scintillators remains inferior to semiconductor spectrometers, especially to that of high-purity Ge and Si spectrometers (see Fig. 20.25).

20.5.4 Spectroscopy with Semiconductors

The physics and performance of semiconductor detectors are described in Chapters 15 and 16, including sections on device designs, efficiencies, and energy resolution. A few more details are offered here that are pertinent to radiation spectroscopy with semiconductor detectors. Otherwise, the general discussions on spectroscopy found elsewhere in this chapter also apply to semiconductor detectors.

IEEE Standard for HPGe Peak Efficiency The detection efficiency of a HPGe detector is defined in ANSI 325-1996, and is actually an absolute efficiency under a specific geometry. A calibrated point ^{60}Co source is placed exactly 25 cm from the center of the cryogenic end cap face of a HPGe detector. The source activity is calculated and the total number of counts appearing in the 1332.5 keV full energy peak is divided by the total number of 1332.5-keV gamma rays emitted by the source during the measurement. The ANSI 325-1996 document suggests that a pulser set at an energy channel 5% higher than 1332.5 keV ($\approx$ 1400 keV) can be used for timing calibration.[9]

A background measurement is conducted without the ^{60}Co source present. After subtracting the background spectrum (as described earlier in Sec. 20.5.2), the *absolute* efficiency of the HPGe detector is then quoted as

$$\eta_a = 100\frac{A_p}{N_s}\%, \tag{20.131}$$

where A_p is the integrated number of counts (area of) in the 1332.5-keV background-corrected full energy peak and N_s is the total number of 1332.5-keV gamma rays emitted by the ^{60}Co source during the measurement live time. It is assumed any source or air absorption is negligible.

[9] The concrete of radiation counting laboratories may be contaminated with ^{40}K, which emits a 1460.8 keV gamma ray. Although the energy 1400 keV falls in the Compton gap of the ^{40}K spectrum, the possible interference from ^{40}K can be eliminated altogether by setting the pulser at 15% above 1332.5 keV (1530 keV).

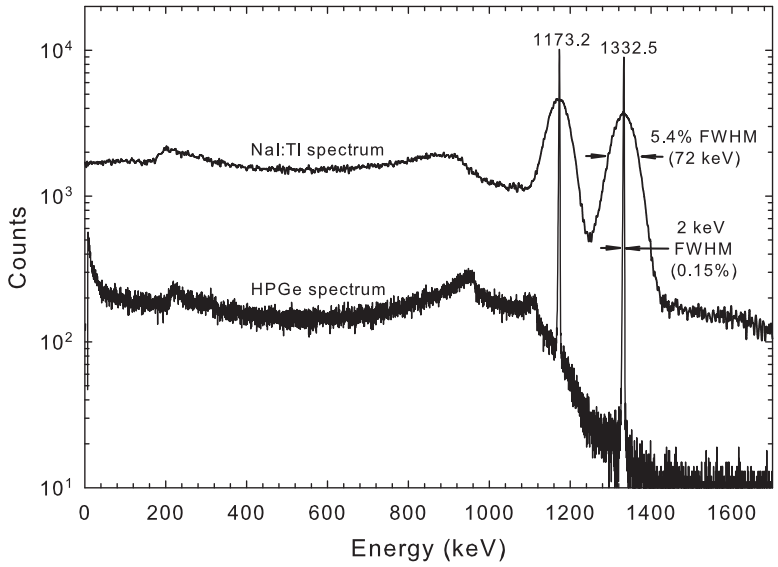

Figure 20.25. Comparison gamma-ray spectra of ^{60}Co taken with a NaI:Tl detector and an HPGe detector.

Traditionally, the efficiency of a HPGe detector is quoted as a relative comparison to the expected efficiency of a 3 in × 3 in (or 7.62 cm × 7.62 cm) NaI:Tl detector.[10] Such an efficiency is referred to as the *relative* efficiency. The expected number of counts per unit activity in the 1332.5-keV full energy peak of such a NaI:Tl detector, when set back 25 cm from the source, is well established as 0.0012 cps per Bq. The measurement is conducted, as before, with a calibrated ^{60}Co source placed exactly 25 cm from the center of the cryogenic end cap face of a HPGe detector. After first subtracting the background spectrum, the relative efficiency is found as

$$\eta_{rel} = 100\frac{A_p}{0.0012 \times A_{^{60}\mathrm{Co}}}\%, \tag{20.132}$$

where $A_{^{60}\mathrm{Co}}$ is the activity of the source at the time of the measurement. It is this relative efficiency that is usually quoted for coaxial HPGe detectors. However, because other (non-coaxial) HPGe detector configurations may not be efficient at 1332.5 keV, the relative efficiency is usually not used for non-coaxial designs. Usually the manufacturer makes clear the standard being used to report detector efficiency.

Reporting Energy Resolution The energy resolution dependence for semiconductors was derived in Sec. 16.3.2, repeated here for convenience,

$$\mathrm{FWHM}_{\mathrm{energy}} = 2\sqrt{2\ln(2)wFE_n} \approx 2.355\sqrt{wFE_n}, \tag{16.24}$$

where w is the average ionization energy, E_n is the radiation particle energy, and F is the Fano factor. For semiconductor detectors the energy resolution is traditionally reported in units of keV for both gamma-ray and charged particle detectors. The reason for this standard is that the energy resolution is generally below 1% FWHM for high-performance semiconductors, and reporting the FWHM in terms of percent generally is less descriptive than reporting the actual energy. Regardless, there has been a departure from this historic

[10] This historic standard dates from the early introduction of semiconductor detectors, when it was common to directly compare efficiency to what had become the standard for gamma-ray spectroscopy, the 3 × 3 NaI:Tl detector.

standard for some of the lower resolution compound semiconductors, and often the energy resolution FWHM is reported in terms of percent for compound semiconductors.

HPGe detector energy resolution has historically been measured at 1332.5 keV (one of the gamma rays emitted by ^{60}Co) and is also the IEEE standard. However, because compound semiconductors are typically smaller and have less efficiency at 1332.5 keV, the energy resolution of these devices is commonly reported at 661.7 keV (a gamma ray emitted by ^{137}Cs). Si(Li) detectors are relatively inefficient at energies below 60 keV, and are generally reserved for use at lower energies. Typical gamma-ray energy resolution is on the order of approximately 2 keV FWHM at 1332.5 keV for some of the high-performance HPGe detectors, and around 200 eV FWHM at 5.9 keV for Si(Li) x-ray detectors. The more mature compound semiconductors (CdTe, HgI_2, CdZnTe) typically have between 6 to 20 keV FWHM at 661.7 keV.

20.6 Factors Affecting Energy Resolution

The energy resolution achievable from a spectrometer is largely determined by the average energy required to produce a fundamental signal carrier, statistical fluctuations in signal carrier production, non-linearity in signal carrier production, and electronic noise. Energy resolution is also compromised by non-linear light yield in scintillators. In semiconductors, charge carrier recombination and trapping produces non-linear charge collection and affects the resolution. Electronic noise also adds to the variance in the pulse height distribution. Common factors that affect the energy resolution of radiation spectrometers are discussed below, with the emphasis on scintillation and semiconductor spectrometers. Also discussed are the primary sources of electronic noise, which also affects the resolution.

Variation in Charge Collection

The production of information carriers in a spectrometer is usually modeled as a Gaussian process. For instance, the average number $\overline{N}_{eh}$ of electron-hole pairs produced by a gamma-ray in an HPGE semiconductor detector is the gamma-ray energy absorbed E_γ divided by the average ionization energy w. In Sec. 16.4.2, a Fano factor F was used to correct for differences from Gaussian predications, i.e., $\sigma^2(\overline{N}_{eh}) = F\overline{N}_{eh}$. For semiconductors, the Fano factor is usually on the order of 0.1, but varies between materials as can be seen from Table 16.2. Hence, the energy resolution in terms of energy is defined by

$$\mathrm{FWHM}_{\mathrm{energy}} = 2\sqrt{2\ln(2)}\sigma_{eh}(f)E_\gamma = 2.355\sqrt{wFE_\gamma}. \tag{20.133}$$

It is apparent the FWHM increases as the square root of the gamma-ray energy. Traditionally, the energy resolution of a semiconductor spectrometer is reported in units of keV. However, for some applications, the percent energy resolution is of interest, namely

$$\mathrm{FWHM}_{\%} = 235.5\sqrt{\frac{wF}{E_\gamma}}\ \%. \tag{20.134}$$

Equations (20.133) and (20.134) are relatively good predictors for well-behaved semiconductors that do not suffer from severe recombination or trapping. However, large losses from charge carrier trapping cause the full energy peak to distort, as shown by examples in Sec. 15.5.1, with the development of a low-energy tail on the low-energy side of the full energy peak. If trapping is severe, the tail can cause such a large distortion that a full energy peak is difficult or impossible to discern.

Scintillator Non-linearities

Another source of variance in the number of signal carriers is due to a non-linear light yield response to deposited gamma-ray energy in many scintillators as shown in Figs. 13.4 and 13.5. Although the average photon yield is often estimated by the product E_γ and the average light yield per unit energy (photons/MeV),

such an estimate is based on a linear response. For many scintillators, the non-linearity in light yield can be severe for gamma-ray energy deposition below 500 keV. Hence, the manner by which a photon interacts in the scintillator affects the total light yield. For example, a 1.332-MeV gamma ray completely absorbed by the photoelectric effect produces less light in NaI:Tl than if the photon scattered twice, depositing approximately 400 keV for each scatter before finally being absorbed by the photoelectric effect. Even though the same amount of energy is absorbed in both cases, the amount of light produced is different and, thus, increases the variance in the output signal. Consequently, scintillators with a linear response, but perhaps lower light yields, can still perform well. An example is YAP:Ce, which is a linear scintillator with about 40% of the light yield produced by NaI:Tl. Although not as bright, the energy resolution of YAP:Ce has been reported at 4.4% FWHM at 661.7 keV, much lower than NaI:Tl (typically greater than 6% FWHM at 661.7 keV). The output from the light collection device, a PMT for example, also contributes to the total variance as quantified by Eq. (13.30). Traditionally, the energy resolution at FWHM is reported in terms of percent for scintillators.

Electronic Noise

Electronic noise arises from fluctuations in the speed and number of electrons and is present in both pulse mode and current mode detector systems. The fluctuations may be from thermal effects, leakage currents, or generation-recombination effects and may originate in the actual detectors and/or in the system electronics. Regardless of the source, electronic noise determines the minimum FWHM energy resolution that is possible for a given detector and its associated electronics. Noise from current fluctuations is commonly named *parallel noise*, while noise from voltage fluctuations is often called *series noise*. Thermionic leakage current from a reverse biased diode produces *shot noise*, while resistors produce *Johnson noise*. The appearance of so-called periodic $1/f$ noise, where f is the noise frequency, is a consequence of non-random emissions, such as carrier generation and recombination, or trapping and detrapping, in the detector or system electronics. The goal in designing a detector system is to reduce the electronic noise as much as possible, so as to improve the signal-to-noise ratio η (SNR), defined as the ratio of the detector mean signal pulse voltage $\mathrm{V_{avg}}$ to the square root of the mean-square noise voltage (the variance in the noise V_n^2), i.e.,

$$\eta = \frac{V_{\mathrm{avg}}}{\sqrt{V_n^2}}. \tag{20.135}$$

As discussed in Chapter 22, if the noise is modeled as a Gaussian distribution, then the contribution to the detector and system energy resolution can be approximated by

$$\frac{V_{\mathrm{FWHM_{noise}}}}{V_{\mathrm{avg}}} = 2.355\frac{V_n}{V_{\mathrm{avg}}}. \tag{20.136}$$

Ultimately, this contribution to the variance must be added, by error propagation, to the other resolution limiting variances to predict the overall detector resolution

$$\begin{aligned}\mathrm{FWHM} = \big[&(\mathrm{FWHM_{noise}})^2 + (\mathrm{FWHM_{trap}})^2 \\ &+ (\mathrm{FWHM_{eh}})^2 + (\mathrm{FWHM_{non-linear}})^2 + \ldots\big]^{1/2}.\end{aligned} \tag{20.137}$$

The electronic noise component $\mathrm{FWHM_{noise}}$ can be measured by inserting an electronic pulser into the system. The pulser delivers a constant voltage pulse into the system, usually through the preamplifier, and the FWHM of the pulse can be directly measured. The square of this measurement can be subtracted from the square of Eq. (20.137) to determine the limiting resolution of the actual detector.

20.7 Experimental Design

Proper experimental design can make the difference between an accurate and a questionable measurement. Previously in Chapter 6 there was some discussion about the minimal detectable activity (MDA) and the critical detection limit (CDL). These measurements are used when the radiation activity of interest is similar to that of the background. There are also situations in which discernment between similar energies is important, an issue partly covered in Sec. 20.4.8 of this chapter. Rather than just start by making measurements, an experimental outcome can be generally much improved by designing a procedure or protocol for the experiment before the taking measurements. Some experimental design considerations are described here.

20.7.1 Optimization of Measurement Time

Sometimes the time allocated t_A to an experimenter to use a particular system that is in high demand is limited, such as with a low-level deep-underground counting facility. In such cases it is important to optimize the counting times for the background and the source or foreground measurements so as to minimize the uncertainty in the background corrected source measurements.

A Single Source Measurement

In this case the allowed time t_A must be divided between the time t_G for the foreground or source measurement and the time t_B for the background measurement. Typically, the background count rate b is subtracted from the count rate g observed for the source measurement to determine the net counting rate n, and the two independent measurements are used to calculate the experimental error. Minimizing this error can be achieved by optimizing the foreground measurement time t_G and the background measurement time t_B, subject to the constraint $t_A = t_G + t_B$. The radiation counting rate g, which represents contributions from both the radioactive or foreground source and the background, is

$$g = \frac{G}{t_G}, \tag{20.138}$$

where G is the total number of counts recorded during time t_G. The background counting rate is

$$b = \frac{B}{t_B}, \tag{20.139}$$

where B is the total number of background counts recorded during time t_B. The net counting rate is

$$n = g - b = \frac{G}{t_G} - \frac{B}{t_B}, \tag{20.140}$$

The estimated net counting error, as derived in Sec. 6.9.2, is

$$\sigma(n) = \left[\frac{G}{t_G^2} + \frac{B}{t_B^2}\right]^{1/2} \tag{20.141}$$

or

$$\sigma^2(n) = \frac{g}{t_G} + \frac{b}{t_B}. \tag{20.142}$$

To optimize this result with the total allowed time fixed at $t_A = t_G + t_B$ Eq. (20.142) is differentiated as

$$\frac{d\sigma^2(n)}{dt_G} = \frac{d}{dt_G}\left\{\frac{g}{t_G} + \frac{b}{t_B}\right\} = -\frac{g}{t_G^2} + \frac{b}{(t_A - t_G)^2} \tag{20.143}$$

and this result is set to zero to find t_G/t_B to produce the minimum σ_n^2. The result is

$$\frac{g}{t_G^2} = \frac{b}{(t_A - t_G)^2} = \frac{b}{t_B^2} \tag{20.144}$$

or

$$\frac{t_G}{t_B} = \sqrt{\frac{g}{b}}. \tag{20.145}$$

This result may seem counter-intuitive because it implies that the higher the source count rate is to the background count rate, the smaller is the fraction of the available time that should be given to determine b. But if $g \gg b$, then the background has a very minor influence on the net count rate and hence need not be determined very accurately. However, there is one obvious problem with this optimization procedure. To use it, the experimenter must already have knowledge of the expected background count rate b and the expected radiation response rate g. Such *a priori* knowledge must be obtained from past experience or initial measurements of small duration.

20.7.2 Discernment Between Two Outcomes

Determination of the appropriate number of counts in a measurement is straightforward for a measurement with little or no background and no overlapping energy peaks. However, for low-level counting and for identification of isotopes emitting gamma rays of almost equal energies, it is necessary to design the experiment to discern the correct result among multiple possibilities.

Suppose there is a measurement background with rate b recorded by your detector and you have a sample which yields a count rate g with a source. This result can be for any source that deposits sufficient energy to provide a count in the measurement. Hence, g is the sum of the background count rate b and the source count rate or net rate n. The problem is that the measurement of g includes both background and source detector events. Typically, it is sufficient to simply subtract the background rate from g to obtain n, but at times the rate of the measurements may be extremely low. Hence, some understanding of the minimum number of total counts required is necessary.

If the background measurement time is t_B and source measurement time is t_G, how many counts must be recorded to provide confidence in the measurement? For a Gaussian model, the average number of background counts is

$$\overline{B} = bt_B \pm \sqrt{bt_B}, \tag{20.146}$$

and the average number of recorded source counts is

$$\overline{G} = gt_G \pm \sqrt{gt_G}. \tag{20.147}$$

If gt_G is relatively large compared to bt_B, then it is easy to distinguish between the two measurements. However, if gt_G is similar to bt_B, it is difficult to determine the actual source activity. This problem is addressed in Sec. 6.10.1, in which the minimum detectable activity (MDA) and critical detection limit (CDL) were examined and practical results were determined. Here the discernment between two possible outcomes is considered.

Consider a situation in which identification of a collection of events is a function of a theoretical average. The tallied events may be a collection of counts or a collection of pulse heights. If the outcome of two such averages are similar, how does one identify the proper outcome? For instance, if two gamma-ray energies from different isotopes are similar, how does one identify the proper isotope? Detectors with high energy resolution reduce this uncertainty, a consequence of the Gaussian spread about the peak channel, but do not totally eliminate the uncertainty. A similar situation exists in radiation counting where two predictions from

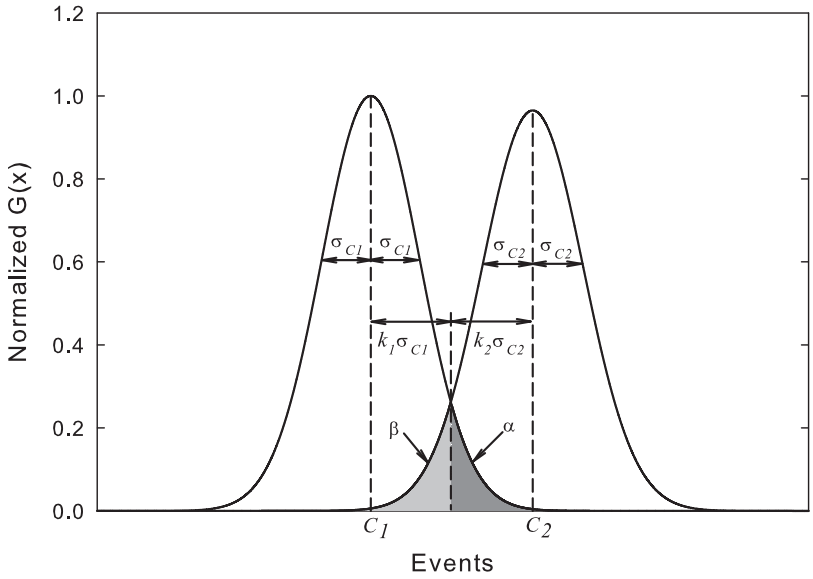

Figure 20.26. The situation in which two similar possible experimental outcomes exist, either $C_1 = c_1 t$ or $C_2 = c_2 t$.

different phenomena (e.g., counting rate or efficiency) may be similar. Hence, a measurement is conducted that results in a collection of counts within a time period, the outcome of which can be easily misinterpreted.

Assume a count rate c_1 for one outcome and a count rate of c_2 for a second but similar outcome. The total number of events is either $c_1 t$ or $c_2 t$ where t is the observation time. In either case, the expected outcome has experimental uncertainty such that the number of events observed for $c_i t$ is

$$C_i = r_i t \pm \sqrt{r_i t}, \qquad i = 1, 2. \tag{20.148}$$

What then is the probability of an incorrect conclusion? The situation is best understood with the help of Fig. 20.26. If the outcome is identified as the average count rate c_1, what is the probability that it is actually c_2, and if c_2 is chosen, what is the probability that it is actually c_1? The uncertainty in this situation can be decreased by first deciding on an acceptable error $k\sigma$, and then conducting a measurement to ensure that adequate counts are acquired. Note that the average count rate does not change for either situation, but the uncertainty for either situation decreases as more counts are accumulated.

The probability distributions for C_1 and C_2 are assumed to be Gaussians, and a portion of the two probability distributions overlap, represented by the shaded area in Fig. 20.26. If a condition is set that the outcome is identified as C_1 provided that the measured result is below $C_1 + k_1\sigma(C_1)$, where k_1 is the number of standard deviations from the mean of C_1, then the shaded area β represents the probability that the outcome is actually C_2. If instead the outcome is identified as C_2 if the measured result is above $C_1 + k_1\sigma(C_1)$, then the shaded area α represents the probability that the outcome is actually C_1. The difference between the averages of the two possible outcomes is represented by

$$\Delta C = C_2 - C_1 = [k_1\sigma(C_2) + k_2\sigma(C_1)], \tag{20.149}$$

where k_2 is the number of standard deviations from the mean of C_2. Because the two distributions are relatively close, it can be assumed that at the crossover point $k_1 \simeq k_2$ so that

$$\Delta C = C_2 - C_1 \simeq k(\sigma(C_1) + \sigma(C_2)) = k(\sqrt{C_1} + \sqrt{C_2}). \tag{20.150}$$

From this result

$$C_1 = C_2 - k(\sqrt{C_1} + \sqrt{C_2}). \tag{20.151}$$

The measurement time can now be adjusted to increase the value of k by increasing the C_i, which are related by

$$k = \frac{C_2 - C_1}{\sqrt{C_1} + \sqrt{C_2}}. \tag{20.152}$$

The theoretical outcomes C_1 and C_2 are calculated from the measurement time t. For example, if $k = 1.65$, then the shaded area α or β represents 5% of either Gaussian distribution and indicates the possibility of a 5% error for either outcome at the point $C_1 + k\sigma_{C1}$. To decrease this error to only 1%, then the calculated outcomes must change such that $k = 2.33$, which can be accomplished by increasing the measurement time t.

Example 20.6: An experimental neutron detector is under development that uses a semiconducting compound with boron as a constituent in the form of B_4C. These films are usually grown on well-established semiconductors such as Si. Because B_4C is difficult to produce, the layers are very thin. However, boron is a p-type dopant in Si, and instead of a thin B_4C semiconductor detector, the device may actually be a boron-coated pn-junction Si diode. For thin films, it is difficult to discern between the two possible outcomes. Find an expression to determine the measurement time required to fulfill the desired confidence for any k given a film thickness x and monodirectional thermal-neutron beam of intensity ϕ_n normally incident on the film.

Solution:

The counts obtained in measurement time t from a bulk device should be

$$C_2 = \phi_n A t \left(1 - \exp[-x\Sigma_F]\right),$$

where ϕ_n is the neutron flux intersecting the detector, A is the area, Σ_F is the macroscopic cross section of the film material, and x is the thickness. The counts from a coated device can be described by the ratio of counts recorded from thin-film device to a that of a bulk device, namely

$$C_1 = \phi_n A t \frac{\epsilon_{TF}}{\epsilon_{BK}} \left(1 - \exp[-x\Sigma_F]\right),$$

where ϵ_{TF} is the expected efficiency from the thin-film device and ϵ_{BK} is the efficiency of the bulk device. The difference between the two possible outcomes is

$$C_2 - C_1 = \phi_n A t \left(1 - e^{-x\Sigma_F}\right)\left(1 - \frac{\epsilon_{TF}}{\epsilon_{BK}}\right) = k\left(\sigma_{TF} + \sigma_{BK}\right).$$

Square the expressions,

$$\left[\phi_n A t \left(1 - e^{-x\Sigma_F}\right)\left(1 - \frac{\epsilon_{TF}}{\epsilon_{BK}}\right)\right]^2 = k^2\left(\sigma_{TF} + \sigma_{BK}\right)^2.$$

From this result the measurement time is found to be

$$t = \frac{k^2}{\phi_n A} \frac{\left(\left[\frac{\epsilon_{TF}}{\epsilon_{BK}}\left(1 - e^{-x\Sigma_F}\right)\right]^{1/2} + \left[\left(1 - e^{-x\Sigma_F}\right)\right]^{1/2}\right)^2}{\left[\left(1 - e^{-x\Sigma_F}\right)\left(1 - \frac{\epsilon_{TF}}{\epsilon_{BK}}\right)\right]^2}.$$

20.7.3 Coincidence and Anti-Coincidence Measurements

Detectors can be connected to interact together so as to record or reject events from radiation interactions. For instance, two detectors may be connected in such manner that both must receive a radiation interaction and produce a pulse within a certain time period Δt in order to record a count. Interaction events that do not comply with this restriction are rejected. Such measurements are named *coincidence counting*. Further, with spectrometers, an energy window can be used for one or more detectors to reduce the recording of down-scattered or background gamma-ray coincidences. The opposite case can also be employed so that, if two or more detectors record radiation interactions within a time Δt, all detectors reject the events. This mode of operation is named *anti-coincidence counting*. The operation of such systems is summarized in Chapter 21.

Compton Suppression

Compton suppression is an anti-coincidence method used to enhance the full-energy peaks in a gamma-ray pulse height spectrum. In this method the gamma-ray spectrometer is surrounded by a second detector (or a ring of detectors). For example, a HPGe detector is often used as the spectrometer, with a scintillator detector (or detectors), formed into a ring around the HPGe detector, operated as a coincidence detector. Because the total coincidence energy is of less concern than the recording of a full-energy event in the HPGe detector, low-resolution scintillators with relatively high gamma-ray absorption efficiency are preferred (e.g., BGO and NaI:Tl). With this configuration an incident photon that Compton scatters in the HPGe detector and then escapes has a reasonable chance of subsequently interacting in the surrounding scintillation detector(s). Both interactions occur at almost the same time. The partial photon energy deposited by the Compton scattered photon in the HPGe detector can thus be suppressed by an anti-coincidence gate that accepts only pulses in the HPGe detector that are anti-coincident with pulses in the scintillator(s). Thus, events in the HPGe detector are recorded only if no simultaneous event occurs in the surrounding scintillator detector(s). The resulting HPGe spectrum has a much reduced Compton continuum at all energies, thereby enhancing the full-energy peak in the spectrum. Dramatic improvements in the pulse height spectrum can be achieved [Molnar 2004; Bender et al. [2015]. Example spectra recorded with the technique are shown for $LaBr_3$:Ce in Fig. 20.27 and HPGe in Fig. 20.28, both having an annular NaI:Tl guard detector for the coincidence gate [Bender et al. [2015].

The Compton suppression method can be used to improve significantly prompt gamma-ray analyses. Because prompt gamma rays tend to be of high energy (most are $1 < E < 12$ MeV) there normally is a large Compton component to the spectra, especially for relatively small semiconductor detectors. Suppression of the Compton continuum with the anti-coincidence method, thus, produces a pulse height spectrum in which full-energy peaks are more easily identified and quantified.

Positron Emission and Pair Production

Recall that when a positron comes nearly to rest, it combines with an electron to produce two 511-keV annihilation photons. These 511-keV photons are emitted in opposite directions in order to preserve the zero total linear momentum.[11] If two detectors are placed on opposite sides of a source emitting positrons isotropically (such as ^{22}Na), the two detectors can be connected such that a count is tallied only when both detectors record a count within a small time interval Δt. The probability of recording a count is determined by the geometry of the counting arrangement. Suppose that two cylindrical detectors with radii a_1 and a_2 are connected in coincidence and are placed opposite and at distances d_1 and d_2 from a positron source with the cylindrical axes pointed at the source. The probability of recording a count is proportional to the

[11] Very rarely does the positron annihilate with an ambient electron before it has completely slowed. In this case the annihilation gamma rays are not emitted in opposite directions.

smallest fractional solid angle[12] Ω_f for either detector, namely

$$P_{\text{record}} \simeq \epsilon_1\epsilon_2 \min(\Omega_{f1}, \Omega_{f2}) = \epsilon_1\epsilon_2 \frac{1}{2} \min\left(\left[1 - \frac{d_1}{\sqrt{d_1^2 + a_1^2}}\right], \left[1 - \frac{d_2}{\sqrt{d_2^2 + a_2^2}}\right] \right), \tag{20.153}$$

where ϵ_i $i = 1, 2$ is the detector gamma-ray interaction efficiency at 511 keV for detector i. Here it is assumed that if one photon enters the detector with the smaller solid angle, then the other photon traveling in the exact opposite direction must enter the opposite detector. However, any intervening material reduces this ideal recording probability. The recorded pulse height spectrum consists almost entirely of a spectrum produced by the 511-keV photons. The method almost entirely eliminates background, although the possibility of accidental coincidence from background and other source emissions remains. Also, for example, with a ^{22}Na source, the 511-keV annihilation spectrum would appear, but the 1.28-MeV gamma-ray spectrum would be almost entirely absent, with perhaps a few counts from accidental coincidences.

Another radiation source that spontaneously emits two photons per decay is ^{60}Co; however, these gamma-rays are randomly emitted in all directions. Using the same arrangement for coincidence counting with identical detectors, the probability of a coincidence is now

$$P_{\text{record}} \simeq \epsilon_1\Omega_1\epsilon_2\Omega_2, \tag{20.154}$$

mainly because the two photons are not necessarily emitted in opposite directions and the solid angles of both detectors must be taken into account. Hence, for radiation sources that emit more than one gamma ray (e.g. ^{57}Co, ^{133}Ba), coincidence counting requires accounting for the solid angle of the two (or more) radiation detectors as well as the branching ratios of the emissions. Shown in Fig. 20.10 are several sum peaks from a ^{60}Co source recorded with an HPGe spectrometer.

Positron Emission Tomography

An example of coincidence counting, which is widely used for medical imaging applications, is positron annihilation tomography (PET). The system generally has a ring of individual detectors connected in coincidence as depicted in Fig. 20.29. The patient is administered a positron emitting radiopharmaceutical, usually one of $Na^{18}F$, ^{82}RbCl, $^{13}NH_3$, or ^{18}FDG (fluorodeoxyglucose), which accumulates in the organ or tissue under investigation. For instance, $Na^{18}F$ accumulates in bone tissue while ^{18}FDG accumulates rapidly in brain tumors. The inoculated patient is passed through the detector ring, incrementally, in lengths more or less equivalent to the detector ring width. Annihilation photons emitted from the patient may interact in two detectors arranged in the ring about the patient, and through coincidence circuitry and ray tracing algorithms, the two detectors responding within Δt to 511-keV annihilation photons can be used to identify a straight line through the patient between the two detectors. An energy window can be set about 511 keV to help reject scattered photons and accidental coincidences. Although BGO has been used in PET scanning systems, mainly because of its high gamma-ray absorption from Bi, the superior energy resolution of LSO, also having high gamma-ray absorption from Lu, is now used as a replacement in most modern PET scanning systems. A backprojection algorithm is used to produce a three-dimensional image of the patient, particularly the location where the positron emitters reside. An example of a PET scan image is shown in Fig. 20.30.

Phoswich Detector

The phoswich detector is a special scintillation spectrometer designed to measure low radiation levels in the presence of high-energy ambient background radiation. The name comes from "phosphor sandwich", where two scintillation detectors are layered one atop the other [Wilkinson 1952]. The crystals are arranged as shown in Fig. 20.31, where light from both crystals is measured by a single photomultiplier tube. The signals from the different crystals are discerned by measuring the different light decay times.

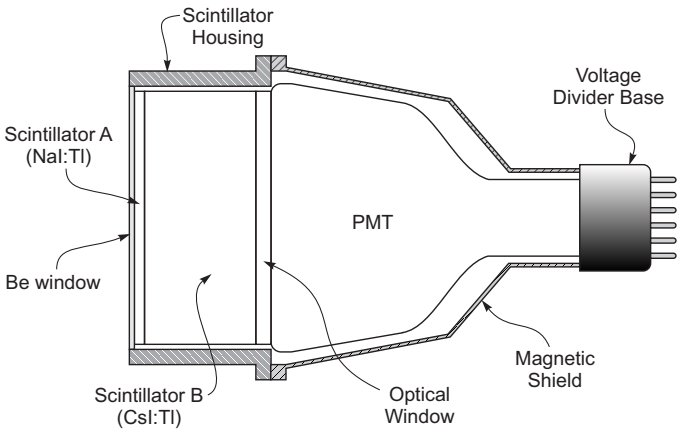

Figure 20.31. The basic components of a phoswich detector. In this example, the front detector is a thin crystal of NaI:Tl, while the back detector is a thicker slab of CsI:Tl. After Lindow et al. [1978].

The phoswich detector has a thin Be window that allows the passage of low-energy photons. These low-energy photons can be absorbed in the thin front detector, labeled A, which is designed to have sufficient thickness to absorb the radiation energies of interest, commonly on the order of 1.5 to 3 mm thick. Higher energy photons generally pass through the front detector and can be absorbed in the much thicker back detector, labeled B, commonly on the order of 50 mm thick. Pulse shape discrimination is used to determine the pulses from different scintillators, which includes photons that Compton scatter from scintillator B into scintillator A. Hence, pulses recognized as coming from scintillator A can be accepted while those from scintillator B are rejected, thereby producing a spectrum primarily from only low energy photons. Coincident events from both scintillators can be rejected outright. Operated in anti-coincidence mode, background events are substantially reduced. Consequently, the resulting spectrum has substantially re-

duced background so that low energy photon events can be seen. One interesting feature of this design is that the signals are developed from a single PMT output. Coincident events are determined from pulses of different rise times arriving within a preset time window. Detectors for low-energy gamma rays commonly have combinations of either a thin NaI:Tl crystal upon a thicker CsI:Tl crystal, or a thin CaF_2:Eu crystal upon a thicker NaI:Tl crystal. Other combinations have been explored, which for example include the use of BGO, GSO, and BaF_2 in various combinations [Costa et al. 1986; Kamae et al. 1993; Futami et al. 1993]. The use of YSO with LSO and LuYAP with LSO has also been explored for positron emission tomography applications [Dahlbom et al. 1997; Eriksson et al. 2013].

Although phoswich detectors are often designed for low-energy gamma-ray and x-ray detection, they have also found use with charged particle detection [de Celis et al. 2007]. For instance, the combining of ZnS:Ag as a thin front detector with an organic (plastic) scintillator as a back detector, alpha particle events can be separated from beta particle events [Usuda 1992]. Recall from Chapter 13 that ZnS:Ag is used for heavy particle detection, but is inefficient as a gamma-ray or electron detector. Hence, alpha particles can lose all energy in the thin ZnS:Ag front detector (usually only tens of microns thick), while the back detector can absorb the full electron energy. The small amount of energy deposited by electrons in the front detector is negligible. Hence, the particle counts can be separated by either pulse shape or pulse height discrimination.

Note that the same method can be used to discriminate gamma rays and charged particles from neutrons, where neutrons slip through the first detector (low cross section) and scatter in the second (organic scintillator) [Watanabe et al. 2008]. If the first detector has adequate gamma-ray and charged-particle interaction efficiency, coincident events can be rejected while recognizing neutron scatters in the second detector.

Special designs with fast (front) and slow (back) plastic scintillators are used for particle energy spectroscopy and identification [Wilkinson 1952; Bodansky and Eccles 1957; Saint-Gobain 2019a]. Particles passing through the first detector (fast response) yield information about the stopping power, or dE/dx, while summing the total integrated light from both detectors yields the particle energy.

Anger Camera

The Anger camera, or gamma-ray camera, was introduced by Hal Anger [Anger 1958]. A cross section of the basic components of the device is depicted in Fig. 20.32. The device can be used with single photon emission computed tomography (SPECT) or PET. The system consists of an array of photomultiplier tubes populated upon a thin sheet of NaI:Tl scintillator. The scintillator is usually on the order of 6 mm to 12 mm thick. The patient is administered a radiopharmaceutical, commonly containing ^{99m}Tc which emits 140-keV gamma rays, and placed adjacent to the Anger camera. Other radiopharmaceuticals used for SPECT include ^{123}I (159 keV) and ^{111}In (mainly 23 keV, 171.3 keV, and 245.4 keV, although there are other emissions). Gamma-ray photons emerging from the patient can be absorbed in the relatively thin NaI:Tl scintillator, spontaneously producing scintillation photons emitted isotropically. To reduce the measurement of scattered gamma rays, which can blur the image and produce an erroneous correlation to the emission point, a collimator is aligned in front of the NaI:Tl scintillator. The collimator also im-

proves the spatial resolution, but consequently also greatly reduces the detection efficiency. Multiple PMTs are usually involved with measuring the light and the closest PMT to the gamma-ray event produces the largest voltage signal. An algorithm weights the different PMT signals in the x and y directions and ensures the signals arrive within some Δt coincidence time interval to be included in the measurement. This algorithm was originally a clever resistor circuit capable of identifying the interaction location within 5 mm. Advanced electronics and algorithms in modern Anger cameras can reproduce the interaction location with spatial FWHM of 3 mm [Cherry et al. 2003).

Compton Spectrometer

A Compton spectrometer is a coincidence mode device used to extract information from the combination of two or more detectors. The basic geometry of the method is depicted in Fig. 20.33. Two radiation detectors are connected in coincidence, with one acting as the main detector (detector 1, for example) and the second detector acting as the coincidence witness. A collimator is used for detector 1 and also (preferably) detector 2, to narrow the directions of both the initial and scattered gamma rays. Sometimes a narrower witness detector is used instead of the collimator for detector 2. The geometric arrangement is important, because detector 2 is set at a specific angle θ with respect to the collimated gamma-ray trajectory.

The Compton spectrometer is a method, albeit inefficient, originally intended to produce a gamma-ray spectrum from counters instead of spectrometers. Obviously, the energy resolution depends on the uncertainty in the scattering angle. Hence, better collimation of both the initial gamma-ray and the Compton scattered gamma-ray decreases this uncertainty, but it also reduces the efficiency and, consequently, requires an increased measurement time. Gamma rays absorbed in the first detector by the photoelectric effect do not produce a coincidence event with the witness detector and are excluded. The method can be used to map out the Compton continuum, the Compton edge energy yielding the initial gamma-ray energy. Yet, there is still the possibility that multiple Compton scatters occur in detector 1, with the final scattered photon emerging and still producing a coincidence in detector 2, giving a false indication of the original gamma-ray energy. This problem can be reduced by using smaller detectors or replacing the counters with detectors capable of spectroscopy.

Compton Spectrometer for Light Yield Measurements In Figs. 13.4 and 13.5, it is seen that many scintillators have non-linear light yields for electron energies below about 500 keV, i.e., the emitted light is not proportional to the electron energy deposited in the scintillator. One method to measure the light yield as a function of energy deposition is to measure directly the light yield with multiple gamma-ray sources, preferable monoenergetic sources. However, this method relies, in practice, on only a few sources and, thus, leaves wide energy gaps in the measurements. A type of Compton spectrometer can be used

to measure the light yield of scintillators over a much larger range of deposition energies than possible with common monoenergetic gamma-ray sources [Valentine and Rooney 1994]. This device is a regular Compton spectrometer, shown in Fig. 20.33, with the change that the first detector is now made from the scintillation material being studied and the second detector is a gamma-ray spectrometer. A known monoenergetic gamma-ray source, ^{137}Cs for instance, is used to irradiate the test scintillator (detector 1). Scattered gamma-ray events in detector 2 are tallied in coincidence with events in detector 1. The energy of the scattered gamma rays is known from the collimated scattering angle. At the same time the light yield from the test detector is measured with a photomultiplier tube. With this technique the light yield for many different deposition energies, determined by the scattered photon energies $(E_\gamma - E'_\gamma)$, can be measured using the same monoenergetic source by simply changing the coincidence scattering angle.

Also designed for light yield measurements, a relatively complicated Compton coincidence spectrometer system was reported, named the SLYNCI for Scintillator Light Yield Non-proportionality Characterization Instrument, with five HPGe detectors connected in coincidence with the test scintillator [Choong et al. 2008]. This device still requires source collimation between the source and the test scintillator, although no collimators are used between the test scintillator and the multiple HPGe coincidence detectors. The SLYNCI system was designed to reduce the measurement time required to characterize the light yield from a test scintillator.

The design of the Compton coincidence light yield system was significantly simplified by Ugorowski et al. [2008] by placing a small gamma-ray check source adjacent to the test scintillator and using a high-resolution HPGe detector for the coincidence witness detector. Because there are no collimators in this design, the HPGe detector is placed near the test scintillator, thereby increasing the solid angle of the witness detector. These three simple design changes remove the need for any collimators, decrease the uncertainty in the measurement, and reduce the measurement time. This simpler arrangement also negates the need to know the Compton scattering angle because the HPGe detector provides the residual energy, from which the energy deposited in the test scintillator can be inferred.

Compton Camera System The Compton imaging system also depends on the properties of photon scattering to locate gamma-ray sources. The basic device has a position sensitive front detector following by another position sensitive back detector [Schönfelder et al. 1973]. The device is designed so that some gamma rays scattered in the front detector are subsequently absorbed in the back detector. The two detectors are operated in a coincidence mode to ensure that scattering and absorption events are correlated. Because this system does not require a collimator, the overall gamma-ray detection efficiency is improved compared to gamma-ray cameras that require collimators to exclude background. In this device the location of where an incident gamma ray interacts in the first detector and the location of where the scattered photon is absorbed in the second detector are measured, within the spatial resolution limits of the front and back detectors, and a ray can be traced between the two interaction locations.

If the incident gamma-ray energy is known, the energy deposited in the first detector and the interaction locations in both detectors can then be used to extract information about the location of the gamma-ray source. From the Compton scattering condition of Eq. (4.32), the energy deposited in the first detector is

$$E_e = E_\gamma - E'_\gamma = E_\gamma \left(\frac{E_\gamma (1 - \cos\theta)}{511 \text{ keV} + E_\gamma (1 - \cos\theta)} \right). \tag{20.155}$$

The direction of the scattered gamma ray is traced between the two interaction positions in the two detectors. Hence, E_γ and E_e are both known, leaving θ as the only unknown. This angle θ can be reconstructed as a cone with the surface forming all possible directions as depicted in Fig. 20.34(a) [Everett et al. 1977]. A second gamma-ray scatter produces a new angle, depicted as ϕ in Fig. 20.34(b), and a new cone is reconstructed, overlapping the first cone in two locations. After several additional cones from more gamma

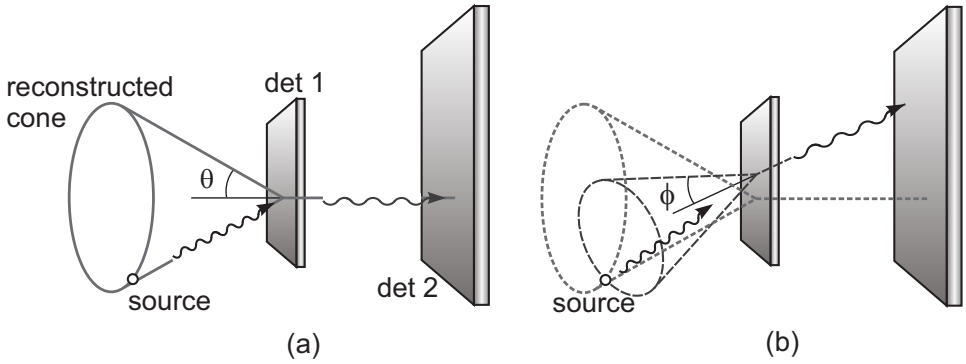

Figure 20.34. The Compton camera concept; detector 1 is the position sensitive scatter spectrometer; detector 2 is the position sensitive absorber detector. (a) A reconstructed cone with angle θ from a Compton scatter. (b) Another reconstructed cone with angle ϕ. The cone perimeters overlap at the source location.

rays are reconstructed, a specific location where all of the cones overlap becomes apparent and so the source location is identified. The method becomes more complicated if multiple sources are in the field of view. However, the reconstructed cones can still image the location of these sources because the images increase at the multiple crossover points.

If the energies of the gamma rays emitted by the source are not known *a priori*, then, with E_γ unknown, the scattering angle θ cannot be calculated from Eq. (20.155). However, this problem can be overcome by using a position-sensitive high-resolution gamma-ray spectrometer as the second detector. The sum of energies deposited in the first and second detectors can then be used to determine E_γ, preferably with the scattered gamma ray completely absorbed in the second detector by the photoelectric effect. The weakness of this approach is that the Compton scattered gamma ray may not be completely absorbed in the second detector but instead be scattered out of it. This incomplete energy absorption leads to an erroneous estimation of E_γ. The probability of fully absorbing the scattered gamma ray is improved if the second detector is made from high Z materials. Also, the device thickness can be increased with the consequence that multiple scatters may occur in the second detector, thereby confusing the interaction location. Another remedy is to use multiple stacked position sensitive spectrometers as scatter planes to back trace the gamma-ray path, ultimately producing a reconstructed cone that intercepts the source location(s) [Dogan et al. 1990]. Also, an anti-coincidence detector surrounding or near the Compton camera can eliminate a significant number of events when the scattered gamma rays escape the system [Dogan et al. 1990].

Compton Spectrometer and Imager The Compton spectrometer and imager (COSI) is a Compton camera instrument designed for the study of astronomical gamma-ray bursts [Lowell et al. 2016, 2017]. It has a 2 $\times$ 2 $\times$ 3 position-sensitive array of double-sided HPGe strip detectors [Amman et al. 2007] operated in coincidence as a Compton camera with an additional CsI:Tl scintillator shield surrounding the array that operates in anti-coincidence to reduce background [Kiernans et al. 2016]. The CsI:Tl shield rejects escaping Compton scattered gamma rays that interact in the shield so they are not used in the estimation of the incident gamma-ray energy. The shield also passively and actively blocks albedo radiation and vetoes high-energy charged particles. The position resolution of the HPGe strip detectors is reported to be 2 mm in the x and y directions and approximately 0.2 mm in the z direction. Designed to detect gamma rays between 200 keV to 5 MeV, the FWHM energy resolution of the COSI is 2.7 keV at 661.7 keV. The detector is kept cool with a mechanical Stirling cycle cryocooler. The device is deployed on a high pressure balloon, complete with solar panels to maintain power. When deployed, the COSI field of view is approximately 25% of the

sky. In at least one launch, the COSI stayed aloft and collected gamma-ray data for 46 days [Kiernans et al. 2016].

Portable Compton Scatter Cameras There are portable variants of the Compton camera used mainly as gamma-ray imagers and source identifiers. These detectors are used to rapidly locate gamma-ray sources in a region and often need only a few dozen interactions to locate the sources. A relatively complex Compton scatter camera is the position sensing CdZnTe gamma-ray spectrometer, named the Polaris spectrometer [Wahl et al. 2015; H3D 2018]. This device has various numbers of position sensitive CdZnTe spectrometers arranged in layers of arrays. Each CdZnTe detector can sense the interaction position within the detector volume using a depth sensing technique based on a pixelated electrode configuration.

A gamma-ray camera with dual capability as a Compton scatter camera and a pin-hole camera is reported by Hull et al. [PHDS 2018]. The detector, named GeGI for germanium gamma-ray imager, has a single slab of pixelated HPGe attached to a Stirling cycle mechanical cryocooler. The 9-cm diameter and 1-cm thick spectrometer is a position sensitive strip detector, with strip pitches of 5 mm. Instead of several detectors operating as scatter and absorption spectrometers, the GeGI operates by position tracking the signals produced within separate pixels formed by the x and y positions of the strips. The z direction is inferred from the charge collection signal by using the three dimensional sensing system developed by He and Zhang [2008].

A scintillation Compton camera alternative is a device built with GAGG:Ce scintillators [Kishimoto et al. 2014; Kataoka et al. 2018]. The GAGG:Ce Compton camera is based on the original concept proposed by Schönfelder et al. [1973], in which two arrays of position sensitive scintillators are aligned as the scatter and absorption spectrometers. The three-dimensional sensing device is constructed with individual GAGG:Ce scintillators, with nominal dimensions of 2 mm $\times$ 2 mm $\times$ 4 mm, arranged in 11 $\times$ 11 pixel arrays. The scintillators are separated by reflectors and have multi-pixel photon counters (MPPC, alternatively named SiPMs) attached to both sides. Both the scattering plane and the absorbing plane have four scintillator array blocks each separated by 12 mm. The x and y interaction positions are determined by the location of the affected pixels while the z component is determined by pulse height ratios measured with the dual MPPCs. Although the energy resolution ($\sim$ 8.6% FWHM at 661.7 keV) is not as good as the CdZnTe and HPGe counterparts, the device is relatively lightweight ($\sim$ 1.9 kg) and provides an angular resolution of about 8° to 9° FWHM.

20.8 Gamma-Ray Spectroscopy—Summary

Gamma-ray spectroscopy seeks to determine, first, the gamma-ray energies emitted by radionuclides (which emit gamma rays of distinct energies) that are present within a sample. This goal can be called *qualitative analysis*. However, generally, one also seeks either the source strength of the particular gamma rays or the concentration of the radionuclide emitting the gamma rays. This more demanding task often is referred to as *quantitative analysis*.

The objectives of gamma-ray spectroscopy are realized by analyzing the pulse height spectra. In this chapter, pulse-height spectra in which the number of counts are specified by discrete channel number are considered. This approach is used because channel number is directly proportional to pulse height and, thus, to the photon energy deposition. Consequently, quantitative information can then be obtained from the pulse height spectrum whether or not the spectrometer is linear. Spectroscopic analysis techniques begin by attempting to determine the continuous channel number that corresponds to the centroids of the full energy peaks in the spectrum that are of interest. The MCLLS approach focuses on the entire spectrum and seeks to determine the parameters of models that best fit all or major portions of the spectra. The symbolic Monte Carlo approach holds promise for spectroscopic applications in which the model is non-linear in terms of the radionuclide concentrations of samples.

Depending upon the need, there are several devices that can be used for gamma-ray spectroscopy. Efficiency with adequate energy resolution can be provided with large volume scintillators, whereas high energy resolution can be achieved with semiconductor detectors. Both scintillator and semiconductor detectors can be acquired as portable units with good detection efficiency for gamma rays. For ultra-high energy resolution, microcalorimeters or WDS diffractometers offer excellent performance (as described in Chapter 19). Yet, microcalorimeters and WDS spectrometers are generally restricted to laboratory-based instrumentation for low energy gamma rays and x rays. Note that the spectrometers discussed in the present chapter represent only a select sample of variations that are commercially available. More information can be found in earlier chapters dedicated to semiconductor and scintillation detectors.

20.9 Charged-Particle Spectroscopy

With charged-particle spectroscopy it is possible to identify some radioisotopes, provided that certain experimental precautions are exercised. As charged particles travel in a medium, they lose energy, mainly through Coulombic interactions. The amount of kinetic energy lost depends on the material stopping power, the particle energy, and the particle mass and charge. Regardless, energy is lost, even if the particle is emerging from its own source material. If some small and variable energy is lost before the particle enters the active region of the detector where it is subsequently stopped, the measured deposited energy is not the initial energy of the particle. Consequently, the uncertainty in the energy of a particle is increased and the energy resolution of the spectrometer decreases. To reduce energy losses while improving energy resolution, charged-particle measurements of relatively small samples are often conducted in a vacuum. Sample preparation is also important to ensure the mass thickness of a laboratory sample is kept relatively low so as to reduce energy self-absorption losses. It is also important to reduce the mass thickness of any material between the source and detector.

20.9.1 Electrons, Positrons, and Beta Particles

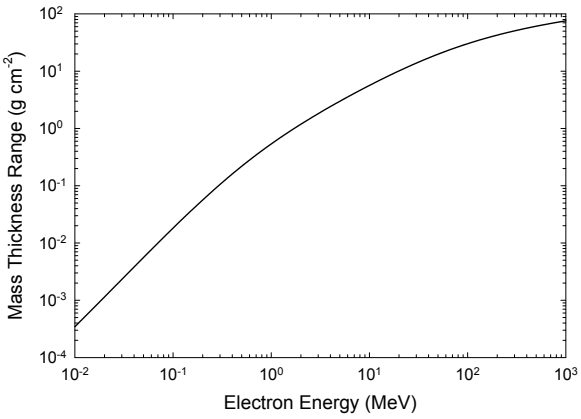

Figure 20.35. Average electron range in Si as a function of energy. Data are from ESTAR [NIST 2018].

Electron, conversion electron, positron, and beta particle spectroscopy can all be conducted with organic and liquid scintillation counters; however, the preferred method to achieve high-energy resolution is to use low Z semiconductor detectors, mainly Si detectors. The reason for low Z materials becomes evident from Fig. 7.7 in which it is seen that the backscattering of electrons and beta particles from a material increases with atomic number. The electron backscatter coefficient ranges between 0.14 at 50 keV down to 0.06 at 2 MeV, reducing to 0.0125 at 10 MeV. Any variety of planar Si detector can detect electrons, yet because the range of electrons can be significant (see Fig. 4.23 and Fig. 20.35), the type of detector is important. For instance, the mass thickness range for 100 keV and 1 MeV electrons is 0.018 g cm^{-2} and 0.54 g cm^{-2}, corresponding to ranges in Si of 77 μm and 2.36 mm, respectively. In the former case, a silicon surface barrier or implanted junction detector can be depleted, with reasonable voltage, to absorb all energy. However, the latter case would require excessive voltage to achieve a 2.31-mm-thick depletion region, and it would be better to instead use a Si(Li) detector. Note that the trajectory of electrons in a solid undergoes significant scattering as shown in Fig. 4.22. Hence,

it is still possible to absorb the total electron energy in the detector even if the active thickness is somewhat less than the average linear range.

To preserve the electron energy distribution of the source, the measurement should be conducted in a vacuum. Such a measurement is straightforward for SSB and *pn* junction detectors, but Si(Li) detectors are often cooled during operation and, hence, require encapsulation to prevent contamination. Consequently, the use of a Si(Li) detector for low-energy electron spectroscopy requires a thin, low Z, window (such as Be) and the ability to produce a vacuum between the detector window and the source. Ahmad and Wagner [1974] describe a Si(Li) detector operated in vacuum with apparently no window between the source and detector face, although there was a 2-micron-thick contact layer.[13]

The pulse height energy deposition of monoenergetic electrons in Si was studied by Berger et al. [1969a] who compared Monte Carlo calculations to measured energy spectra. A few of their comparisons are shown in Fig. 20.36. Three detector types were used (of six different thicknesses) for the measurements, including silicon surface barrier (SSB) detectors, a diffused junction detector, and Si(Li) detectors. In Fig. 20.36 (left column), different detectors were used to measure 250-keV electrons with an average range of 343 microns in Si. Although the 105-micron-thick detector was less than the electron range, some scattered electrons did deposit their full energy in the detector. The full energy peak also appears in the two thicker detectors. In Fig. 20.36 (right column), the detectors were used to measure 1-MeV electrons (range of 2.36 mm). These electrons pass through the SSB detector, depositing only a fraction of their energy. The thicker diffused junction detector does show a full energy peak, but of low efficiently. The thicker 3 mm Si(Li) detector showed a significant full energy peak. Detailed response functions and range tables for electrons in Si detectors can be found in the literature [Berger et al. 1969b].

A low-energy tail, a consequence of partial energy deposition in the detector, usually appears, regardless of detector thickness. For relatively thin detectors, electrons may pass directly through the device and leave only a fraction of energy, as shown in Figs. 20.36(a, left and right). Backscatter losses can also cause partial energy deposition, as shown in Figs. 20.36(b,c left and right). Self-absorption energy loss as electrons or beta particles emerge from a sample, or energy attenuation between the sample and detector active volume, are other sources of energy loss that can contribute to the low-energy tail. The angle that electrons enter the detector can also cause a difference in backscattering, increasing as the angle increases from that of normal incidence. Also, the escape of characteristic and bremsstrahlung x rays may contribute to the energy loss tail. For positron detection, there is a small chance that 511-keV annihilation photons emitted from the eventual recombination of an electron and positron may simultaneously deposit some (or all) energy in the detector, thereby producing a high-energy tail above the full-energy positron peak. Measured response functions for monoenergetic electrons and positrons were reported by Frommhold et al. [1991] and compared to Monte Carlo simulations. The basic components of a monoenergetic electron or position spectrum are identified in Fig. 20.37(left). Unlike an electron spectrum, a positron spectrum has a high-energy tail above the full energy positron peak as a result of the Compton scatter of 511-keV annihilation photons.

Additional distortions of the true electron energy distribution arise from detector and electronic effects. If $T(E)$ is the number of electrons, per unit energy, incident on the detector, the measured energy deposition $M(E')$, per unit energy, in the detector by these electrons is

$$M(E') = \int_0^\infty \mathcal{R}(E, E')T(E)\, dE, \tag{20.156}$$

[13] The authors refer to the Au contact as a window, but this is traditionally improper nomenclature. Such contacts are usually referred to as "dead layers."

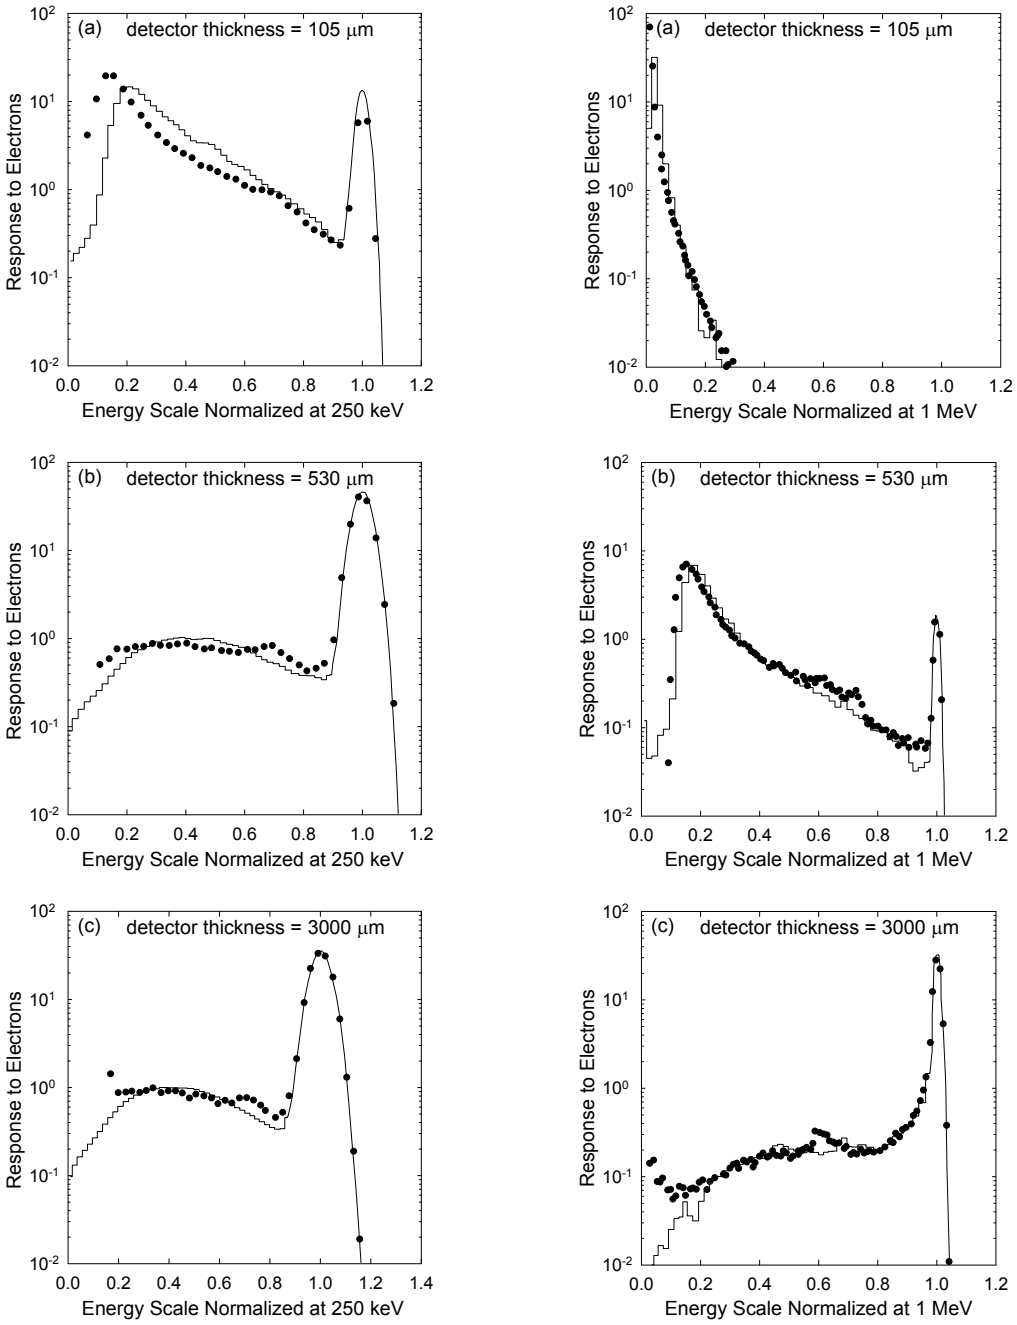

Figure 20.36. Comparison of Monte Carlo calculated and measured pulse height spectra for (left column) 250-keV electrons and (right column) 1-MeV electrons for different Si detector thicknesses: (a) 105-μm SSB detector; (b) 530-μm diffused-junction detector; (c) 3-mm Si(Li) detector. The points are experimental and the lines are calculated results. Data are from Berger et al. [1969a].

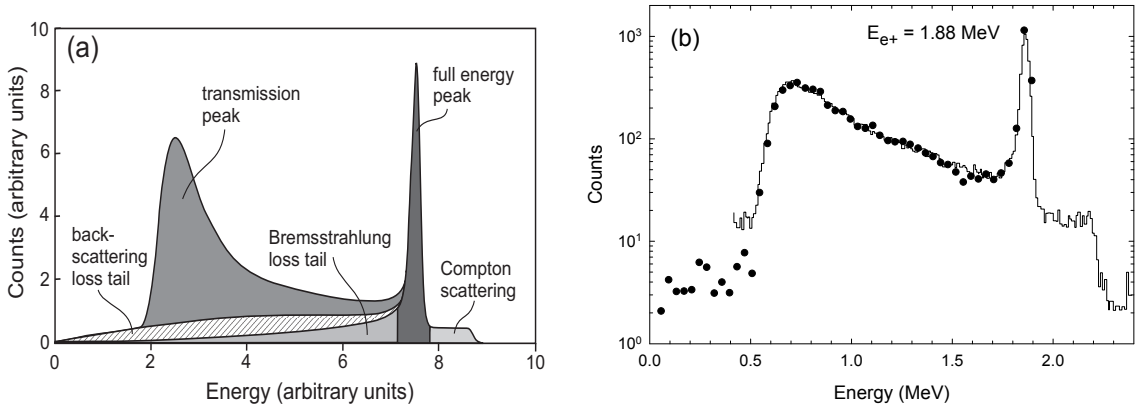

Figure 20.37. (a) Response function components of a monoenergetic electron or positron spectrum (after Frommhold et al. [1991]). The Compton scattering distribution from 511-keV annihilation photons is absent from an electron spectrum. (b) A measured positron spectrum compared to a Monte Carlo calculation. Data are from Frommhold et al. [1991].

where $\mathcal{R}(E, E')$ is the detector response function normalized such that

$$\int_0^\infty \mathcal{R}(E, E')dE' = 1. \tag{20.157}$$

Tsoulfanidis et al. [1969] developed the following response function to describe the energy deposition E' by monoenergetic electrons of energy E in a plastic scintillator:

$$\mathcal{R}(E, E') = \frac{b}{2E'}\text{erfc}\left[\frac{E - E'}{\sigma\sqrt{2}}\right] + \frac{1-b}{\sigma\sqrt{2\pi}}\left[\exp\frac{-(E-E')^2}{2\sigma^2}\right] \tag{20.158}$$

where the complimentary error function is

$$\text{erfc}(z) = 1 - \frac{2}{\sqrt{\pi}}\int_0^z \exp(-t^2)dt, \tag{20.159}$$

σ is the standard deviation of the modeled Gaussian function and b is the fraction of electrons appearing in the tail region,

$$b^{-1} = 1 + \sqrt{2\pi}\left(\frac{g}{t} - 0.5\right)\frac{\sigma}{E'}, \tag{20.160}$$

where g is the height of the full energy peak and t is the height of the backscattering tail region. The energy response function for beta particles with their continuous energy distribution is certainly more complex, but can be addressed by dividing the beta source spectrum into energy groups. The matrix of response functions can then be used to unfold energy deposition spectral data. For instance, beta particle spectra have been produced from pulse height energy deposition spectra acquired with scintillators and Si(Li) detectors with the use of unfolding methods [Tsoulfanidis et al. 1969; Dakubu and Gilroy 1978].

20.9.2 Alpha Particles

The best detectors for alpha particle spectroscopy are low-Z semiconductor detectors such as SSB and implanted junction Si detectors. The range of most alpha particle emissions from calibration check sources is

less than 60 microns in Si, which is a depletion region thickness that can be produced in SSB and implanted junction detectors with a reasonable voltage. With very pure Si, the width of the depletion region may be sufficiently wide from just the junction potential (V_{bi}). However, it is recommended that reverse voltage be applied to improve charge collection and reduce detector capacitance.

Because each alpha particle emission is monoenergetic, although some sources have multiple alpha particle emission energies, the general expectation is the formation of a Gaussian full-energy peak for each alpha particle energy. However, the full-energy deposition peak usually is not perfectly Gaussian for several reasons. First, the variance is actually less than that predicted with Poisson or Gaussian statistics because the FWHM with units of energy must be corrected with a Fano factor F as

$$\text{FHWM} = 2\sqrt{2\ln(2)E_\alpha wF} = 2.355\sqrt{E_\alpha wF}, \tag{20.161}$$

where w is the average ionization energy and E_α is the alpha particle energy. The Fano factor for Si is generally quoted to be about 0.115 (see Table 16.2).

Second, a low-energy tail inevitably appears in the energy-deposition spectrum because some of the alpha particle's initial energy is lost as a result of self-absorption as the particle emerges from the source material and also as the particle passes through the detector dead layer. The energy loss from the source self-absorption and detector dead layer also decrease the energy resolution. Another contributor to the tail arises from backscattering of the alpha particle which varies with the incident direction of the particle on the detector although this backscatter effect is usually minor [Bertolini and Coche 1968]. Backscattering and attenuation effects were addressed in Sec. 7.2.1. As is observed in electron and positron energy-deposition tails, escaping x-ray emissions from excited electron states produced by the passage of alpha particles in the detector material may also contribute to counts in the spectral tail. Alpha particles can also backscatter from the source backing. Consequently, the count rate recorded by an alpha particle detector may need several corrections to account for the many contributors of the low energy tail.

Third, the value of mean ionization energy w is usually somewhat greater for alpha particles than that for gamma rays. The reason for this difference is that alpha particles have sufficient energy and mass to cause nuclear recoil events in Si, events which do not produce electron-hole pairs. Consequently, there is an additional source of variance in the pulse height spectrum from the distribution of Si recoils, along with a reduction in the total number of charge carriers produced. Bertolini and Coche [1968] estimate this contribution to the energy resolution is about 6 keV for 5-MeV alpha particles. Fourth, although Si is a mature semiconductor, some part of the low-energy tail may be a consequence of incomplete charge collection [Steinbauer et al. 1994].

Finally, at certain orientations, ions can enter the semiconductor crystal and pass between adjacent atomic planes, an effect called *channeling*. The consequences of channeling include extended ion ranges and reduced linear energy transfer (LET or stopping power) [Gibson 1965]. Channeled alpha particles can have significantly longer ranges than those shown in Fig. 4.23. Hence, channeling alpha particles may pass well beyond the depletion region, thereby depositing only a fraction of their energy in the active region of the detector [Dearnaley 1964] and producing counts only in the low-energy tail region. The LET is lower for channeled alpha particles, and thin transmission detectors designed for dE/dx measurements produce incorrect results [Madden and Gibson 1964]. Channeling also has an effect on detector fabrication in which ion implantation is used to introduce dopant impurities to form a pn junction. The actual junction depth increases beyond the predicted depth, producing a much thicker surface dead layer. Detectors are usually oriented at a slight angle from normal towards the source to prevent channeling.[14] There is a critical angle θ_c from a major crystal plane beyond which channeling is negligible [Seidel 1983] and, for heavy ions, is

[14] Semiconductor wafers are usually oriented between 7° to 11° from normal to the ion trajectories.

calculated as [Morgan 1973]

$$\theta_c = \left(\frac{2Z_1 Z_2 q_e^2}{Ed}\right)^{1/2} \text{ radians}, \tag{20.162}$$

where Z_1 is the ion, Z_2 is the target material, q_e is the fundamental electronic charge, E is the particle energy, and d is the interplane spacing along the channeling direction. The transition between high and low energy ions is generally defined by

$$E \simeq \frac{2dZ_1 Z_2 q_e^2}{a^2}, \tag{20.163}$$

where a is the Thomas-Fermi screening radius in angstroms

$$a = 0.8853\ a_0 \left(Z_1^{2/3} + Z_2^{2/3}\right)^{-1/2}, \tag{20.164}$$

where a_0 is the Bohr radius of 0.529 Å (5.29 nm). For low-energy ions, the critical angle is [Middleman and Hochberg 1993]

$$\theta_{cL} = \left(\frac{\sqrt{3}a}{\sqrt{2}d}\theta_c\right)^{1/2} \text{ radians}. \tag{20.165}$$

It turns out for Si, the transition energy for alpha particles defined by Eq. (20.163) is 104.4 keV. Alpha particles are invariantly emitted at higher energies than 100 keV, hence the use of Eq. (20.162) is appropriate for alpha particle spectroscopy with Si detectors.

The response signal from protons and alpha particles is linear for semiconductors in the absence of heavy charge carrier trapping. Deviations from linearity may be a consequence of energy loss in the contact dead layer, recombination of electron-hole pairs (especially near the end of the particle range), trapping, and nuclear recoils. Energy calibration with zero offset can be accomplished with the assistance of spectrometer grade check sources (see Sec. 20.5.1). There are some alpha particle sources of special interest for calibration purposes, including ^{241}Am, ^{148}Gd, ^{226}Ra, and ^{228}Th. Perhaps one of most used calibration sources is ^{241}Am, mainly because of its long half-life (432.7 years), average emission energies, and absence of interfering radiations, save for a 59.5-keV gamma-ray emission and some Np x-ray emissions at low energies. Although it appears to be monoenergetic, it actually has five energy emissions, all near 5.5 MeV [Chanda and Deal 1970]. When operated in vacuum with a well-prepared source, surface barrier and implanted junction Si detectors with excellent energy resolution can resolve all five emissions. However, usually only four alpha-particle emissions are discernible (see Fig. 16.12).

The ^{148}Gd source is of special interest for two main reasons: it is truly monoenergetic with a (relatively) low-energy alpha-particle emission of only 3.18 MeV and it has a comfortably long half-life of 70.9 years. ^{148}Gd has at times been difficult to acquire, mainly because it is a spallation byproduct from accelerator targets that are not always available.[15] Two sources with relatively high-energy alpha-particle emissions are ^{226}Ra and ^{228}Th. Both of these sources emit multiple alpha-particle energies from daughter products. ^{226}Ra has a half-life of 1599 years, with its highest energy emission being from daughter ^{214}Po of 7.69 MeV (see Fig. 16.12). However, a daughter product is also ^{222}Rn, which emits a 5.49-MeV alpha particle. Because ^{222}Rn is a gas, this daughter product can diffuse from the source and contaminate the detector, causing the appearance of a background peak. Fortunately, the half-life of ^{222}Rn is only 3.82 days and almost all daughters in the chain also have short half-lives; hence the background peak disappears after a few weeks. Regardless, for measurements requiring a low background environment, the operator may wish to avoid using

[15] It took over five years of waiting for the authors to get a spectroscopic grade ^{148}Gd source.

this source with a dedicated low-background detector. ^{228}Th has a relatively short half-life of only 1.91 years. ^{228}Th, with daughter products, is also a multi-energetic alpha-particle emitter. The highest emission energy is 8.78 MeV from daughter ^{212}Po, amongst one of the highest alpha-particle energies available as a check source.

20.9.3 Heavy Ions

Heavy ions, such as fission fragments, generally do not produce a linear spectrometer response. Instead, there is a marked signal loss with heavy ions, i.e., they produce a significantly smaller signal than that predicted for lighter ions of the same energy [Schmitt et al. 1965]. This difference in the expected and the observed results is called the *pulse height defect* (PHD) [Miller 1961]. The specific energy loss is highest for heavy charged particles at the entrance point in the detector, quite the opposite of alpha particles and protons which have their highest energy loss at the end of their paths as shown in Fig. 4.28. Consequently, energy loss in the dead layer of the detector is higher for heavy charged particles than that observed for alpha particles and protons. As is well documented, the pulse height defect can be sizeable for heavy ions [Bertolini and Coche 1968] and is reported to be between 10±3 MeV to 20±3 MeV [Miller 1961; Finch 1973].

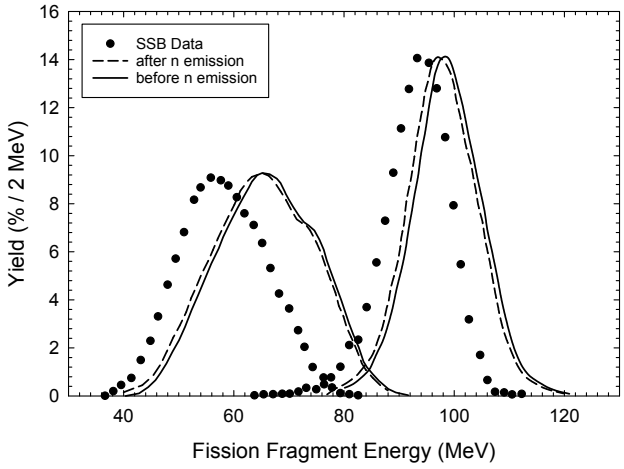

Figure 20.38. Fission fragment energy distribution for (–) time-of-flight before neutron emission, (- -) time-of-flight after neutron emission, and (•) data from an SSB detector. Data are from Kobayashi et al. [1965].

A measurement method used to reduce the effect of PHD is the time-of-flight (TOF) technique, briefly mentioned in Sec. 17.10 for thermal neutron detectors. However, a thin *zero time detector* is used to discern the timing start condition instead of a "chopper", while a second detector is used to define the transit time and (with limited resolution) particle energy. A particle passing through the zero time detector triggers the start time, while the second detector determines the stop time or t and residual energy E'. The zero time detector may be active or passive. In the passive case, the ion passes through a thin window (e.g., polymer or carbon film) that causes the emission of electrons [Fraser and Milton 1958; Milton and Fraser [1962]; DiIorio and Wehring 1977], and these electrons are then deflected into a detector that provides the fission fragment start time. A simple active zero time detector is a thin ΔE device, such as a thin gas-filled detector, a thin plastic scintillator, or a thin fully depleted SSB detector. Knowledge of the travel distance provides the velocity, while the sum of $E' + \Delta E$ provides energy, or

$$M = \frac{2(E' + \Delta E)t^2}{d^2} = \frac{2Et^2}{d^2}, \tag{20.166}$$

where d is the distance between the detectors and M is the particle mass. If ΔE is negligible, then $E \simeq E'$. Time resolution is usually on the order of 250 ps or less, and the uncertainty in timing can be decreased by increasing t (i.e., the transit distance) [Butler et al. 1970; Zeidmen et al. 1974]. Hence, timing resolution can be designed to contribute less than 0.1% to the overall measurement uncertainty. Consequently, it is the energy resolution that strongly affects the mass resolution. Because fission fragments are emitted with various charge states, the energy resolution of the stop detector is limited. For example, an SSB detector

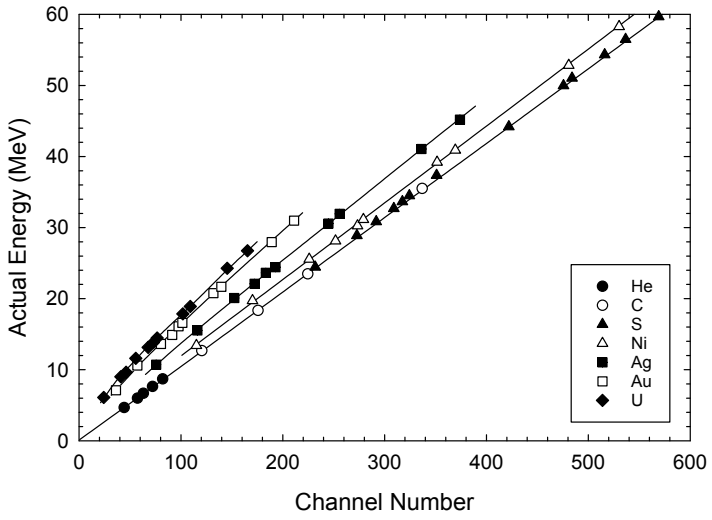

Figure 20.39. Actual ion energy versus pulse height channel number for a few heavy ions measured with an SSB detector. Data are from Wilkins et al. [1971].

is limited to 2%–4% FWHM for fission fragments. DiIorio and Wehring [1977] use an electrostatic analyzer between the zero time detector and an SSB stop detector to sort different kinetic-energy-to-ionic-charge ratios, and, thereby improve the particle mass resolution to less than 0.5 amu.[16] A comparison of the energy measured for fission fragments using time-of-flight methods and an SSB detector is shown in Fig. 20.38. The solid curve depicts the energy distribution of fission fragments before prompt neutron emission, the dashed curve depicts the energy distribution of fission fragments after prompt neutron emission, and the data points were collected by the Si detector (after prompt neutron emission). The PHD is clearly shown by the difference with the SSB detector response and the time-of-flight responses.

However, the high energy loss from source self-absorption and dead layer losses (nominally only about 2 MeV) are not the only loss mechanisms. Dearnaley and Northrop [1966] emphasize that non-ionizing nuclear recoils (in Si) are a major source of energy loss that contributes to the PHD. There are even more mechanisms that contribute to the PHD. These include electron and hole recombination in the dense charge cloud produced by the heavy charged particles. Also charge carriers are lost by being trapped in crystal lattice defects, an effect which increases as the semiconductor is exposed to increasing numbers of heavy particles. Finally, increased recombination losses also occur as the density of recombination centers increases with crystal damage (see Sect. 15.2.3). Thus, in general, one must correct for the PHD in heavy ion spectroscopy. The measured pulse height P and the energy E of the heavy charged particle is often related by

$$E = Sn + \delta, \tag{20.168}$$

[16] The active zero time detector provides another method to determine the mass-energy relationship, albeit generally less accurate [Sachs et al. 1966]

$$E\frac{dE}{dx} = (E' + \Delta E)\Delta E = k_1 M Z^2 \ln\left[\frac{E}{k_2 M}\right] \simeq K M Z^2. \tag{20.167}$$

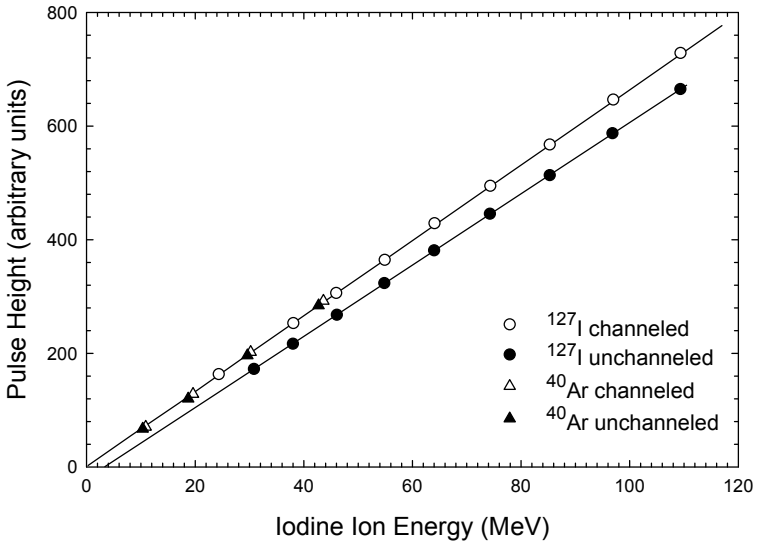

Figure 20.40. Pulse height dependence for channeled and non-channeled ^{40}Ar and ^{127}I ions along the [110] axis. Data are from Moak et al. [1966].

where S is a scaling constant and δ is the pulse height defect. For a common multichannel analyzer system, S may be the equivalent energy per channel and n would be the channel number. Shown in Fig. 20.39 is a comparison between the actual ion energies of various heavy ions and the associated pulse heights indicated by channel number on a multichannel analyzer [Wilkins et al. 1971] and from which it is apparent that the PHD increases with the Z number of the heavy ion.

It is notable that in at least one study the PHD seems to disappear with channeled ions [Moak et al. 1966]. The comparison was drawn between ions of two different masses, ^{40}Ar and ^{127}I. Much like sulphur in Fig. 20.39, the PHD for Ar ions (with an atomic mass close to that of S) was small with little difference between ions with or without channeling. However, there was clearly the appearance of a PHD for the unchanneled iodine ions, which have a slightly larger atomic mass than that of silver, and the PHD for iodine was similar to that of silver in Fig. 20.39. However, the PHD was similar to that of Ar when channeled, as shown in Fig. 20.40. The reason for the difference is attributed to a lower stopping power $-dE/dx$ of the channeled ions and the reduction or absence of nuclear collisions. Further, the energy resolution reportedly improved by a factor of three for the channeled ions. The experiment performed by Moak et al. [1966] seems to confirm that it is nuclear collisions that are responsible for most of the PHD observed with heavy ions, although the lower $-dE/dx$ also reduces recombination losses. The observed energy resolution improvement is probably because the variance term for non-ionizing energy losses becomes negligible for the channeled ions. Attempts to correlate measured PHD to empirical formulas are in the literature (for example, Schmitt et al. [1965]; Wilkins et al. [1971]). One general correlation offered by Schmitt et al. [1965] is based on the assumption that two linear functions can be used to describe both the scaling constant and the PHD in Eq. (20.168), namely

$$E = (a + a'M)P + (b + b'M), \tag{20.169}$$

where $M \simeq A$ is the mass (in u) of the ion and a, a', b, and b' are experimentally determined constants particular to the detector. The constants can be found by using a spectroscopic grade fission source, such as ^{252}Cf. If P_L denotes the 3/4-maximum in the pulse height for the lower mass (higher energy) peak ($P_L = 0.75N_L$ in Fig. 20.41) and P_H denotes the 3/4-maximum in the higher mass (lower energy) peak

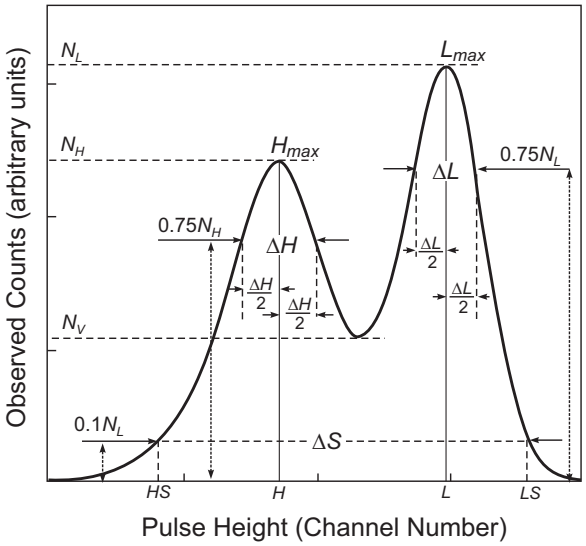

Figure 20.41. Identifying parameters for a ^{252}Cf pulse height spectrum. After Schmitt and Pleasonton [1966].

Table 20.3. Summary of SSB detector spectral metrics for Fig. 20.41.

Parameter	Reasonable Limit	^{252}Cf Expected Value	^{235}U Expected Value
N_L/N_V	> 2.85	~ 2.9	~ 19
N_H/N_V	~ 2.2	~ 2.2	~ 12.5
N_L/N_H	–	~ 1.3	1.49-1.55
$\Delta L/(L-H)$	< 0.38	~ 0.36	0.22-0.23
$\Delta H/(L-H)$	$\lesssim 0.45$	$\lesssim 0.44$	0.35-0.36
$(H-HS)/(L-H)$	< 0.70	$\lesssim 0.69$	0.38-0.39
$(LS-L)/(L-H)$	$\lesssim 0.49$	$\lesssim 0.48$	0.27-0.28
$(LS-HS)/(L-H)$	$\lesssim 2.18$	~ 2.17	~ 1.66

($P_H = 0.75N_H$ in Fig. 20.41) , the constants are found to be [Weissenberger et al. 1986]

$$a = \frac{a_0}{P_L - P_H}, \quad a' = \frac{a'_0}{P_L - P_H}, \quad b = b_0 - aP_L \quad \text{and} \quad b' = b'_0 - a'P_L. \tag{20.170}$$

For a ^{252}Cf source,[17]

$$a_0 = 24.300, \quad a'_0 = 0.0283, \quad b_0 = 90.397, \quad \text{and} \quad b'_0 = 0.1150, \tag{20.171}$$

all in units of MeV.

[17] These constants are slightly different from the original work by Schmitt et al. [1965]. Weissenberger et al. [1986] state the prior values systematically overestimated the kinetic energies by 1-2%.

For a ^{252}Cf source measured with an SSB detector, certain parameters can be used to provide quantitative metrics for the particle detector [Schmitt and Pleasonton 1966] that are shown in Fig. 20.41. The vertical axis, with labels N, refer to the number of observed counts at relative pulse heights (channel numbers). These metrics include peak ratios, such as N_L/N_V, N_H/N_V, and N_L/N_H. Of these, Schmitt and Pleasonton [1966] indicate that most important is the peak-to-valley ratio N_L/N_V with a reasonable lower limit of 2.85. With N_L/N_V, the FWHM resolution for a 70-MeV ion (Br, for instance) should be approximately 1 MeV, while that for a corresponding iodine ion is 1.4 MeV. Listed in Table 20.3 are other performance metrics.

PROBLEMS

1. Consider the design of an experiment to obtain the data in Example 20.1. The total interaction coefficient μ of the absorbing foils contains a scattering component which, instead of absorbing photons traveling from the point source to the detector, scatter some of the source photons. Some of these scattered photons still reach the detector and are counted as uncollided or unattenuated photons. Design an experiment, i.e., the size and placement of the foils with respect to the source and detector, that minimizes the scattered component of photons that reach the detector.

2. Show that for small $\overline{r}t_r$ Eq. (20.29) is approximately the same as Eq. (20.27).

3. Derive Eqs. (20.90).

4. Consider the count data in Table 20.4. (a) Write a program to find the best fit parameters of this isolated peak. With the fit model of Eq. (20.71), use the linear least-squares method as in Example 20.2 and by trial and error find the peak centroid and standard deviation to obtain the best fit. (b) How many counts are there under the peak?

Table 20.4. A portion of a spectrum around the 911.2-keV ^{228}Ac full-energy peak in the background spectrum shown in Fig. 21.7.

E_i (keV)	y_i cnts	E_i (keV)	y_i cnts	E_i (keV)	y_i cnts	E_i (keV)	y_i cnts
0.9066	589	0.9088	601	0.9109	2349	0.9131	537
0.9069	625	0.9090	692	0.9112	1985	0.9134	568
0.9071	596	0.9093	878	0.9115	1467	0.9137	591
0.9074	582	0.9096	1039	0.9118	1148	0.9139	597
0.9077	590	0.9099	1511	0.9120	831	0.9142	586
0.9079	640	0.9101	1867	0.9123	721	0.9145	581
0.9082	624	0.9104	2287	0.9126	585	0.9148	606
0.9085	615	0.9107	2430	0.9128	590	0.9150	594

5. Use the non-linear least-squares method to fit simultaneously all the parameters of Eq. (20.71) to the data in the above problem.

6. Derive Eq. (20.155).

7. Show that fitting Eq. (20.104) to N_E, N_F and N_P the parameters in the quadratic fit are

$$\alpha = (1/2)[N_E + N_F - 2N_P], \qquad \beta = (1/2)(N_F - N_E) - n_P(N_F + N_E - 2N_P)$$

and

$$\gamma = N_P + n_P \frac{N_E - N_F}{2} + n_P^2 \frac{N_E + N_F - 2N_P}{2}.$$

Then derive the expressions for the channel number and the maximum peak count given by Eqs. (20.105) and (20.106).

8. Show that the skewness factors defined in Eq. (20.111) are unity for a Gaussian peak.

9. Determine the corrected peak channel and counts for the peak shown in Fig. 20.18, but shifted slightly so that now $C_P = 10,000$ at channel 3365 and $C_E = 9910$ and $C_F = 7748$. The peak is still located between channels $N_L = 3351$ and $n_R = 3374$.

10. In Tables 20.5 and 20.6 are the channels and counts observed for the ^{214}Bi 2204.1-keV and ^{40}K 1460.8-keV full-energy peaks, respectively. Estimate the resolution in keV and % of the HPGe detector used to obtain these data.

Table 20.5. A portion of a spectrum around the 2204.1-keV ^{214}Bi full-energy peak in the background spectrum shown in Fig. 21.7.

11. Explain why the resolution of a gamma-ray spectrometer that uses a scintillator is usually expressed as a percentage, while that of a semiconductor spectrometer is usually given in energy units.

12. Using the detector configuration of Fig. 20.20, derive the expression for Eq. (20.121).

13. With the result of Eq. (20.145) and the constraint that $T_A = t_G + t_B$, derive an expression for the optimum source count time t_G in terms of the available time t_A.

14. You have a total of 5 minutes each to conduct measurements of numerous radioactive activation samples, including the background measurement and the gross measurement. Given that on average $g \simeq 3500$

cm and the average background is $b \simeq 100$ cpm, find the optimized times for the gross and background measurements.

15. You have a 300-nm-thick B_4C detector claimed to be a semiconductor neutron detector. The film was grown with natural boron on *n*-type Si and has area 2 mm × 2 mm. Given a thermal neutron (2200 m s^{-1}) flux of 10^4 cm^{-2} s^{-1}, how long should a measurement be to discern with 98% confidence that it really is a B_4C semiconductor detector and not a thin-film Si *pn*-junction detector? Hint: the thin-film neutron detector expressions in Chapter 17 might be helpful.

16. Given the two different cylindrical NaI:Tl detector configurations in Fig. 20.42, find the detection efficiency of coincidence events if the source is ^{22}Na for both configurations. Repeat for ^{60}Co.

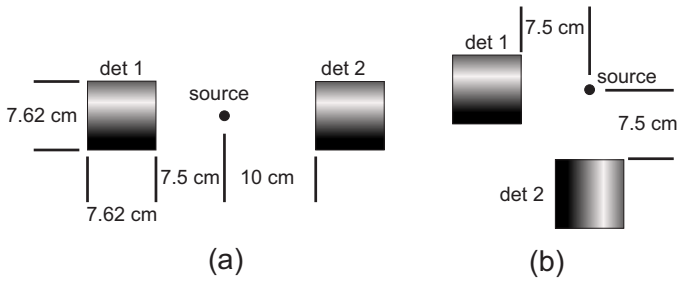

Figure 20.42. Coincidence counting geometry for two NaI:Tl detectors.

17. Determine the critical angle required to prevent alpha particle channeling in a Si SSB detector with surface direction ⟨100⟩.

Chapter 21

Mitigation of Background in Gamma-Ray Spectroscopy

Eventually, we reach ... the utmost limits of our [instruments]. There, we measure shadows, and we search among ghostly errors of measurement for landmarks that are scarcely more substantial.

Edwin Powell Hubble

Everything in the universe is constantly being irradiated by different types of directly or indirectly ionizing radiation. On Earth we and our scientific instruments are bathed in radiation from many different sources. In particular, radiation detectors respond in varying degrees to the different types of background radiation incident on them (or even produced by them). Thus, any measurement of the radiation from a particular source with any of the many detectors discussed in this book also contains responses from the ever present background radiation field. The separation of the foreground response from the source under study from the background response is a key element in radiation measurements. This separation generally becomes increasingly difficult as the foreground component decreases in the combined responses and as the stochastic nature of the detector response becomes more pronounced.

To increase the strength of the foreground component and to reduce stochastic fluctuations in the detector measurement, several approaches can be used. Generally placing a detector close to a compact radiation source that is being analyzed increases the response rate by way of the inverse square law while keeping the background response rate relatively unchanged. Increasing the measurement time also generally reduces statistical uncertainties in the output response provided that the radiation source does not vary appreciably during the measurement time. The use of a detector with a larger sensitive volume, while increasing the foreground response rate, also increases the background response rate; however, because of the larger number of recorded events, statistical uncertainties are reduced. Often shielding structures are used to reduce the amount of background radiation that reaches the detector. The use of detector shielding is especially important to reduce the background in *low-level* counting applications involving weak sources. Finally, in some cases multiple detectors with coincident and anti-coincidence circuitry can be used to reject signals produced by background radiation.

To understand how background radiation affects the response of a detector, it is important to know how the detector responds to different types of radiation (well covered in the preceding chapters), the sources and strengths of background radiation, and how different materials and techniques can be used to shield a detector from background radiation. Background radiation and methods to reduce its impact are the subject of this chapter.

21.1 Sources of Background Radiation

There are many sources of background radiation which can affect the response of a detector. These include (1) cosmic rays incident on the earth's atmosphere, (2) secondary particles produced by cosmic rays interacting in the atmosphere, (3) naturally occurring radionuclides in materials near the detector, (4) naturally occurring radionuclides in the detector itself, (5) radioactivity in the earth that produces *terrestrial radiation* and in materials far from the detector, (6) radioactivity in the air surrounding the detector, and (7) man-made radiation sources from particle accelerators, x-ray machines, and radionuclides from weapons tests or created for medical or industrial use.

21.1.1 Cosmic Radiation

The earth is bombarded continuously by radiation originating from our sun, from sources within our galaxy, and from sources far beyond our galaxy. The radiation as it reaches the earth's atmosphere consists of 99% of high-energy atomic nuclei and 1% electrons. Cosmic rays also contain some photons but with energies far below those of the atomic nuclei. The highest observed photon energy is about 10^{14} eV, while the highest energy for a fermionic cosmic ray is an astounding 3×10^{20} eV. The origins of the extra galactic cosmic rays is still somewhat mysterious, but recent satellite observations suggest the supernova explosions and active galactic centers produce some of this radiation.

Hydrogen nuclei (protons) constitute the major material component (90%) of cosmic rays, along with alpha particles (9%) and some heavier atoms, decreasing in importance with increasing atomic number. Cascades of nuclear interactions in the atmosphere, initiated by primary cosmic rays, give rise to many types of secondary particles such as neutrons, kaons and pions. The kaons almost all decay to muons before reaching the surface of the earth.[1] The fluxes (in units of $\text{cm}^{-2}\ \text{s}^{-1}\ \text{MeV}^{-1}$) of the various cosmic rays at the earth's surface are shown in Fig. 21.1. The primary and secondary cosmic rays also interact in the soil (or water) and produce yet more photons and neutrons. The neutron flux is affected mostly by the water content or the soil as is shown in Fig. 21.2. Below 1 MeV the secondary atmospheric produced neutrons begin to slow down as they are moderated by the soil and air producing a characteristic $1/E$ slowing down spectrum that at thermal energies assumes Maxwellian shape. The data for Fig. 21.1 and Fig. 21.2 were generated by the freely downloadable program EXPACS [2018] which is based on the work of Sato et al. [2006, 2008]. With this program the cosmic ray components can be determined at any altitude, location, and at any time in the solar cycle.

As can be seen in Fig. 21.1, the intensity of cosmic rays reaching the surface of the earth is anti-correlated with the solar activity, i.e., when the sun is most active in its 22-year cycle the cosmic ray intensity is the lowest and, when the sun is least active, the cosmic ray intensity is at its highest. This counterintuitive anti-correlation is a result of changes in the solar magnetic field. When the sun spot activity is at its greatest, the solar magnetic field is at its strongest and deflects more cosmic rays away from the inner solar system. Likewise, when the sun is least active, its magnetic field is weakest and allows more cosmic rays to reach earth. Although this effect appears small on the logarithmic scale of Fig. 21.1, the intensity swing is about 50% for neutrons and 30% for photons at an energy of 1 MeV.

[1] Muons μ^+ and antimuons μ^- are radioactive elementary particles with a rest mass energy equivalent of 105.7 MeV and a mean lifetime of 2.197 μs. They decay as

$$\mu^- \rightarrow e^- + \overline{\nu}_e + \nu_\mu \qquad \text{or} \qquad \mu^+ \rightarrow e^+ + \nu_e + \overline{\nu}_\mu .$$

They interact with electrons, but lose little energy per interaction, and produce little bremsstrahlung. Consequently, they are very penetrating. For example, a 1-MeV muon has a CSDA range of 470 cm in water, while a 1000-MeV muon has a 2426-m range [Bevelacqua 2008].

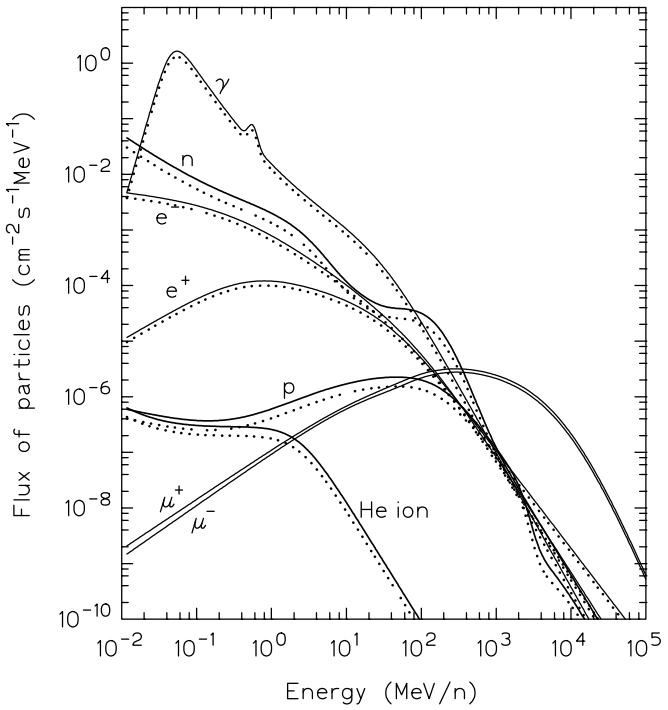

Figure 21.1. Ground-level fluxes of the various components of cosmic rays at the minimum (solid lines) and at the maximum of the solar cycle (dotted lines). The ground is at average elevation of the U.S. (2493 ft). Data generated by EXPACS [2018].

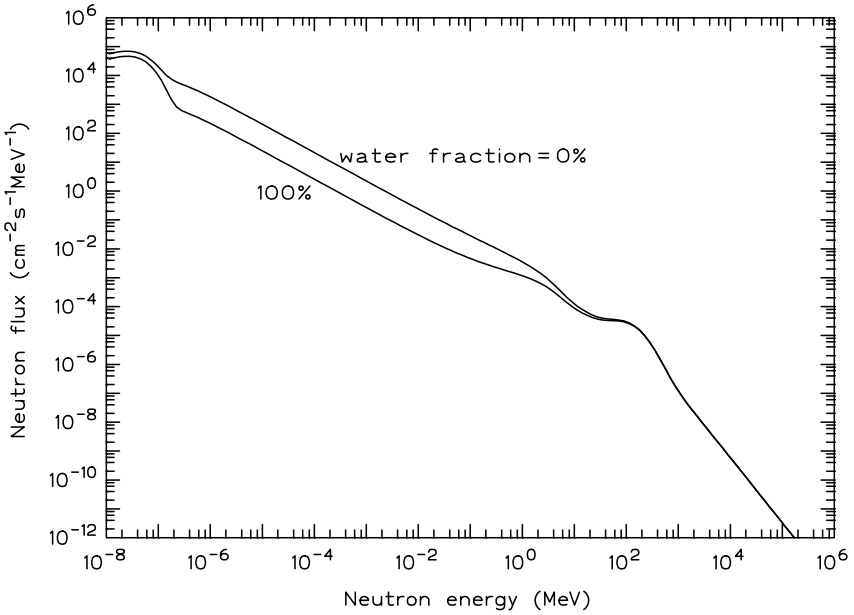

Figure 21.2. The neutron flux produced by cosmic radiation at ground-level for two extreme volume fractions of water in the ground. Data generated by EXPACS [2018].

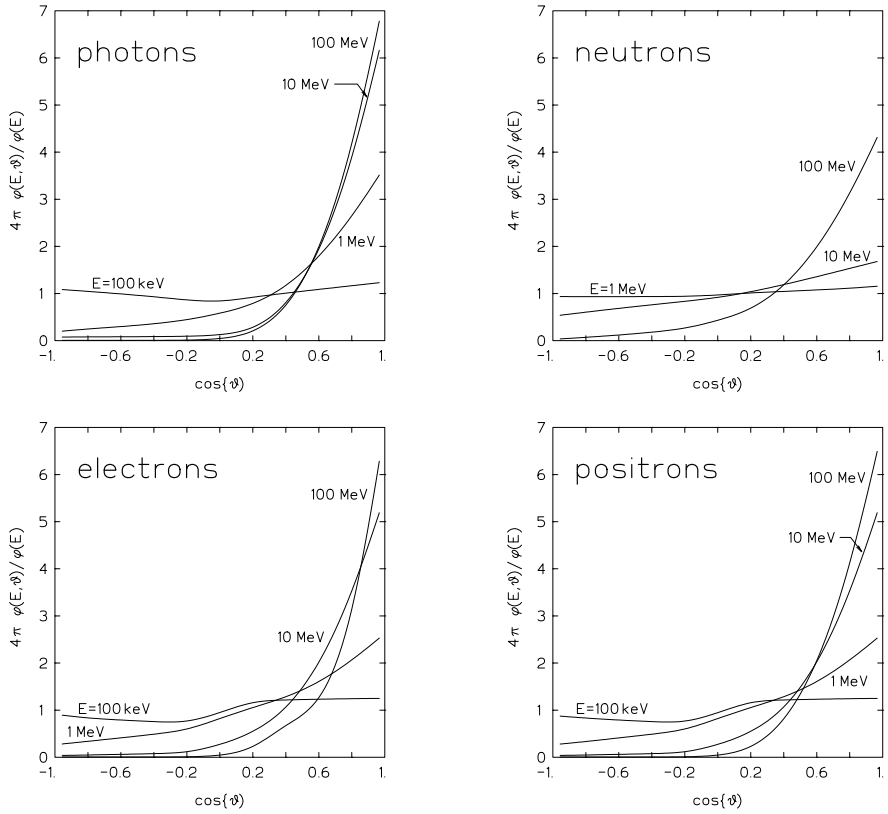

Figure 21.3. Anisotropy of gamma rays, neutrons, electrons and positrons produced by cosmic radiation at ground-level. Plotted is the ratio $R = 4\pi\phi(E,\theta)/\phi(E)$ versus cosine of the zenith angle. For an isotropic flux $R = 1$. The direction $\cos(\theta) = 1$ is the vertically downward direction. The 4π integrated flux is shown in Fig. 21.1. Data were obtained from EXPACS [2018].

The angular distribution of cosmic radiation that reaches the earth's surface depends on the radiation particle since the earth's surface can affect, especially at lower energies, the reflection of the radiation into the atmosphere. For example, muons are negligibly reflected and their angular flux $\phi(E,\theta) \equiv d^2\phi(E,\theta)/\{dE\, d\Omega(\theta)\}$ cm^{-2} s^{-1} MeV^{-1} sr^{-1} is essentially zero in the upward directions, i.e., for nadir angles $\theta > \pi/2$. By contrast, neutrons at energies below about 0.1 MeV are almost isotropically distributed as can be seen in Fig. 21.3. In the figure the ratio $R \equiv 4\pi\phi(E)/\phi(E,\cos(\theta))$ is plotted versus the cosine of the nadir angle. Here $\cos\theta = 1$ refers to the directly downward direction. If the angular flux is isotropic $R = 1$. As can be seen from Fig. 21.3 the angular flux becomes increasingly anisotropic in the downward direction.

Both as a useful measure and as a single cosmic-ray metric, the effective dose equivalent is widely used to describe the intensity of cosmic rays. At earth's surface, cosmic radiation dose rates are largely due to muons and electrons. The intensity and angular distribution of galactic radiation reaching the earth is affected by the earth's magnetic field and perturbed by magnetic disturbances generated by solar flare activity. Consequently, at any given location, cosmic ray doses may vary in time by a factor of 3. At any given time, cosmic ray dose rates at sea level may vary with geomagnetic latitude by as much as a factor of 8, being greatest at the pole and least at the equator. The global average cosmic ray dose equivalent rate at sea level is about 240 μSv per year for the directly ionizing component and 20 μSv per year for the neutron

component [UN 1988]. Cosmic ray dose rates also increase with altitude. At geomagnetic latitude 55^o N, for example, the absorbed dose rate in tissue approximately doubles with each 2.75 km (9000 ft) increase in altitude, up to 10 km (33,000 ft). The neutron component of the dose equivalent rate increases more rapidly with altitude than does the directly ionizing component and dominates at altitudes above about 6 km [UN 1988].

Solar cosmic rays associated with flares are mainly hydrogen and helium nuclei. While of too low an energy to contribute to radiation doses at the surface of the earth, solar-flare radiation, which fluctuates cyclically with an 11-year period (from to minimum to minimum sun spot activity), perturbs earth's magnetic field and thereby modulates galactic cosmic-ray dose rates with the same period. As the sun becomes more active, the solar wind from the sun increases and deflects more of the cosmic radiation from reaching earth. This decrease in cosmic ray activity at ground level with increasing solar activity is seen in Fig. 21.1 where the dotted lines are ground-level fluxes at maximum solar activity which are seen to be slightly lower than the solid lines at the solar minimum. Thus, maxima in solar flare activity lead to minima in dose rates. Solar flare radiation, in comparison to galactic cosmic rays, is of little significance as a hazard in aircraft flight or low orbital space travel. On the other hand, solar-flare radiation presents a considerable hazard to personnel and equipment in space travel outside the earth's magnetic field.

Released continuously from the sun, as an extension of the corona, is the solar wind, a plasma of low-energy protons and, presumably, very low-energy electrons. The solar wind does not present a radiation hazard, even in interplanetary space travel. However, it does affect the interplanetary magnetic field and the shape of the geomagnetically trapped radiation belts. These radiation belts are thought to be supplied by captured solar-wind particles and by decay into protons and electrons of neutrons created by interactions of galactic cosmic rays in the atmosphere. The trapped radiation can present a significant hazard to personnel and equipment in space missions.

Galactic Cosmic Rays

Cumulative energy spectra for the various components of the galactic cosmic radiation incident on the earth's atmosphere are illustrated in Fig. 21.4. These spectra may be approximated as

$$\phi(E > E_o) \simeq \frac{A}{(M_o c^2 + E_o)^n}, \tag{21.1}$$

in which $\phi(E > E_o)$ is the flux density of particles with energies greater than E_o, $M_o c^2$ is the rest-mass energy equivalent of the particles, A and n are parameters which, generally, depend on the state of the solar cycle.

As a result of nuclear spallation reactions with constituents of the atmosphere, secondary neutrons, protons, and pions, mainly, are produced. Subsequent pion decay results in electrons, photons, neutrons, and muons. Muon decay, in turn, leads to secondary electrons, as do Coulombic scattering interactions of charged particles in the atmosphere.

Except for short-term influences of solar activity, galactic cosmic radiation has been constant in intensity for at least several thousand years. The influence of solar activity is cyclical. The principal variation is on an 11-year cycle, but there are very small diurnal variations and evidence of a 22-year cycle as well as 27-day quasi-periodic variations [Haffner 1967].

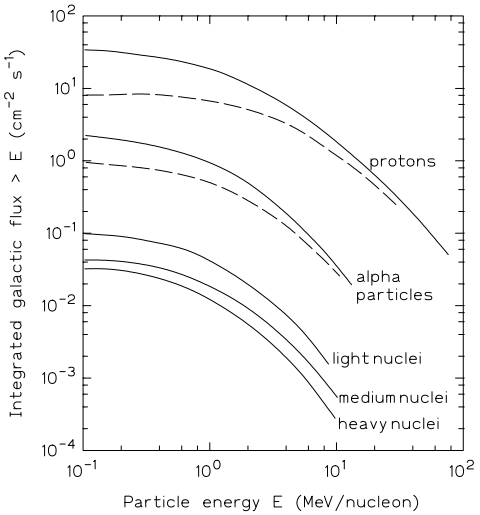

Figure 21.4. Integral energy spectra (i.e., the flux of particles with energies $> E$) for various components of the galactic cosmic radiation. Light nuclei, $3 \leq Z \leq 5$, medium nuclei $6 \leq Z \leq 9$, and heavy nuclei $Z \geq 10$. Solid lines are for the solar minimum and dashed lines are for the solar maximum. Data from Haffner [1967].

The geomagnetic field of the earth is responsible for limiting the number of cosmic rays which can reach the atmosphere. For particles of atomic number Z vertically incident at geomagnetic latitude λ, the minimum momentum for a cosmic ray to reach the atmosphere is proportional to $Z \cos^4 \lambda$ [Haffner 1967]. This dependence accounts for a strong effect of latitude on cosmic-ray dose rates.

Solar Flare Particulate Radiation

Solar flare particles are mostly protons and alpha particles, predominantly the former. Electrons are thought to be emitted as well, but with energies less than those of protons by a factor equal to the ratio of the rest masses. These flares can disrupt earth's ionosphere which affects long-range radio communications. They have little effect at the earth's surface and produce little change in the background experienced by radiation detectors. However, solar flares can be accompanied by coronal mass ejections (CME) which can cause large geomagnetic storms that, in turn, can disable satellites and shut down electrical grids for hours. For space missions outside the atmosphere, solar flares must be considered in order to protect both astronauts and their equipment.

Table 21.1. Measured fluences (cm^{-2}) outside earth's atmosphere produced by the solar flare that occurred July 10, 1959. Source: Haffner [1967].

protons		alpha particles	
$E > 10$ MeV	4.5×10^9	$E > 40$ MeV	1.6×10^8
$E > 30$ MeV	1.0×10^9	$E > 120$ MeV	2.4×10^7
$E > 100$ MeV	1.4×10^8	$E > 400$ MeV	5.0×10^5

Energy spectra are highly variable, as are temporal variations of intensity. Haffner [1967] describes records of solar flares during the 1956-1961 interval which encompasses the 1959 maximum in activity. The large event of 10 July, 1959, for example, resulted in the fluences (cm^{-2}) outside the earth's atmosphere given in Table 21.1. A typical course of events for a flare is as follows. Gamma and x-ray emission takes place over about 4 hours as is evidenced by radio interference. The first significant quantities of protons reach the earth after about 15 hours and peak proton intensity occurs at about 40 hours after the solar eruption [NCRP 1989].

21.1.2 Natural Occurring Radioactivity

Cosmogenic Radionuclides

Cosmic-ray interactions with constituents of the atmosphere, sea, or earth, but mostly with the atmosphere, lead directly to radioactive products. Capture of secondary neutrons produced in primary interactions of cosmic rays leads to the formation of many more radionuclides. However, the thermal-neutron flux at sea level is only about 8 cm^{-2} h^{-1} [Morgan 1967] and the total neutron flux density is only about 30 cm^{-2} h^{-1} [UN 1988]. Thus, neutron capture in the earth's crust or the sea is of little importance in comparison with capture in the atmosphere, except for production of long-lived ^{36}Cl [NCRP 1975]. Of the nuclides produced in the atmosphere, only ^{3}H, ^{7}Be, ^{14}C, and ^{22}Na contribute appreciably to human radiation exposure. The distribution of these cosmogenic radionuclides is shown in Table 21.2. Radionuclides borne by the 10^7 kg of "space dust" reaching the earth annually have a total specific activity of less than 450 pCi kg^{-1} and result in only extremely low atmospheric concentrations [NCRP 1975].

Table 21.2. Global distribution of cosmogenic radionuclides produced in the atmosphere.

	^{3}H	^{7}Be	^{14}C	^{22}Na
Global Inventory (PBq)	1300	37	8500	0.4
Distribution (%)				
stratosphere	6.8	60	0.3	25
troposphere	0.4	11	1.6	1.7
land surface/biosphere	27	8	4	21
mixed ocean layer	35	20	2.2	44
deep ocean	30	0.2	92	8
ocean sediments			0.4	

Source: UN [1982].

Over the past century, combustion of fossil fuels and the emission of CO_2 not containing ^{14}C has diluted the cosmogenic content of ^{14}C in the environment. Moreover, since World War II, artificial introduction of

^{3}H, ^{14}C, and other radionuclides,[2] into the environment by human activity has been significant, especially as a result of atmospheric nuclear-weapons tests. Consequently, these nuclides no longer exist in natural equilibria in the environment.

Tritium is produced in the atmosphere mainly from the ^{14}N(n,t)^{12}C and the ^{16}O(n,t)^{14}N reactions. It has a half-life of 12.3 years and, upon decay, releases one beta particle with maximum energy 18.6 keV (average energy 5.7 keV). Tritium exists in nature almost exclusively as HTO but may be partially incorporated into organic compounds such as those in wood, a common construction material. In continental surface waters the ratio of ^{3}H to stable hydrogen is 3.3×10^{-18} (corresponding to 0.00039 Bq cm^{-3}). Because ^{3}H emits only a low-energy beta particle, it is generally of little concern in most low-level counting applications. Only if a liquid scintillator is used to look for tritium leaks from nuclear facilities that also produce tritium does the incorporation of cosmogenic tritium in the scintillator become a concern.

The nuclide ^{14}C is produced mainly from the ^{14}N(n,p)^{14}C reaction. It exists in the atmosphere as CO_2, but the main reservoir is the ocean. It has a half-life of 5730 years and decays by beta particle emission, each decay resulting in an electron of maximum energy 157 keV (average energy 49.5 keV). The natural atomic ratio of ^{14}C to stable carbon is 1.2×10^{-12} (corresponding to 0.226 Bq ^{14}C per gram of carbon) [NCRP 1975]. Because ^{14}C emits only beta particles, it contributes negligibly to the photon background save low-energy bremsstrahlung photons below 157 keV. Only in low-energy beta counting measurements is it of concern.

The ^{7}Be radionuclide, with a half-life of 53.4 days, is also produced by cosmic ray interactions with nitrogen and oxygen in the atmosphere. It decays by electron capture, 10.4 percent of the captures resulting in the emission of a 478-keV gamma ray. Environmental concentrations in temperate regions are about 3000 Bq m^{-3} in surface air and 700 Bq m^{-3} in rainwater [UN 1982]. A background gamma-ray spectrum often shows a very small 478-keV full energy peak.

The radionuclide ^{22}Na is produced in spallation interactions of atmospheric argon with high-energy cosmic-ray secondary neutrons. It has a half-life of 2.602 y, decaying by positron emission (90 percent) and electron capture (10 percent). The positron has a maximum energy of 546 keV (average energy 216 keV). Essentially all decays are accompanied by emission of a 1.275-MeV gamma ray from the excited ^{22}Ne daughter. Although the 1.275-MeV gamma ray may be observed in a background spectrum taken by a very sensitive gamma-ray spectrometer, the 0.511-MeV positron annihilation photon which usually is present in a background spectrum is attributable mostly to cosmic-ray positrons.

Activation by Cosmic Ray Neutrons

The neutrons produced by spallation reactions in the atmosphere and ground by cosmic rays can lead to the buildup of radionuclides in materials stored at ground level. Although of little radiological concern, these radionuclides can contribute to the background spectrum in underground ultra-low-level facilities. For example, pre-World War II steel, i.e., steel without any fission products, was tried as a shield against the gamma rays emitted from lead shielding but found to be too contaminated by ^{54}Mn ($T_{1/2}$ = 312.1 d) that was produced by cosmic ray neutrons interacting with ^{54}Fe when the old steel was stored for years at ground level [Brodzinski et al. 1985]. Thus, steel should not be used in such ultra-low-level facilities unless it has been stored underground for many years. However, for less sensitive facilities, activation of steel is usually of little concern.

One other example is the use of copper, which is used in spectrometer facilities for both shielding and detector electronics. Electrolytic copper, while expensive, generally has very low impurity levels from the

[2] One such nuclide is ^{137}Cs ($T_{1/2}$ = 30.0 y) which, upon decay, emits a 661.7-keV gamma ray, which is found in most background gamma-ray spectra. The presence of this radionuclide in a sample measured in a low-level counting chamber indicates the sample dates from the post 1950 era and is used, for example, to determine if a purportedly old wine (or its bottle) is truly made of pre-1950 material.

naturally occurring radionuclides. However, storage at ground level allows the buildup of ^{60}Co from energetic cosmic ray neutrons through the ^{63}Cu(n,α)^{60}Co reaction. So copper for use in ultra-low-level counting facilities must be moved underground as soon as possible after its purification.

Primordial Radionuclides

Of the many radioactive species present when the earth formed 4 billion years ago, some 17 extremely long-lived radionuclides still exist as singly occurring or isolated radionuclides, i.e., as radionuclides not belonging to a decay chain. These terrigenous (primordial) radionuclides are listed in Table 5.1. Of these primordial radionuclides, only ^{40}K contributes significantly to the gamma-ray background.

The radionuclide ^{40}K is a major contributor to human exposure from natural radiation. Present in an isotopic abundance of 0.0118 percent, it has a half-life of 1.227×10^9 y, decaying both by electron capture (11 percent) and beta-particle emission (89 percent). The beta particle has a maximum energy of 1312 keV (average energy 509 keV). Electron capture results in emission of a 1461-keV gamma ray in 10.7 percent of decays. Very low energy Auger electrons and x rays are also released from electron capture (Kocher 1981). The average elemental concentrations of potassium in Reference Man[3] is 2 percent. Annual doses in Reference Man are 140 μGy to bone surface, 170 μGy on average to soft tissue, and 270 μGy to red marrow (UN 1982). ^{40}K also contributes in a major way to external exposure. The average specific activity of the nuclide in soil, 12 pCi g^{-1} (0.44 Bq g^{-1}), results in an annual whole-body dose equivalent of 120 μSv (12 mrem) [UN 1982]. However, actual specific activities can vary considerably depending on the type of soil as is shown later in Table 21.5.

Decay Series of Primordial Origin

Each naturally occurring radioactive nuclide with $Z > 83$ is a member of one of three long decay chains, or radioactive series, stretching through the upper part of the Chart of the Nuclides. These radionuclides decay by α or β^- emission and they have the property that the number of nucleons (mass number) A for each member of a given decay series can be expressed as $4n + i$, where n is an integer and i is a constant (0, 2, or 3) for each series. The three naturally occurring series are named the thorium ($4n$), uranium ($4n + 2$), and actinium ($4n + 3$) series, named after the radionuclide at, or near, the head of the series.

Two of these primordial decay series, identified by the long-lived parents ^{238}U and ^{232}Th contribute appreciably to the natural gamma-ray background. Another series headed by the primordial ^{235}U radionuclide contributes very little to the radiation background and makes a negligible contribution to the radiation background.[4]

The three naturally occurring series are shown schematically in Figs. 21.5 and 21.6, and the principal radiations emitted by members of the two important series are given in Tables 21.3 and 21.4. Within each series are subseries headed by a radionuclide with a half-life much greater than those of its daughters. Although all the members of a series are not likely to be in radioactive secular equilibrium in nature because of chemical or physical reasons, members of a subseries are more likely to be so. The subseries headed by the gases ^{220}Rn and ^{222}Rn are of special importance and are treated separately in a subsequent section.

The radiations emitted by members of the primordial decay chains and listed in Tables 21.3 and 21.4 are but a small fraction of all the radiations emitted. Most have frequencies less than the 0.5% cutoff used in

[3] The Reference Man is a hypothetical person with the anatomical and physiological characteristics of an average individual and is widely used in calculations that assess internal doses to various organs from various radiation sources. Specifically, he is 20-30 years of age, weighs 70 kg, is 170 cm in height, and lives in a climate with an average temperature of 10° to 20°C [ICRP 1975].

[4] There is no naturally occurring series represented by $4n+1$. This series was recreated after $^{241}_{94}$Pu was made in nuclear reactors. This series does not occur naturally since the half-life of the longest lived member of the series, $^{237}_{93}$Np, is only 2.14×10^6 y, much shorter than the lifetime of the earth. Hence, any members of this series that were in the original material of the solar system have long since decayed away.

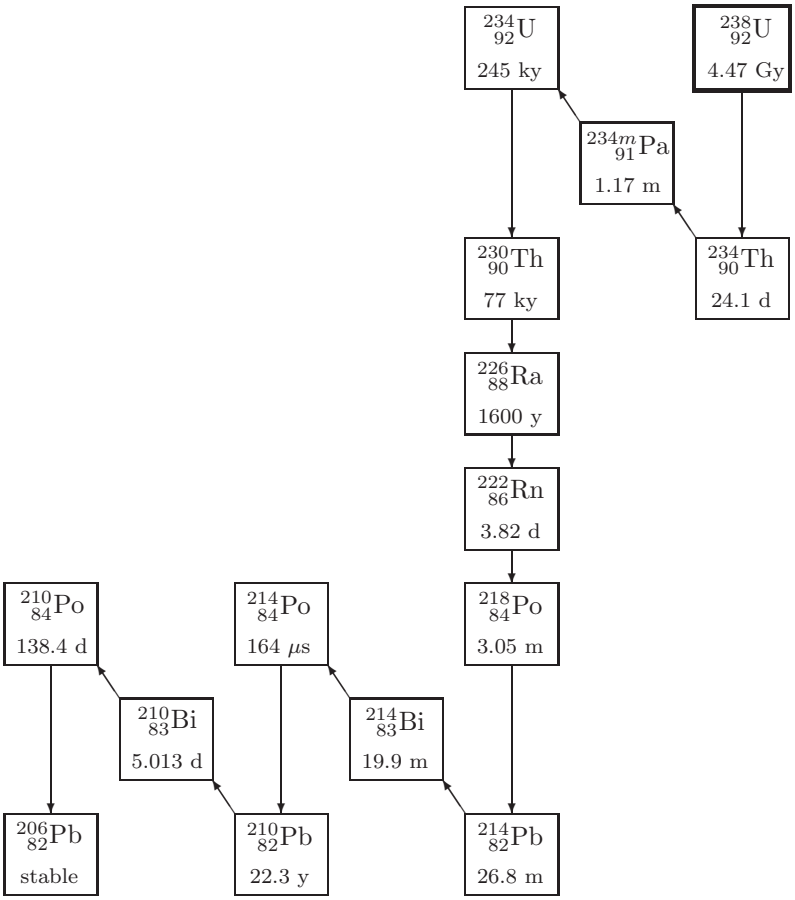

Figure 21.5. The $^{238}_{92}$U $(4n + 2)$ natural decay series. Alpha decay is depicted by downward arrows and β^- decay by arrows upward and to the left. Not shown are (1) the isomeric transition to $^{234}_{91}$Pa (0.16%) followed by beta decay to ^{234}U, (2) beta decay of ^{218}Po to ^{218}At (0.020%) followed by alpha decay to ^{214}Bi, (3) alpha decay of ^{214}Bi to ^{210}Tl (0.0210%) followed by beta decay to ^{210}Pb, and (4) alpha decay of ^{210}Bi to ^{206}Tl (0.000132%) followed by beta decay to ^{206}Pb. From Shultis and Faw [2017].

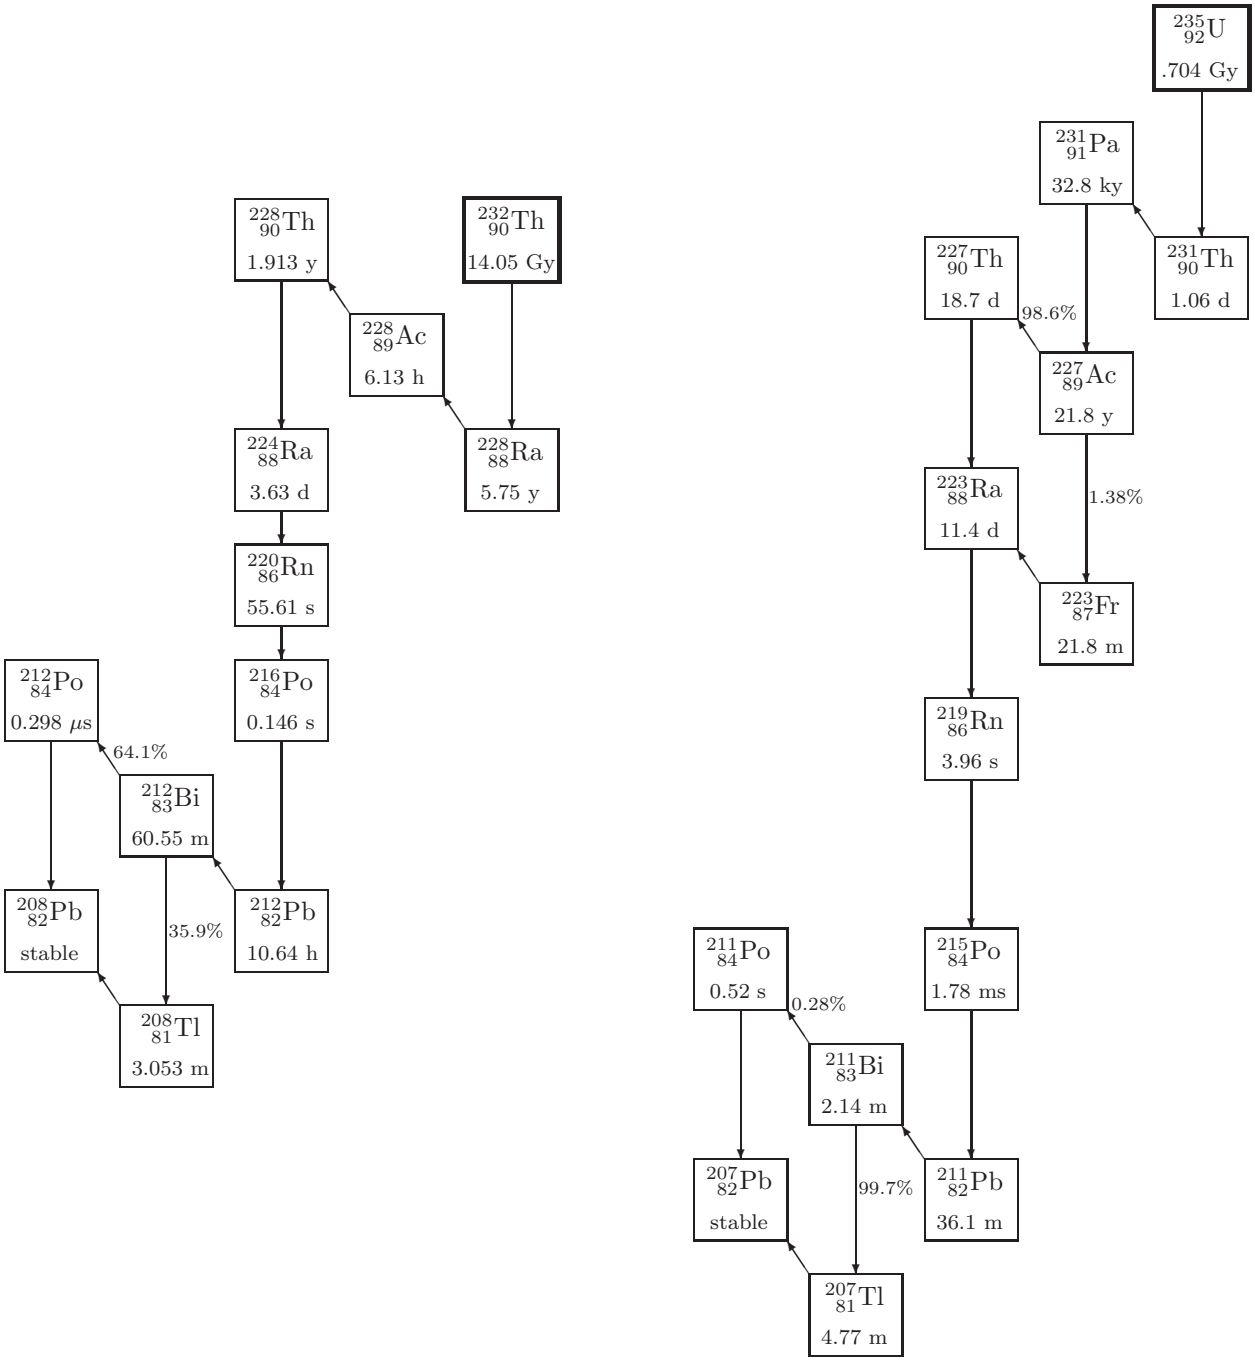

Figure 21.6. The $^{232}_{90}$Th ($4n$) natural decay series (left) and the $^{235}_{92}$U ($4n+3$) natural decay series (right). Alpha decay is depicted by downward arrows and β^- decay by arrows upward and to the left. Not shown in the $^{235}_{92}$U series on the right are two very minor side chains: (1) alpha decay of ^{223}Fr (0.004%) to ^{85}At which beta decays to ^{223}Ra (3%) or alpha decays to ^{215}Bi which beta decays to ^{215}Po, and (2) the beta decay of ^{215}At ($< 0.001\%$) followed by alpha decay to ^{211}Bi. From Shultis and Faw [2017].

these tables. For example ^{228}Ac emits a known 54 different beta particles and an astounding 246 different energy gamma rays! The background energy spectrum, thus, is almost a continuum of different energy particles emitted by the decay chain radionuclides, of which only a few occur sufficiently frequently that their contribution to the gamma-ray spectrum is identifiable.

Radionuclide Concentrations in Different Materials

Primordial radionuclides and their radioactive daughters are present in all natural materials. Such radioactive material is classified as NORM (Naturally Occurring Radioactive Material). The concentrations of these radionuclides is often altered by extraction, manufacturing, and processing of the natural materials. These materials with altered radionuclide concentrations are sometimes classified as TENORM (Technologically Enhanced Normal Radioactive Material). For regulatory purposes some man-made radioactivity such as fallout from nuclear weapons tests, is also considered part of the natural background.

Table 21.5. Typical naturally occurring radionuclide concentrations in U.S. rocks and soils.

Rock/soil	Average specific activity (Bq kg^{-1})			absorbed dose rate in air (nGy h^{-1})
	^{40}K	^{238}U	^{232}Th	
Igneous Rock				
acidic	100	60	80	120

United States	50	20	22	

Source: UN [1977].

Typical natural radionuclide activity concentrations in several soils and rocks are listed in Table 21.5. Also listed are dose rates in air 1 m above the nuclide-bearing material, calculated on the basis of radioactive equilibrium throughout the entire series. These dose rates are seen to be quite comparable to the background dose rate of 88 nGy/h to which the average person in the U.S. is exposed from external terrestrial radionuclides.

21.1.3 Airborne Radioactivity

Sources of radiation are also present in the air. Dust from soil or construction activities can lead to airborne naturally occurring radionuclides. However, a constant source of airborne radioactivity is from radon and its daughters. Decay of radon and its daughters in the atmosphere leads first to individual unattached ions or neutral atoms. The ions or atoms may become attached to aerosol particles, the attachment rate depending in a complex manner on the size distribution of the particles. Radioactive decay of an attached ion or atom, because of recoil, usually results in an unattached daughter ion or atom. Either attached or unattached species may be deposited (plate out) on surfaces, especially in indoor spaces, the rate depending on the surface-to-volume ratio of the space. Because of plate out, radon daughter products in the atmosphere are not likely to be in equilibrium with the parent.

^{222}Rn and its daughters ordinarily present a greater radiological hazard than ^{220}Rn (thoron) and its daughters, largely because the much shorter half-life of ^{220}Rn makes decay more likely prior to release into the atmosphere. Relatively little is known about the rates of release, diffusion, inhalation, plate-out, attachment, etc. for ^{220}Rn and its daughters, and most studies have emphasized the more important ^{222}Rn series shown below.

$$^{222}_{86}\mathrm{Rn} \xrightarrow[3.82\ \mathrm{d}]{\alpha} {}^{218}_{84}\mathrm{Po} \xrightarrow[3.05\ \mathrm{m}]{\alpha} {}^{214}_{82}\mathrm{Pb} \xrightarrow[26.8\ \mathrm{m}]{\beta^-} {}^{214}_{83}\mathrm{Bi} \xrightarrow[19.9\ \mathrm{m}]{\beta^-} {}^{214}_{84}\mathrm{Po} \xrightarrow[164\mu\mathrm{s}]{\alpha} {}^{210}_{82}\mathrm{Pb}\ (22.2\ \mathrm{y}). \tag{21.2}$$

Airborne decay products beyond ^{214}Po are of little consequence since ^{210}Pb has such a long half-life that it becomes bound to surfaces before it decays.

The alpha particles emitted by these airborne radionuclides are of little concern in most radiation measurements except in the case of alpha-particle spectrometers for which they contribute to the energy spectrum. The alpha particles from radon daughters are also of radiological concern because they can become lodged in the pulmonary-bronchial system and produce large doses to the epithelial lung tissues [Faw and Shultis 1999]. Of greater concern from a radiation measurement perspective are the gamma rays emitted by ^{214}Pb and ^{214}Bi (see Table 21.4). These gamma rays are prominent in most gamma-ray background spectra.

Outdoor Radon Activity

The noble gas radon diffuses into the atmosphere from rocks, soils, and building materials containing progenitor radionuclides. The exhalation rate of ^{222}Rn from rocks and soils is highly variable, ranging from 0.2 to 70 mBq m^{-2} s^{-1}. An area-weighted average for continental areas, exclusive of Antarctica and Greenland, is 16 mBq m^{-2} s^{-1} [UN 1988]. Exhalation from the surface of the sea is only about 1% of that from land areas. Rain, snow, and freezing decrease exhalation rates so that they are generally lower in winter than in summer. Barometric pressure and wind speed also affect exhalation rates, decreasing pressure or increasing wind speed causing the rate to increase.

Radon and daughter products are dispersed in the atmosphere by turbulent diffusion and convection. Extreme conditions of atmospheric stability can lead to ground-level concentrations differing by as much as a factor of 100. Associated with conditions of atmospheric stability are marked diurnal variations in ground-level concentrations, with minima at noon and maxima at midnight being associated respectively with greater and lesser atmospheric instability. Concentrations decrease with altitude, with those of ^{220}Rn decreasing more rapidly because of the shorter half-life of the parent. In the absence of precipitation, parent-daughter equilibrium is approached at elevations exceeding about 100 m. However, rainfall may remove daughter products from the atmosphere, causing absorbed dose rates in air at ground level to be as much as twice normal.

Mean annual concentrations of ^{222}Rn above continental areas range from 1 to 10 Bq m^{-3}, with 5 Bq m^{-3} and an equilibrium factor of 0.8 being typical (UN 1988). Typical mean annual concentrations over the ocean and over island areas are 0.1 Bq m^{-3}. Concentrations of ^{220}Rn daughters are typically 10% of those

of ^{222}Rn daughters. Anomalously high levels often exist near coal-fired and geothermal power stations and near uranium-mine tailings.

Indoor Radon Activity

Most spectroscopy is performed inside some structure or in rooms that are located at or below ground level where concentrations of radon and its daughters can build up to levels several times those outdoors. Because of the short lifetimes of the daughters, the members of the radon decay chain ideally would be in secular equilibrium, i.e., the activity concentration of the daughters C_i would equal that of ^{222}Ra C_o. However, because of plate-out and settling, members of the decay chain are seldom in equilibrium. An *equilibrium factor* f_i, defined as $f_i = C_i/C_o$, typically has values around 0.5.

Indoor radon sources include exhalation from soil, building materials, water, ventilation air, and natural gas if unvented (as used in cooking). Exhalation from soil can be a significant contribution if a building has cracks or other penetrations in the basement structure or if the building has unpaved and unventilated crawl spaces. Water usage in buildings can present a significant source of Rn if concentrations in the water exceed about 10 kBq m^{-3}. In the United States, concentrations of ^{222}Rn in natural gas average 0.7 kBq m^{-3} but in some states the average is as high as 2 kBq m^{-3}. Radon precursor concentrations in building materials are highly variable. Greater concentrations occur in phosphogypsum and in concrete based on fly ash or alum shale. Sealing concrete surfaces with materials such as epoxy-resin paints greatly reduces radon exhalation. Indoor airborne radon and daughter concentrations depend not only on exhalation of the parent gas from surfaces, but also on intake and loss of radionuclides through ventilation and plate-out of daughters on interior surfaces. The rate of plate-out depends on the unattached fraction which is influenced greatly by humidity and by the presence of aerosols (smoke, dust, etc.).

21.1.4 Modern Radiation Sources

In our modern technological world, new sources of ionizing radiation have been introduced. Radioisotopes made by humans are used in many applications in medicine and industry. Likewise machines that produce penetrating radiation are now widely used. For example, electron accelerators are widely used in cancer therapy and in x-ray machines for inspecting welds and forgings. Radiation measurement facilities, such as border inspection portals are often subjected to industrial sources of x rays. Although sources of high-energy photon radiation are usually well shielded horizontally by thick building walls, they often have limited shielding provided by a roof and, hence, radiation escaping upwards can scatter in the atmosphere and contribute to the background radiation at locations far removed from the radiation facility. This source of background is termed *skyshine* and requires special techniques to assess its severity [Shultis and Faw 2000].

21.2 Mitigation of the Radiation Background

The design goal for a radiation measurement system is to reduce the background to sufficiently low levels so that meaningful measurements of a sample can be made and analyzed. For the case of samples with extremely small activities, the background must be made very low, sometimes to a few counts per day or per week. Fortunately, most measurement requirements are not as severe. Ideally, the background signals should be comparable or less than those produced by the sample being analyzed.

In this section the background for gamma-ray and x-ray measurements are primarily considered. To appreciate the background we all live in, a typical gamma-ray energy spectrum is shown in Fig. 21.7 and the most often seen contributors to the various full energy peaks seen in such a spectrum are listed in Table 21.6. The background spectrum of Fig. 21.7 has an overall (sum over all energy channels) of about 35 cps, which is higher than one might like, but is unavoidable in this measurement laboratory with little protection from cosmic rays and which also is enclosed by thick concrete walls, floor and ceiling, all containing significant ^{40}K.

Table 21.6. Full energy gamma-ray peaks observed in a Ge detector background spectrum. The most intense are indicated by boldface type.

Origin	Energy (keV)	Origin	Energy (keV)	Origin	Energy (keV)

Gamma-ray counting facilities can be classified into three broad categories. First *ultra-low-level* facilities are characterized by extremely low background count rates, often less than a few counts per day. Such facilities require heroic effort and expense: detector, electronics, and support material, all constructed from radiopure materials, are placed deep underground at depths up to 10,000 m (water-equivalent). There are several tens of these facilities currently in operation most intended to investigate various rare phenomena such as proton decay, neutrinoless double beta decay, magnetic monopoles, dark matter, neutrino physics, etc. A few are also used to measure very low levels of radioactivity.

In the second category are *very low-level* facilities, which use, in addition to passive lead and copper shielding around the spectrometer, electronic coincidence shielding to suppress the Compton plateau and the cosmic ray background. Many are placed several hundred to a few thousand meters (water-equivalent) underground. Background count rates in such facilities can thus be reduced to a few cps. The third category of counting facilities are at or near ground level and simply rely on passive shielding around the spectrometer and isolation from man-made radiation sources. These relatively inexpensive facilities typically have background count rates of several tens of counts per second.

Almost all the peaks seen in Fig. 21.7 are attributable to ^{40}K and members of the ^{238}U and ^{232}Th decay chains.[5] Although not seen in Fig. 21.7, the radionuclide ^{9}Be ($T_{1/2}$ = 53.3 d), produced by cosmic rays, can also sometimes be seen. The fission product ^{137}Cs, produced by atomic bomb tests, can be seen. Other background spectra sometimes also show the fission products ^{95}Zr, ^{95}Nb, ^{106}Ru and ^{144}Ce.

[5]These radionuclides are sometimes referred to simply as the KUT nuclides.

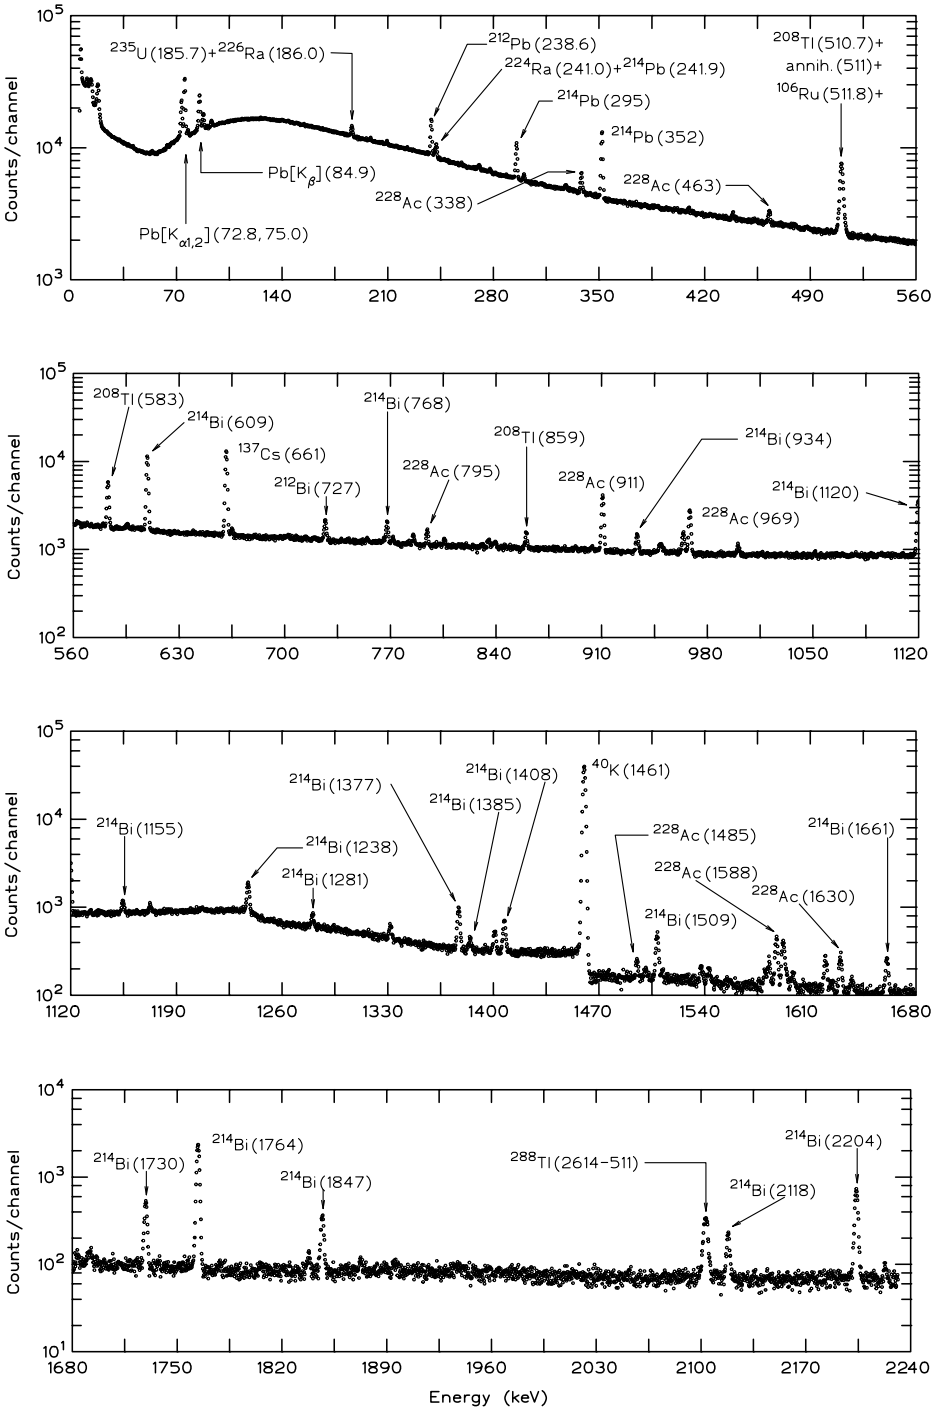

Figure 21.7. Background energy spectrum obtained over 162.5 h with a 180-cm^3 HPGe detector in the Radiation Detection Instructional Laboratory of Kansas State University. Courtesy of Nathaniel Edwards, KSU.

Before discussing ways to minimize the effect of background on the analysis of a sample, it must be recognized that the choice of detector type depends on the specific application. If radionuclide identification is the purpose, then a high-resolution spectrometer should be selected. However, if detection of contamination is of interest, then a high-efficiency detector, generally with poorer resolution, should be chosen. In either case, the larger the active volume the better the statistics for a given count time. Nevertheless, while increasing the detector size increases the measured foreground counts, it also proportionally increases the number of background counts. Thus, increasing a detector's size does little to improve the foreground-to-background ratio, although it is usually easier to separate the background from a foreground spectrum with a high-resolution detector such as HPGe compared to a NaI:Tl spectrometer.

There are several ways to improve the foreground-to-background ratio so that the background-corrected spectrum depends less on the background spectrum. These methods are discussed below.

21.2.1 Sample Placement

To increase the foreground count rate from a sample, the sample should be placed as close to the source as possible. Unless the sample activity is weak, source placement too close to the source may increase the deadtime of the detection system beyond acceptable limits. Also the position of a sample with respect to the detector is further limited if activities of the radionuclides in the sample are sought (as distinct from just the identification of the radionuclides through the energies of their gamma rays). For absolute counting it is important that the efficiency of the spectrometer as a function of gamma-ray energy is known. This energy-dependent efficiency is determined by "point" calibration sources placed at well-defined positions, typically tens of centermeters on the axis from the detector. Thus samples must be made physically small and placed at a calibration position to appear as a point source. Sometimes the distance between source and detector may be very difficult or impossible to change, such as measurement systems designed to study solar neutrinos and cosmic rays.

If background radiation is weak compared to the sample activity, the source (and detector) should also be placed as far as possible from walls and other objects from which gamma rays emitted by the source could be reflected into the detector. The minimization of this reflection contribution when the detector must be shielded from background radiation is considered in more detail later. Also if a sample is physically large compared to the detector volume, then corrections must be made to account for photon absorption by the sample itself, thereby preventing sample radiation from reaching the detector.

21.2.2 Minimize Radioactivity in the Detector System

Because all materials contain radionuclides to a lesser or greater degree, it is important in the construction of a low-level detection system to use materials with very low radionuclide (RN) concentrations for both the material that detects the energy of the incident radiation as well as the detector assembly itself.

In Table 21.7 are listed representative specific radionuclide activities in materials commonly used in many spectrometer systems. Most of the KUT radioisotopes appear as impurities and their concentrations often vary by factors of ten or more depending on how the materials were prepared. Materials with low levels of radionuclide contaminants are essential to reduce the background in a spectrometer. This is particularly true for components that are very close to the detector and include the detector material itself, the casing of the detector, radiation shields near the detector, the air surrounding the detector, and various system components such as preamplifiers, photomultipliers, and cryostat endcaps. Selection of materials for low-level spectrometer systems is a lengthy but vital aspect of the design of a spectrometer system with an inherent low background. Guidance can be found from published accounts of the construction of systems in existing facilities such those described by Brodzinski et al. [1985] and Leonard et al. [2008] who also provide specific radionuclide activities in over 200 materials considered for the EXO-200 facility.

Table 21.7. Typical naturally occurring radionuclide concentrations in various materials used in detector systems.

Sources: Zvara et al. [1994], Brodzinski et al. [1985] and Camp et al. [1974].

In gas-filled detectors, the working gas may contain ^{222}Rn and ^{220}Rn and their daughters. This contribution to the background can be reduced by purifying the gas or by just letting the gas age for several half-lives of ^{222}Rn ($T_{1/2} = 3.38$ d). The material of inorganic detectors such as NaI:Tl and CsI:Tl contribute to the background mainly through ^{40}K and to a lesser extent through U and Th impurities, although with modern manufacturing methods these contributors to the background have been largely eliminated. Ger-

manium detectors require a very high degree or purity to produce crystals suitable for radiation spectral measurements and so background from RN impurities is quite small. Nevertheless, manufacturers of ultra-low-level spectrometers can, for an additional cost, provide Ge detectors with extremely low concentrations of impurities. Typically such highly pure crystals have an inherent activity about ten times lower than that of conventional ones [Zvara et al. 1994].

Bismuth germanate (BGO) crystals can have an appreciable background from the impurity ^{207}Bi ($T_{1/2}$ = 38 y), which is thought to be produced by cosmic ray protons in (p,n) reactions with ^{206}Pb in the same ore from which the Bi was extracted. BGO produced from lead-free ores does not have this background component. Some of the newer inorganic scintillators that are presently attractive are compounds containing lanthanum or lutetium (see Sec. 13.2). However, these elements contain naturally occurring radioisotopes and, thus, have an inherent built-in background gamma-ray source. To eliminate these radionuclides would require isotopic separation, an expensive process not routinely available. Consequently, these scintillators are not well suited for low-level spectrometric applications.

Certain materials such as pyrex glass have KUT radionuclides as normal constituents and, thus, can be a significant background source. Most materials contain these radioisotopes as impurities and so they can be reduced by various purification processes. Electrolytic copper and magnesium generally have low levels of radioactivity and are good choices for the construction of low-background counters. Stainless steel also generally has low-background activity. However, aluminum, which is widely used structurally for many experimental systems because of its reasonable cost and ease of cutting and machining, can have relatively high levels of radioactivity from uranium and/or radium contaminants. Brass also generally has low specific radioactivities (if its lead content is low). Indeed, one facility replaced stainless steel screws with brass ones to reduce ever so slightly the background [Brodzinski et al. 1985]. Electric solder and circuit boards often have high levels of radioactive impurities and, thus, electrical components in a spectrometer system must be evaluated as a source of background radiation.

Scintillation spectrometers rely on photomultiplier tubes (PMTs), but the glass enclosures of these tubes and the tube base or socket are often a significant source of radiation background. Manufacturers of PMTs offer, at a higher price, versions that have significantly smaller radioactive content. Likewise, tube bases are also available that have much less activity that normal sockets. Detector housings are usually made of aluminum, magnesium or beryllium for scintillator materials and of stainless steel for gas tube detectors. These housing materials must be chosen to have the lowest radioactivity possible. Germanium detectors must be cooled cryogenically for proper operation, and so another possible source of background is the radioactivity contained in the endcap of the cryostat which is usually positioned adjacent to the Ge crystal. Material for such endcaps must contain very low levels of radioactivity.

Although not widely used in the construction of radiation spectrometers, materials such as plastics and carbon fibers, which do not derive from ores, contain extremely low levels of radioactivity. Almost all radioactivity in these materials comes from the cosmogenic radionuclides of ^{3}H and ^{14}C, which emit only beta particles and, thus, do not contribute to the background in a gamma-ray spectrometer (save through low-energy bremsstrahlung). Indeed, sample holders and calibration source encapsulations are usually made from plastic to avoid the introduction of background gamma rays.

21.2.3 Passive Shielding of Radiation Spectrometers

To reduce the background response inherent in any radiation measurement, it is routine to use some sort of radiation shield to minimize the amount of background radiation that reaches a detector. Shields are usually composed physically of matter, although shields of a non-corporeal nature could be used. In fact one of the most important shields for us on earth are magnetic fields produced by the sun and earth that deflect charged cosmic radiation from our detectors on the earth's surface. In principle, one could use strong electro magnetic fields around a detector to shield the detector from incident charged particles.

Another extreme shield is to use the earth itself as a shield by moving the detector deep underground in old mine shafts, for example, to prevent almost all cosmic rays from reaching the detector. This is done in large research facilities that seek to study neutrinos or seek the half-life for proton decay. Such experiments have extremely weak foreground signals (some as low as counts per week or even months) and even the smallest background would swamp the foreground response.

However, for most radiation measurement situations, far less heroic shielding effort is needed to obtain statistically useful results. In the next two sections the use of common shielding materials and their arrangement to reduce background is discussed.

21.2.4 Shielding Against Gamma Rays

To reduce the background in a gamma-ray spectrometer, passive methods employing photon shields are almost always used. Because photons are exponentially attenuated as they pass through a shield, unlike charged particles which have a finite range, no photon shield can stop all photons from reaching the spectrometer. However, proper shield design can be quite effective in reducing the spectrometer background.

Lead

Because of its large interaction coefficient (macroscopic cross section) for gamma and x rays, lead ($> 99.9\%$ pure) is routinely used as a shielding material against these radiations. However, lead is a poor construction material and is not suited for high temperature applications (melting point 327.4°C). To increase its strength, lead is often alloyed with antimony. Lead shields are relatively easy to fabricate because lead may be cast, extruded, rolled, machined and welded. Casting requires special care because lead increases in mass density from the liquid at 10.678 g cm^{-3} to the solid at 11.34 g cm^{-3} [Kirshenbaum et al. 1961], leading to a volume decrease of 5.83% upon solidification. Also, the fumes from lead are toxic and safety precautions should be exercised. Lead is resistant to chemical corrosion, but it is a relatively expensive material (currently about $2.30 per kg).

Lead often is cast into rectangular bricks (typically, 2× 4× 6 inches) which are then used to create simple gamma-ray shields by stacking the bricks. Streaming through the cracks between bricks can be minimized by staggering the brick layout or shaping the bricks so there are no straight line streaming paths through the shield. Alternatively, lead may be cast into cylindrical annuli to produce 2π shielding without corners. When casting lead, care must be taken to avoid voids in the cast. Sometimes lead shot is used to fill containers to produce a lead shield with slightly lower density than solid lead, but with more flexibility in the shape of the shield. Epoxies and plastic putty-like compounds containing high concentrations of lead are commercially available which can be molded and shaped to fill shield gaps or shield penetrations through which radiation could stream.

Lead and uranium are usually found together in ore and, although the uranium and most of its decay daughters are easily removed upon smelting and purification, the primordial Pb decay daughters are retained in the lead. Of these ^{210}Pb ($T_{1/2}$ = 22.3 y) is of concern for shielding for ultra-low-level gamma-ray spectrometers because it emits a 46 keV gamma ray followed by 205 and 304 keV gamma rays from the decay of its daughter ^{210}Bi. After several hundred years this component of background radiation from a lead shield disappears through decay. Lead has been extracted and used by humans for several thousand years. This ancient lead is ideal for constructing shields with low radioactivities for ultra-low-level counting spectrometers. Although quite expensive, sources of old lead are still sometimes available. Lead, first obtained as a byproduct of silver extraction from ore, has been used by humans since about 4000 BC. Romans used it as liners for aquaducts, baths, and almost all other plumbing applications. Later in history, the building of medieval churches consumed much lead as roof liners, masonry joints and even as mortar.[6]

[6] One source of old lead used for the Italian Cryogenic Underground Observatory for Rare Events (CUORE) was from a Roman ship that sank between 80 and 50 BC off the coast of Sardinia. From this shipwreck over 1000 lead ingots, each 33 kg in

Water

Large water-filled tanks offer an inexpensive and flexible way to create gamma-ray shields. On a *per unit mass basis*, water is almost as effective in reducing the energy of photons through Compton scattering, as is lead.[7] Furthermore, water is far less expensive and can be more easily purified to remove essentially all radioactive impurities save tritium which is of little concern for gamma-ray spectroscopy. Only the radioactive impurities in the tank materials are of concern. However, lead has a larger photoelectric cross-section and is a superior material for absorbing low-energy photons. Thus, rather than using a monolithic shield, a layered approach can be used with a water shield used to reduce the high-energy background gamma rays followed by a thinner lead shield near the spectrometer system to absorb the low-energy photons.

To reduce the background, the spectrometer could be lowered into water, thereby creating a much larger water shield. At depths of about 10 meters, the background for surface terrestrial radionuclides and all cosmic rays (except for muons) are eliminated. Only the radionuclides dissolved in the water and incorporated in the spectrometer produce a background. This approach has been taken to an extreme with the IceCube Neutrino Observatory at the Amundsen-Scott South Pole Station in Antarctica where thousands of sensors are spread over 1 km^3 at depths between 1450 and 2450 meters in the Antarctic ice cap. Here the water, in the form of ice, serves both as the neutrino detection medium as well as a shield against cosmic rays.

Steel

Steel (or iron) is sometimes used to fabricate gamma-ray shields although thicker iron shields compared to lead shields are needed to produce the same reduction in transmitted radiation. For example, the tenth thickness[8] for 1-MeV photons in iron is almost 5 cm (compared to 1.2 cm in lead and 14 cm in water). Often a shield has a steel outer layer followed by a thinner inner lead layer.

Steel generally has low concentrations of radioactive impurities and is often a less expensive alternative to a large lead shield. As mentioned earlier in this chapter, energetic cosmic ray neutrons can lead to the buildup of radioactive ^{54}Mn in iron, so steel produced to provide shielding for low-level spectrometers should be moved underground as soon after production as possible. Also because post WW II steel contains fission products from open-air nuclear tests in the 1950s, old pre-WW II steel, typically from old ships, is often sought. But unless stored properly, cosmic ray neutrons may have contaminated this old steel. Also steel produced from scrap iron may also contain unacceptable radioactive impurities as a consequence of radionuclide sources being inadvertently included with the scrap iron.

Tungsten

Tungsten, because of its large $Z = 74$ number and its high density of 19.3 g cm^{-3} is an excellent material for gamma-ray shielding. But pure metal is hard to machine or to cast. To form various shapes of tungsten components, powder technology is often used to produce a sintered product with almost the same density as the metal. More frequently, tungsten is alloyed with nickel, iron, and copper to produce a metal with a density of about 90% of tungsten that is far easier to machine. But because of its cost, machinability, and toxic properties, tungsten is used in limited quantities and usually only for shields adjacent to a source. Its use in low-level spectroscopy is to produce collimated photon beams in a small space.

---

weight, were recovered. Italy's National Institute of Nuclear Physics financially supported the archaeologists in their recovery efforts and, in return, received 120 of the most damaged ingots from which a 3-cm-thick low-activity shield was constructed for the underground Laboratory at Gran Sasso.

[7] The mass interaction coefficient μ/ρ for 1-MeV photons is 0.07066 and 0.06803 cm^2 g^{-1} for water and lead, respectively.

[8] The tenth thickness is the thickness of a material required to reduce the uncollided radiation to 10% of its incident value, and is given by

$$x_{1/10} = \ln 10/\mu(E),$$

where μ is the total interaction coefficient for the material for photons of energy E.

Source: From Shultis and Faw [2000].

Concrete

Concrete is the most widely used shielding material for both gamma rays and neutrons because it is relatively inexpensive and, while still a liquid slurry, can be poured into forms to create shields of all shapes and sizes. It can also be cast into concrete blocks which can later be stacked to form radiation shields. Concrete is prepared from a mixture, by weight, of about 13% cement, 7% water (including water in the aggregate), and 80% aggregate. There are many different types of concretes each with distinctive properties as determined by the choice of aggregate [see Shultis and Faw 2000]. For example, to enhance its photon-attenuation properties, scrap iron or iron ore may be incorporated into the sand-and-gravel aggregate. Examples of elemental compositions of concrete frequently encountered in radiation shielding applications are given in Table 21.8.

However, concrete often has appreciable concentrations of the KUT radionuclides. In any spectrometer facility with concrete walls, floors, and ceilings, the 1.46-MeV gamma ray from ^{40}K is almost always observed in a gamma-ray spectrum. From Table 21.8 it is seen that barytes concrete, which is the most effective concrete for attenuating gamma rays, has the highest K concentration. To reduce the ^{40}K presence, special (and expensive) low potassium sand and gravel can be used. However, as seen in Table 21.7, common cements also have high ^{40}K activities. To ameliorate the radionuclide impurities in concrete shields, steel, or lead liners can be placed on the inner surface of a concrete shield.

Mercury and Molybdenum

Like tungsten, mercury also has low intrinsic radioactivity and, because of its high $Z = 80$ number and density $\rho = 13.53$ g cm^{-3}, is an excellent material for attenuating gamma rays. However, also like tungsten, it is relatively expensive and because it is a liquid it must be placed in containers, which may themselves be another source of gamma rays. Mercury is also toxic and thus requires special care in handling. Nevertheless, shields made from mercury have been used in ultra-low-level counting facilities.

Molybdenum is another material with good gamma-ray shielding properties ($Z = 42$ and $\rho = 10.2$ g cm^{-3}). It generally has low intrinsic radioactivity, but like tungsten and mercury is relatively expensive.

21.2.5 Shielding Against Neutrons

Although most gamma-ray spectrometers are inherently insensitive to neutrons, background neutrons are still of concern in the design of low-level counting facilities. Neutrons produced by cosmic rays have supra-MeV energies, and as they slow through scattering interactions they produce inelastic scattered gamma rays. Further these neutrons are eventually absorbed creating highly excited nuclei which decay by the emission of energetic capture gamma rays. The capture gamma rays are often very energetic, some with energies of 8 to 10 MeV. Also neutrons, particularly after they have slowed, can interact with elements in the detector itself to produce radionuclides, such as ^{24}Na in a NaI:Tl detector whose decay produces gamma rays, or produce reaction products, such as those in the ^{6}Li(n,t)^{4}He reaction in Si(Li) or Ge(Li) detectors. Thus, one must use neutron shielding outside the gamma-ray shielding to minimize the gamma-ray background in the spectrometer system.

Because neutrons are absorbed mainly when they have near thermal energies, a neutron shield for fast neutrons first attempts to slow the neutrons through scattering interactions (or *moderate* them) and then absorb them with materials such as cadmium, boron, or lithium, that have large thermal-neutron cross sections. To moderate neutrons rapidly, materials such as water or polyethylene with a high hydrogen content are normally used because the lighter the scattering nucleus, the more energy a neutron loses on a scatter. However, for cosmic ray neutrons with energies above 10 MeV, the cross section for scattering from hydrogen decreases rapidly and becomes ineffective at slowing the neutrons. Consequently,concrete used for neutron shielding against fast neutrons usually contains high Z materials, such as iron, which slow fast neutrons through inelastic scattering (and also produce unwanted inelastic scattering gamma rays). Once the neutrons are slowed below 1 MeV, hydrogen can then quickly moderate the neutrons towards thermal energies where they are absorbed by impurities or by materials with large neutron absorption cross section that are added to the moderating material.

From ease of fabrication, fast neutron shields are usually composed of laminates of iron and high density polyethylene (HDP). As the neutrons approach thermal energies, ^{6}Li can be incorporated into the HDP to absorb the slow neutrons without the emission of any capture gamma rays. Often a high Z layer is added to the inner surface of the neutron shield to attenuate capture-gamma, inelastically scattered, and bremsstrahlung photons. For instance, cadmium or boron is widely used to absorb thermal neutrons, but such absorptions produce gamma rays that must be shielded from the detector.

21.2.6 Minimize Radioactivity in Air around Spectrometer

Gaseous radon and its airborne daughters are always present in the air in any low-level counting facility. Indeed without adequate ventilation these radionuclides can build up, thereby producing air concentrations many times those in ambient outside air. This is especially a problem for underground facilities. To avoid this activity in the air in a spectrometer counting cavity two main approaches have been used. One is to seal the cavity after the sample has been inserted and then wait several days before counting to allow these

Table 21.9. Typical naturally occurring radionuclide concentrations in various building and structural materials.

Material	Average specific activity (Bq kg^{-1})		
	^{40}K	^{226}Ra	^{232}Th
asbestos	200	10	15
brick, clay (red)	670	50	50
brick, snad-lime	330	10	10
cement	200	20	15
ceramics	500	30	40
clinker	600	60	70
concrete	400	40	30
concrete, aerated	430	60	40
granite	1000	80	80
gravel	150	10	10
limestone	60	10	5
marble	150	10	5
natural gypsum	80	10	10
pearlite	1200	50	80
plaster	250	15	45
phosphogypsum	60	390	20
sand	200	10	10

airborne radionuclides to decay. However, this approach severely limits the rate at which samples can be analyzed because the insertion of a new sample requires a multiday wait before analysis.

The usual approach to minimize airborne radioactivity is to purge the counting cavity with purified gas, such as argon, which has little inherent radioactivity. Some facilities whose spectrometer requires cryogenic cooling with liquid nitrogen use the boil-off nitrogen as a purge gas.

Radionuclides from the soil or radon decay can also be attached to dust particles, which also contribute to the air activity. Thus, it is important to effectively filter the ventilation air to the counting room.

21.2.7 Use Construction materials with Low Radioactivity

Typical concentrations of ^{40}K, ^{226}Ra, and ^{232}Th in common building materials are given in Table 21.9. However, these activity concentrations can vary by several hundred percent depending on the source of the material. Typical radionuclide activities in materials used in construction of radiation detection systems are listed in Table 21.7. Again these activities can vary substantially depending on the manufacturer, but to minimize the effect of background on radiation spectrometers, it is imperative that close attention be given to the choice of materials used.

21.2.8 Counting Enclosures

Almost all low-level counting spectrometers and the radioactive sample to be analyzed are placed in some small enclosure or cavity whose walls act as the primary passive shields against background radiation in the laboratory walls and air. These cavities typically have a rectangular parallelepiped shape because the walls are most conveniently constructed from shielding bricks or plates of various materials. Some cavities are cylindrical in shape with walls made from lead and other materials cast into cylindrical annuli shapes, but these are more expensive and difficult to fabricate than parallelepipeds. The shield material used for these cavities should, of course, contain as little radioactivity as possible. The size of the counting cavity is usually quite small so as to minimize the amount of shielding required.

As background radiation incident on the walls of the counting cavity is attenuated, it also creates a buildup of secondary radiation in the form of Compton scattered photons, bremsstrahlung, and x rays. Even if the shield material is radiopure, low-energy photons produced in the shield walls can still enter the counting cavity. Although lead is a excellent shield material, photoelectric interactions in it from background photons produce significant low-energy x rays ($K_\alpha = 75$ keV, $K_\beta = 84.9$ keV, and $L_\alpha = 10.5$ keV). To absorb these x rays, lower Z materials, such as copper and aluminum, are often used as inner shields. One example of a passive shield described by Zvara et al. [1994] is that at the Comenius University in Czechoslovakia has a mass of 18,000 kg with outer dimensions of $80 \times 90 \times 172$ cm. It is composed, starting from the outside, with 1 cm of Fe, 10 cm of Pb, 5 cm of Cu, 8 cm of polyethylene with boric acid, 1 mm Cu, and 1 cm of Plexiglas. To stop the low-energy, non-muonic cosmic rays, the top of the enclosure has a 12-cm Fe slab shield. Modern materials with no special selection were used.

As an illustration of the use of a Cu inner liner to reduce Pb x rays, the energy dependent flux of ^{60}Co photons leaving a 10-cm bare and 0.5-cm Cu clad lead shield is shown in Fig. 21.8. The flux shown is that entering a NaI:Tl crystal on the cold side of the shield. No Gaussian smearing of the spectrum is used to account for the actual resolution of the detector. Notice the Cu liner totally eliminates all the Pb x rays as well and also suppresses some of the transmitted Compton lead scattered photons, except near the Pb x ray region where the Cu slightly enhances the photon flux. With modern radiation transport codes, calculations such as those in Fig. 21.8 can be used to design shields for counting cavities and can eliminate much of the trial and error and intuition used a few decades ago to design passive shielding for low-level counting facilities.

In measuring the spectrum emitted by a sample with small amounts of radioactivity, radiation from the sample that reflects from the inside of the passive shielding is usually not of too much concern. However, such radiation incident on the inner portions of a lead shield will produce x rays that will be seen by the spectrometer. Again, lining the inner cavity with lower Z materials can ameliorate this effect. An example of the reflected photon flux from ^{137}Cs gamma rays emitted by a sample is shown in Fig. 21.9. Here it is seen that a 0.5-cm-thick Cu liner almost totally eliminates the lead x rays but at the price of significantly enhancing the low-energy part of the reflected spectrum. Such calculations with modern radiation transport codes should be used to customize the inner cavity shielding for a particular type of radiation source that is to be analyzed.

21.2.9 Laboratory Location

Terrestrial and cosmic ray background are greatest at the earth's surface. Consequently, construction of a low-level spectrometer facility at ground level is seldom done. Even a few tens of meters below the surface, the background radiation is greatly reduced, although the cosmic-ray muonic component is affected little. Thus, in a multistoried building, the low-level spectrometer system should be built in the lowest basement room possible.

Cosmic ray background can be almost completely eliminated by building the counting system deep underground or underwater. To this end, there are several tens of low-level counting systems around the world that have been built in abandoned mines, some of which are close to 10,000 m (water equivalent) deep. At such depths all the muons are stopped, leaving only neutrinos, which are the particles being studied in many of these facilities. Of course, the walls of underground caverns or rooms still contain primordial radionuclides so that spectrometer shielding is still required. Ideally, surrounding wall material should have as small as possible radionuclide content. For this reason, abandoned salt mines are very attractive locations. Shown in Fig. 21.10 are the background spectra for four different low-level facilities, two at ground level and two deep underground away from cosmic ray muons. The superiority of an underground location is obvious.

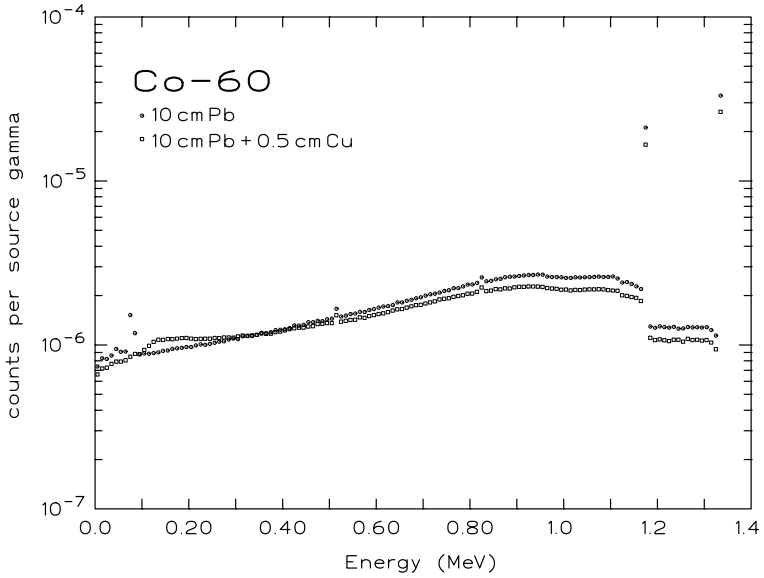

Figure 21.8. ^{60}Co gamma rays transmitted through 10 cm of lead and from the same amount of lead plus 0.5 cm of copper on the exit surface as calculated by MCNP6. Gamma rays are normally incident on the outer surface.

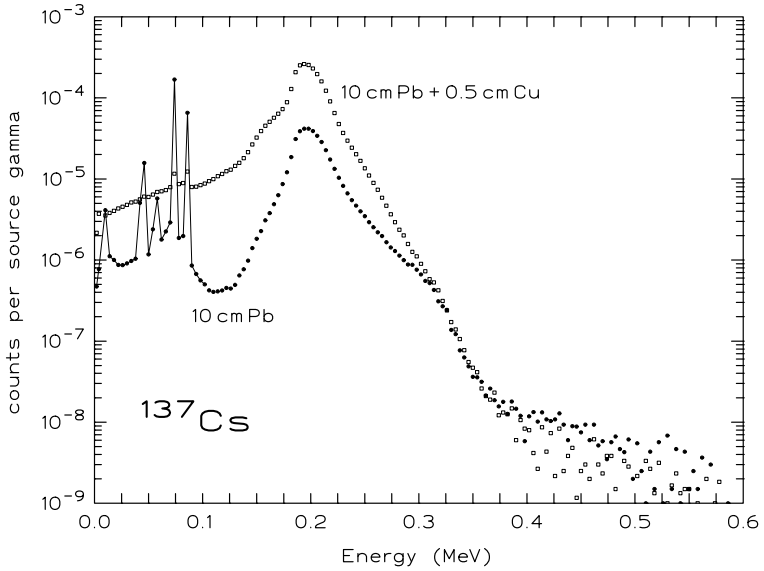

Figure 21.9. ^{137}Cs 0.6617-MeV gamma rays reflected from 10 cm of lead and from the same amount of lead plus 0.5 cm of copper on the reflecting surface as calculated by MCNP6. The gamma rays are normally incident on the inner shield surface.

21.2.10 Other Considerations

The measurement of background spectra from low-activity sources almost always requires long count times, sometimes of multiday or, in extreme cases, multimonth duration. For such long count times, there are a

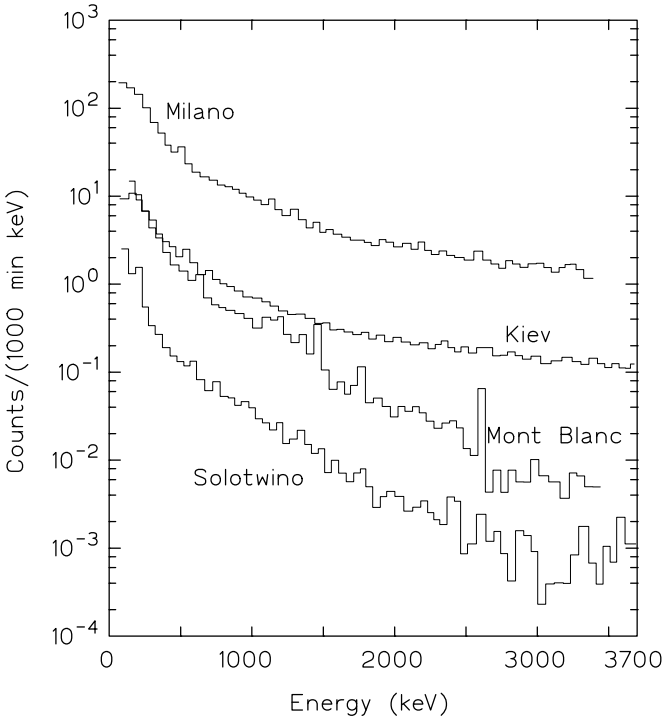

Figure 21.10. Comparison of Ge:Li background spectra in above ground (Milano and Kiev) and underground (Mont Blanc and Solotwino) laboratories. Data are from [Zvara et al. 1994].

myriad of small factors that can affect the spectrometer system and confound the subsequent analysis of the measured spectra. It is essential that stability of the system be maintained during long data collection times. It is always a good practice to interrupt a long accumulation time of a spectrum and perform periodic calibration verifications and recalibrations if necessary.

The response of the electronics is often susceptible to small changes in the ambient temperature. For example, Rizzacacca [1986] reports that a temperature change of 2°C over a 24-hour period can shift the spectrum from a Ge:Li detector by about one FWHM (2 keV at 1.33 MeV). Today the use of electronic spectrum stabilizers reduces such shifts substantially. Also underground facilities are less susceptible to temperature changes because the huge thermal inertia of the surrounding rock and soil minimizes any temperature fluctuations.

Also during long count times, the background radiation field can fluctuate. This is of particular concern for the airborne radionuclides of radon and its daughters. Following rain storms or thawing cycles, the emission of radon from soil and rocks may increase substantially and, depending on how readily airborne contaminants can reach the gas surrounding the spectrometer detector, the count rate can be affected. Likewise, activity such as housekeeping activities can alter the concentration of radionuclides in the air.

It stands to reason that any low-level counting facility be located as far as possible from known sources of radiation such as industrial x-ray sources or other sources used for industrial or research purposes. It is not a good idea to store even weak radioactive "check" sources or radioactive samples near the spectrometer. The authors are amazed at how often they have found radiation sources in desk drawers or on shelves in or near a room used for spectroscopic measurements. It should also be remembered that people are radiation

sources (notably from ^{40}K) and they also act as radiation reflectors and shields. Thus, their presence in and around a spectrometer as it collects data alters the background. Such human activity near a spectrometer can perturb the measured spectrum depending on the effectiveness of the passive shielding surrounding the spectrometer.

Finally, it should be mentioned that contamination of surfaces near and on the spectrometer can occur over time, especially if many unsealed calibration sources and/or samples have been processed. Periodic wipes and checks for such contamination should be made and appropriate remediation taken if such contamination is found. Sometimes sensitive detector windows are protected by plastic film that can be replaced if contamination occurs.

21.3 Self-Absorption of Photons

So far in the discussion about reducing the background in photon spectrometers, the emphasis has been on reducing the radiation reaching the spectrometer detector and radioactive content of various components of the low-level counting facility. However, a radioactive impurity in some facility component does not necessarily lead to a background count. The radiations from a radioactive decay in some material may be absorbed in the material before they can escape and deposit their energy elsewhere. This *self-absorption* effect can be important in assessing the effectiveness of thick shields and walls of the spectrometer facility.

21.3.1 Infinite Slab

Consider a homogeneous slab shield of thickness T which contains a uniform volumetric source of a radionuclide which emits a gamma ray of energy E_o per decay. The number of photons escaping the slab without interaction is, by symmetry, the same for either surface. The probability the gamma ray escapes through one surface is [Case et al. 1953]

$$P_1^o(T) = \frac{1}{2\mu T}\left[\frac{1}{2} - E_3(\mu T)\right], \tag{21.3}$$

where μ is the total interaction coefficient for photons of energy E_o and $E_3(x)$ is the exponential integral function of order three.[9]

The one-sided escape probability of Eq. (21.3) can be approximated to within 1% by

$$\frac{1}{P_1^o(T)} = \begin{cases} 2.077 + 2.951\mu T + 0.1348(\mu T)^2, & 0.003 < \mu T < 3.5 \\ 4\mu T, & \mu T \geq 3.5 \end{cases} . \tag{21.4}$$

The uncollided escape probability for the slab, i.e., through either face is $P_0 = 2P_1^o$. The uncollided escape probability is independent of the slab material and depends only on the thickness of the slab in units of mean free path lengths $\mu(E_o)T$.

Also leaving a slab surface are secondary photons produced by the decay gamma ray interacting in the slab to produce fluorescence, bremsstrahlung, Compton scattered photons, and annihilation photons. These photons have a distribution of energies. The total number of secondary photons escaping through one surface, per source gamma ray, is denoted by P_1^s. No analytic expression is known for the energy distribution or total number of these secondary photons. However, with modern transport codes, it is a fairly simple matter to

[9] The exponential integral function of order n is defined as

$$E_n(a) = \int_1^\infty x^{-n} e^{-ax} dx, \; n = 0, 1, 2, \ldots \; .$$

make such calculations. In Fig. 21.11 results for a concrete slab are shown. Of particular note is the relative insensitivity of P_1^s to the energy of source gamma rays. Unlike P_1^o, P_1^s depends not only on the mean free path thickness of the slab, but it also depends on the slab material because the interaction coefficients for the various reactions that produce secondary photons vary with the material.

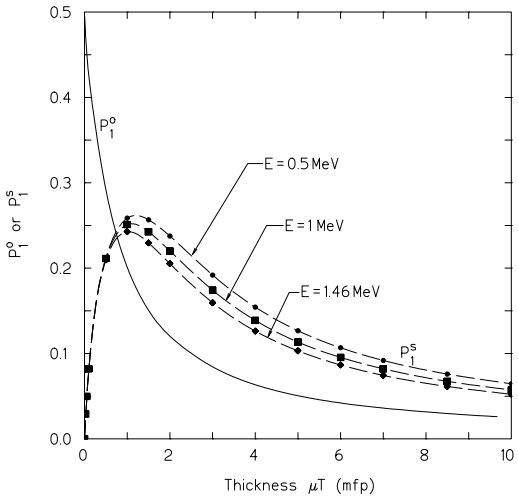

Figure 21.11. One-sided escape probabilities from a concrete slab for a monoenergetic, isotropic, uniformly distributed, gamma-ray source. Concrete is ANSI/ANS-6.6.3 standard concrete with a density of 2.3 g cm^{-3}. The solid line is calculated from Eq. (21.3) and the data points for secondary photons were calculated by MCNP6.

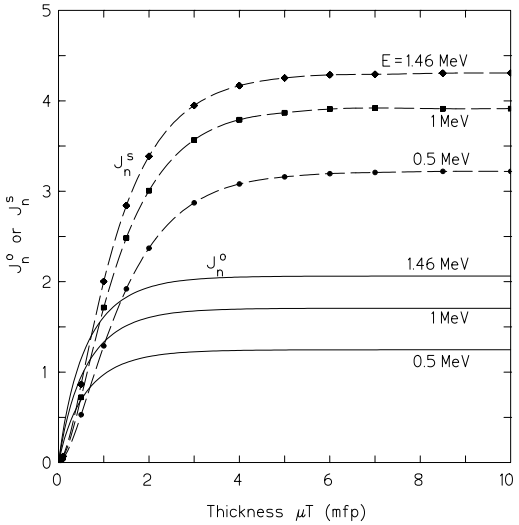

Figure 21.12. The current or flow rate of photons through a unit area of the surface of a concrete shield containing a unit strength volumetric source ($S_v = 1$ cm^{-3}s^{-1}) of monoenergetic photons of energy E_o. The solid lines for J_n^o are from Eq. (21.5) and the data points are values obtained with MCNP6.

For a radioactive contaminant that emits gamma rays of energy E_o and that is uniformly distributed in the slab, the volumetric gamma-ray source strength is $S_v = Af$ cm^{-3} s^{-1}, where A is the activity concentration Bq cm^{-3} and f is the gamma-ray frequency, i.e., the probability a gamma ray of energy E_o is emitted per decay. Then the total flow of uncollided photons crossing a unit area on the surface of the slab is the photon current leaving the slab and is given by $J_n^o = S_v T P_1^o(T)$, where $S_v T$ is the total number of gamma rays of energy E_o emitted per unit time in a 1 cm^2 prism of length T. If gamma rays leave this prism while migrating in the slab they are compensated, by symmetry, by gamma rays that enter the prism. Thus, the uncollided current leaving the slab is from Eq. (21.3)

$$J_n^o \equiv \int_{\mathbf{n}\bullet\mathbf{\Omega}>\mathbf{0}} \mathbf{n}\bullet\mathbf{\Omega}\phi(E_o,\mathbf{\Omega})\,d\mathbf{\Omega} = \frac{S_v}{2\mu}\left[\frac{1}{2} - E_3(\mu T)\right], \tag{21.5}$$

where $\mathbf{n}$ is the outward normal to the slab surface. Likewise the flow through a unit area on the slab's surface is $J_n^s = S_v T P_1^s$. In Fig. 21.12 these surface flows of escaping photons for a unit strength source strength, i.e., $S_v = 1$. Notice for shields greater than a few mean free paths thick, these surface flow rates become almost independent of the shield thickness.

The uncollided flux at a point exterior to the slab is [Shultis and Faw 2000]

$$\phi^o = \frac{S_v}{2\mu}\left[1 - E_2(\mu T)\right]. \tag{21.6}$$

This result assumes that the photons, once outside the slab, no longer interact. Notice the uncollided flux is not dependent of the distance to the slab surface.

The above analysis is for an infinite slab. However, all slab shields are finite in all dimensions. But if the point of interest on the surface of the slab is a few mean free paths away from the slab edges, the above results serve as a good (conservative) approximation.

Example 21.1: A concrete wall 30-cm-thick contains ^{40}K with a specific activity of 250 Bq kg^{-3}. The total interaction coefficient for the 1.46-MeV gamma ray emitted by ^{40}K is 0.1212 cm^{-1} and the concrete has a mass density of 2.3 g cm^{-3}. Estimate the number of uncollided and secondary photons that escape per unit time through a unit area on the concrete wall.

Solution:

The radionuclide ^{40}K emits a 1.46-MeV gamma ray with a frequency of 0.107 per decay. Thus, the volumetric source strength is

$$S_v = 250 \text{ Bq/kg} \times 0.001 \text{ kg/g} \times 2.3 \text{ g/cm}^3 \times 0.107 = 0.0615 \text{ cm}^{-3} \text{ s}^{-1}.$$

The wall thickness in mean free path lengths is μT=(0.1212 cm^{-1})(30 cm) = 3.636. The one-sided escape probability from a concrete slab is, from Fig. 21.11, about $P_1^o = 0.06$ or from Eq. (21.3) is found to be $P_1^o = 0.068176$. The approximation of Eq. (21.4) gives $P_1^o = 0.06855$. Thus, the number of uncollided photons escaping is

$$J_n^o = TS_vP_1^o = (30 \text{ cm})(0.0615 \text{ cm}^{-3} \text{ s}^{-1})(0.068176) = 0.126 \text{ cm}^{-2} \text{ s}^{-1}.$$

Alternatively, from Fig. 21.12 J_n^o for S_v =1 is about 2.0. Multiplication by $S_v = 0.0615$ gives $J_n^o = 0.123$ cm^{-2} s^{-1}.

The flow of secondary photons for $S_v = 1$ is found from Fig. 21.12 to be about 4.1 cm^{-2} s^{-1}. Multiplication by $S_v = 0.0615$ gives $J_n^s = 0.252$ cm^{-2} s^{-1}.

21.3.2 Infinite Cylinder

Analytic expressions are known for the uncollided escape probability for other simple geometric shapes such as spheres, hemispheres, oblate spheroids, and cylinders [Case et al. 1953]. Of interest here are impurity radionuclides in a cylindrical crystal. For a infinite cylinder of radius R, the uncollided escape probability is

$$P_0(R) = \frac{2\mu R}{3}\left\{2\left[\mu a K_1(\mu R)I_1(\mu R) + K_0(\mu R)I_0(\mu R) - 1\right] + \frac{K_1(\mu R)I_1(\mu R)}{\mu R} - K_0(\mu R)I_1(\mu R) + K_1(\mu R)I_0(\mu R)\right\}, \tag{21.7}$$

where I_n and K_n are the modified Bessel functions of the first and second kind and of order n. For radii small compared to a mean free path length $1/\mu$, Eq. (21.7) may be approximated by

$$P_0(a) \simeq 1 - \frac{4\mu R}{3} + \frac{1}{2}(\mu R)^2\left\{\ln\left(\frac{2}{\mu R}\right) + \left(\frac{5}{4} - \gamma\right)\right\}, \tag{21.8}$$

where γ = Euler's constant = 0.577216 . . .. For a much larger than one mean free path length

$$P_0(a) \simeq \frac{1}{2(\mu a)} - \frac{3}{32(\mu a)^3}. \tag{21.9}$$

For a cylindrical crystal of height $2H$ and radius R that is uniformly contaminated by a radionuclide emitting photons of energy E_o, the uncollided flux on the axis at the center of the crystal is given by [Shultis and Faw 2000]

$$\phi^o = \frac{S_v}{\mu} G_2(\mu H, \mu R), \tag{21.10}$$

where the function G_2 is defined as

$$G_2(a,b) \equiv \frac{1}{\pi} \int_0^a [E_1(x) - E_1(\sqrt{x^2+b^2})]\, dx, \tag{21.11}$$

and which must be evaluated numerically. This function is shown in Fig. 21.13.

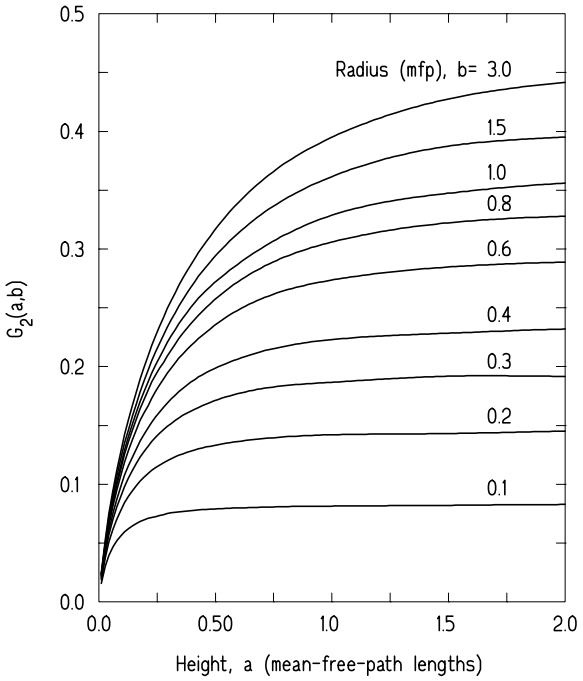

Figure 21.13. The function $G_2(a,b)$ used for the calculation of the uncollided flux at the center of a cylinder of radius $b = \mu R$ and height $a = 2\mu H$ in mean free pathlengths.

21.4 Electronic Methods for Background Reduction

To substantially reduce cosmic ray background generally requires massive amounts of "passive" shielding with radiopure materials and/or the placement of the spectrometer deep underground where the overlying earth provides the needed massive passive shield. An alternative is to use "active" shielding techniques in which multiple detectors and associated electronics are used to reduce the recorded background. Coincidence and anti-coincidence methods were introduced in Section 20.7.3, with examples of the effectiveness of the technique (see Figs. 20.27 and 20.28).

21.4.1 Anti-coincident Background Reduction

Active (anti-coincidence) shielding is a powerful method for reducing the detector background. This method uses several detectors placed near the spectrometer detector to reject a spectrometer detector pulse that coincides within a microsecond or so of a pulse originating in one or more of the surrounding detectors. Such coincident pulses arise from Compton scattered gamma rays from the passive shield or spectrometer detector. Likewise cosmic rays may produce nearly simultaneous pulses in both the spectrometer and a surrounding detector. Thus, not only is the background reduced, but the Compton continuum in the spectrometer is also reduced.

An active anti-coincidence shield can be devised using GM-tubes, proportional counters, plastic or liquid scintillators, NaI:Tl or BGO crystals. If the anti-coincident system is placed inside a passive shield enclosure, then NaI:Tl detector(s) are attractive because they generally have smaller space requirements and have a high detection efficiency. The random direction of gamma rays from the environment calls for a uniform anti-coincidence shield around the spectrometer detector. Cosmic ray muons are quite anisotropic, but do not significantly affect the required shape of the active shield. This outcome is mainly due to the fact that a muon path length of only a fraction of a centimeter, is generally sufficient to produce a usable pulse in the guard detector(s) for the anti-coincidence circuit to reject a spectrometer event.

The Compton scattering process in the detector produces a continuum spectrum that raises the lower detection limit for gamma rays within this continuum spectrum. The scattered photons that escape the spectrometer detector can be detected with a sufficiently large NaI:Tl or BGO crystal surrounding the detector. NaI:Tl has a better energy resolution than that of BGO, but a lower density. As a result NaI:Tl is about 2.5 times less efficient than BGO (averaged over several common gamma-ray energies) at detecting the Compton scattered photon. Because BGO has only about 10–20% the light output of NaI:Tl, it has a higher threshold that consequently causes a lower Compton suppression factor at low gamma-ray energies. If an HPGe spectral detector is placed above the center of a large anti-coincidence NaI:Tl crystal (30×30 cm), a Compton suppression factor of about 10–12 can be achieved for gamma-ray energies below 1.5 MeV [Zvara et al. 1994].

21.4.2 Coincident Counting

Many radionuclides emit two or more radiation quanta upon decay. With the use of coincidence counting techniques using multiple detectors, the background count rate in the spectrometer detector can be sharply reduced. Only if the spectrometer and another detector both detect an event at the same time is the event recorded. Although background events are thus most rejected, some events which should be recorded are rejected because only the spectrometer detector experienced the event. Thus, the efficiency of coincident counting usually reduces the efficiency of the spectrometer for the radiation of interest while at the same time much of the background is eliminated. There are several types of coincidence schemes as briefly mentioned below.

Double Coincidence Spectrometer

This type of spectrometer is used to measure the activity of a radionuclide that emits two or more nearly simultaneous gamma rays. ^{60}C for example is one such radionuclide which upon beta decay to ^{60}Ni, 99+% of the time emit both a 1.173-MeV and 1.333-MeV gamma ray within 0.7 ps of each other. Usually two NaI:Tl crystals, a NaI:Tl and HPGe detector or two HPGe detectors, are used. The HPGe-NaI:Tl spectrometer, which combines the good energy resolution of the HPGe crystal with the high efficiency of the NaI:Tl detector, is preferred for low-level gamma-ray activity.

Triple Coincidence Spectrometer

This type of spectrometer is used as a pair spectrometer for the simultaneous measurement of the annihilation and gamma photons of radionuclides that decay by positron emission. Three NaI:Tl detectors or two

NaI:Tl detectors with one HPGe detector are combined for this type of spectrometer. Sometimes a large NaI:Tl crystal split into two optically isolated regions is used, which can also be used as an anti-Compton spectrometer. A triple coincidence scintillation spectrometer with active and passive shields has been used for the measurement of ^{22}Na, ^{26}Al, and ^{60}Co activities in meteorite samples [Vartanov and Samojlov 1975]. With this spectrometer, the sensitivity for ^{22}Na was greatly increased in the presence of higher ^{26}Al and ^{60}Co activities.

Beta-Gamma Coincidence Spectrometer

If a sample has a radioisotope that emits two different types of radiation that can be measured simultaneously, then coincident techniques between the detectors for each type of radiation can be used to substantially reduce the background signal. For example, many radionuclides decay by beta particle emission whose excited daughter nucleus decays almost immediately by emitting one or more prompt gamma rays that are unique to the parent [Dewaraja et al. 1994]. The sample is placed adjacent to a beta counter and a gamma-ray spectrometer detector. By recording only those events which coincidentally produce signals in each detector, the background is reduced by eliminating events for which only one detector responds.

PROBLEMS

1. The muons μ^- and μ^+ are produced by cosmic ray interactions in earth's atmosphere miles above the surface. These particles are radioactive with a half-life of 1.523 μs and travel at speeds of $\beta = 0.9997c$. Thus half of the muons decay after traveling $(1.523 \times 10^{-6}\text{s})(3 \times 10^{8}\text{m/s}) \simeq 450$ m. How then do muons reach the earth's surface and contribute to our background dose?

2. At what speed must a 58-g tennis ball travel to have a kinetic energy equal to that of the most energetic cosmic rays, protons with energies of about 10^{20} eV. How high would the tennis ball jump if 10^{20} eV of energy were converted into gravitational potential energy?

3. The energy-dependent neutron flux produced by cosmic rays at ground level which has a water fraction of 25% is shown in the table below. Estimate the total thermal flux $\phi_T = \int_0^{.1eV} \phi(E)\, dE$ in units of cm^2 h^{-1}.

E MeV	$\phi(E)$ cm^{-2} s^{-1} MeV^{-1}	E MeV	$\phi(E)$ cm^{-2} s^{-1} MeV^{-1}
1.13E-08	5.22E+04	4.50E-08	5.41E+04
1.42E-08	5.83E+04	5.66E-08	4.30E+04
1.79E-08	6.32E+04	7.13E-08	3.05E+04
2.25E-08	6.61E+04	8.97E-08	1.89E+04
2.84E-08	6.59E+04	1.13E-07	1.00E+04
3 .57E-08	6.19E+04		

4. From the data in Fig. 21.1, how many muons per minute with energies between 100 and 1000 MeV enter a 4×5 inch NaI:Tl detector near the ground at an elevation of 2493 ft?

5. Potassium and sodium are both Group I elements and thus have similar chemical properties. As a consequence, K is a natural impurity found in NaI:Tl crystals. Estimate the concentration of K in ppm (by mass) to produce two cps in a NaI:Tl detector.

6. (a) What is the activity from the decay of ^{238}U in a 1-kg sample of uranium? (b) what is the total activity in the sample? State any assumptions made.

7. Consider a two-storied house 20 × 20 m in size with walls 8 m high and a basement 3 m deep. The basement floor and walls are of concrete 30-cm thick, and the outside walls are brick 1-cm thick. Plaster 1-cm-thick lines along all walls and the ceilings. Estimate the activity in Bq of ^{40}K, ^{226}Ra, and ^{232}Th in the structural material of the house.

8. You are responsible for determining the activity of material to be used to create a very low-level gamma spectrometer facility. You have access to both a HPGe spectrometer and a large NaI:Tl spectrometer. Explain how you would go about determining the specific gamma-ray energies and emission rates and the radionuclides impurities of the construction and shield materials being delivered to the facility.

9. Show that for very thin slabs ($\mu T \to 0$), Eq. (21.3) reduces to $P_1^o = 0.5$. Explain why this result should be expected.

10. Plot the probability that a monoenergetic photon produced by a radionuclide uniformly distributed in an iron slab escapes uncollided through one side of the shield as a function of the photon energy from 0.1 to 10 MeV. Consider iron slabs of thicknesses 0.5, 1 and 2 mfp.

11. Explain in words why most of the variation in J_n^o and J_n^s in Fig. 21.12 occurs in the first few mean free paths of the slab's thickness.

12. Twenty percent of the 1.46-MeV gamma rays produced by the radioactive decay of ^{40}K uniformly distributed in a concrete slab are found to escape uncollided (half from one side and half from the other). Estimate the thickness of the concrete slab.

13. Uncollided ^{40}K gamma rays from a thick concrete wall are measured to be 3.2 per second per cm^2 of the wall surface. Estimate the activity concentration in the concrete in units of Bq/kg.

14. The MCNP6 code used to generate data for Fig. 21.11 and Fig. 21.12 is shown below.

Modify this input deck to calculate the escaping gamma flux of 0.5-MeV photons by using the f2 tally. Note that you must use an FM card to multiply the tally by slab surface area to obtain flux per unit volumetric source. Check your results by comparing the uncollided flux to that of Eq. (21.6).

Chapter 22

Nuclear Electronics

Despite many great achievements in the science of radio and electronics,
what we know today is far less than what we have still to learn.

David Sarnoff

The bulk of this textbook has been dedicated to the description of radiation detectors and their functional operation. However, it would seem incomplete not to discuss, at least cursorily, some of the common electronics used to operate these detectors. Because the field of radiation detector electronics is vast, a complete and thorough examination of the art is simply not possible in this book, and the authors refer the reader to other respected works on the topic, including Gillespie [1953], Chiang [1969], Kowalski [1970], Nicholson [1974], and Spieler [2005]. What follow are brief introductory descriptions of the electronics often used with radiation detectors and how these electronic circuits operate.

In Sec. 2.4 a brief historical review was presented about the reason for and development of modular units for nuclear radiation detection. From this early attempt at standardizing detector electronics, Nuclear Instrument Modules (NIM) were developed. These modules are typically inserted into a universal power supply unit called a Nuclear Instrument Module BIN (or NIM bin). This system has a set of standards, described in U.S. DOE Report ER/DOE-0457T, which specifies a 10-volt processing limit. Pulses greater than 10 volts are rejected or "clipped" upon entering any of the NIM units.

The NIM system is not the only electronic system available. Perhaps the second most popular modular system is Computer Automated Measurement and Control (CAMAC) system. Analogous to the NIM bin, CAMAC instruments are powered by a CAMAC crate. CAMAC is popular for circumstances requiring complicated timing and measurement controls, such as with high-energy collider experiments. Moreover, CAMAC components are not restricted to only complicated radiation measurements but can be used in other electronic applications. But because of the typically higher cost of CAMAC components compared to NIM components, they are usually used only when NIM electronics are less effective. Besides the NIM and CAMAC systems there are stand-alone units, such as those found in survey instruments, which have multiple integrated electronic components, all combined within a single unit. In NIM and CAMAC systems, these different components are separate components. Regardless of the system, the basic electronics described in this chapter are universally applied within the various electronic systems.

22.1 Mathematical Transforms

Before electronic networks and components are discussed, it is first necessary to briefly discuss the traditional methods used to mathematically analyze a network of passive elements. Consider a circuit with an input signal $f_{in}(t)$, be it a voltage or current, to which the resulting output $f_{out}(t)$ is sought. Generally the relation between the input and output is described by a set of time-dependent ordinary differential equations. Rather than solve these equations explicitly, they are often first transformed by either a Fourier or Laplace integral transform. Under such a transform or mapping, the system of differential equations is converted to a set of

coupled linear algebraic equations. In essence a calculus problem is transformed into an algebraic problem, which is much easier to solve than are the differential equations. Once the transformed output is obtained by algebraic means, it can then be mapped back to the time domain by an inverse integral transform to give $f_{out}(t)$. The two most common transforms used to describe linear circuits are the Fourier and the Laplace transforms.

22.1.1 The Fourier Transform

The Fourier transform is a generalization of a Fourier series for functions $f(t)$ that have no periodicity. If $f(t)$ is absolutely integrable, i.e., $\int_{-\infty}^{\infty} |f(t)|\,dt < \infty$ then the Fourier transform $F(\omega)$ of $f(t)$ is given by

$$F(\omega) \equiv \mathcal{F}[f(t)] = \int_{-\infty}^{\infty} e^{-j\omega t} f(t)\,dt \tag{22.1}$$

and the inverse transform by

$$f(t) \equiv \mathcal{F}^{-1}[F(\omega)] = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{j\omega t} F(\omega)\,d\omega, \tag{22.2}$$

where $j \equiv \sqrt{-1}$ and ω is the angular frequency.[1] Here $\mathcal{F}[f(t)]$ transforms $f(t)$ from the time domain to the frequency domain and $\mathcal{F}^{-1}[F(\omega)]$ transforms $F(\omega)$ back from the frequency domain to the time domain.

22.1.2 The Laplace Transform

Often $f(t)$ is not absolutely integrable (e.g., $f(t)$ is any polynomial in t or $f(t)$ is a step function $H(t)$). However, the modified function $e^{-\sigma t}f(t)H(t)$, with σ real and positive, may be integrable, i.e.,

$$\int_0^{\infty} dt\, e^{-\sigma t}|f(t)| < \infty.$$

Then instead of taking the Fourier transform of $f(t)$ (which does not exist), we take the Fourier transform of

$$g(t) = \begin{cases} e^{-\sigma t}f(t), & \text{if } t \geq 0 \\ 0, & \text{if } t < 0 \end{cases} \tag{22.3}$$

The Fourier transform of this function and its inverse are

$$\mathcal{F}[g(t)] \equiv G(\omega) = \int_0^{\infty} e^{-j\omega t}e^{-\sigma t} f(t)\,dt, \tag{22.4}$$

and

$$\mathcal{F}^{-1}[G(\omega)] \equiv g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{j\omega t} G(\omega)\,d\omega. \tag{22.5}$$

This pair of transforms can be simplified by introducing a complex variable $s = \sigma + j\omega$. Clearly, $\omega = (s-\sigma)/j$ and $d\omega = -j\,ds$. Hence for $t > 0$

$$g(t) \equiv f(t)e^{-\sigma t} = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{j\omega t} G(\omega)\,d\omega$$

$$= \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{j\omega t}\int_0^{\infty} f(t')\,e^{-\sigma t'}e^{-j\omega t'}\,dt'\,d\omega = \frac{-j}{2\pi}\int_{\sigma-j\infty}^{\sigma+j\infty} ds\,e^{st}e^{-\sigma t}\int_0^{\infty} f(t')\,e^{-st'}\,dt'\,ds$$

[1] Although the usual mathematical symbol is $i = \sqrt{-1}$, the letter i is also commonly used in electrical engineering calculations for current. To avoid confusion, it is common to use j for $\sqrt{-1}$ in circuit theory.

Table 22.1. Some commonly encountered Laplace transforms.

$F(s)$	$f(t)$	$F(s)$	$f(t)$
$\frac{1}{s}$	$H(t)$ unit step fn	$\frac{s-a}{(s-a)^2+b^2}$	$e^{at}\cos bt$
$\frac{1}{s^n}(\ n=1,2,...)$	$\frac{t^{n-1}}{(n-1)!}$	$\frac{s^2-a^2}{(s^2+a^2)^2}$	$t\cos at$
$\frac{\Gamma(k)}{s^k}\ (k>0)$	t^{k-1}	$\frac{1}{s(s^2+a^2)}$	$\frac{1}{a^2}(1-\cos at)$
$\frac{1}{s-a}$	e^{at}	$\frac{1}{s^2(s^2+a^2)}$	$\frac{1}{a^3}(at-\sin at)$
$\frac{1}{(s-a)(s-b)}$	$\frac{1}{a-b}(e^{at}-e^{bt})$	$\frac{1}{(s^2+a^2)^2}$	$\frac{1}{2a^3}(\sin at-at\cos at)$
$\frac{s}{(s-a)(s-b)}$	$\frac{1}{a-b}(ae^{at}-be^{bt})$	$\frac{s}{(s^2+a^2)^2}$	$\frac{1}{2a}\sin at$
$\frac{1}{s^2+a^2}$	$\frac{1}{a}\sin at$	$\frac{s^2}{(s^2+a^2)^2}$	$\frac{1}{2a}(\sin at+at\cos at)$
$\frac{s}{s^2+a^2}$	$\cos at$	$\frac{1}{(s-a)^2+b^2)^2}$	$\frac{1}{b}e^a t\sin bt$
$\frac{1}{s^2-a^2}$	$\frac{1}{a}\sinh at$	$\frac{s-a}{(s-a)^2+b^2)^2}$	$e^{at}\cos bt$
$\frac{s}{s^2-a^2}$	$\cosh at$	$\frac{s}{s^4+4a^4}$	$\frac{1}{2a^2}\sin at\sinh at$

or

$$f(t)=\frac{1}{2\pi j}\int_{\sigma-j\infty}^{\sigma+j\infty}e^{st}\int_0^\infty f(t')\,e^{-st'}\,dt'\,ds. \tag{22.6}$$

From this identity, one identifies the transform pair, known as the *Laplace Transform*,

$$f(t)=\frac{1}{2\pi j}\int_{\sigma-j\infty}^{\sigma+j\infty}e^{st}F(s)\,ds\equiv\mathcal{L}^{-1}[F(s)] \tag{22.7}$$

$$F(s)=\int_0^\infty f(t)e^{-st}\,dt\equiv\mathcal{L}[f(t)]. \tag{22.8}$$

Here σ is a sufficiently large and positive constant chosen so that $\int_0^\infty e^{-\sigma t}|f(t)|\,dt<\infty$. The Laplace transform is particularly useful for functions $f(t)$ that are zero for negative t.

Unlike that for Fourier transforms, the inversion of the Laplace transforms from Eq. (22.7) is not straightforward because it involves contour integration in the complex s-plane. An alternative is to prepare a 'dictionary' of Laplace transforms of common functions and, when faced with the need to invert a transform, simply look up in the dictionary the parent function that has the transform of interest. An example of such a listing is given in Table 22.1. Perhaps the most complete listing of Fourier and Laplace transforms and their inverses is that of Bateman [1954].

Example 22.1: Find the Fourier and Laplace transforms for the function

$$f(t)=\begin{cases}0, & \text{if } t<0\\ e^{-at}, & \text{if } t\geq 0\end{cases}$$

Solution:
The Fourier transform is

$$G(\omega) = \mathcal{F}[f(t)] = \int_0^\infty e^{-\alpha t} e^{-j\omega t} dt = \frac{-1}{\alpha + j\omega} e^{-(\alpha+j\omega)t}\Big|_0^\infty = \frac{1}{\alpha + j\omega}.$$

The Laplace transform is

$$F(s) = \mathcal{L}[f(t)] = \int_0^\infty e^{-\alpha t} e^{-st} dt = \frac{-1}{\alpha + s} e^{-(\alpha+s)t}\Big|_0^\infty = \frac{1}{\alpha + s}$$

In this case the results are very similar for the Fourier and Laplace transforms. The general naive, and incorrect, impression may be that $j\omega$ in the Fourier transform can be switched for s in the Laplace transform, and vice versa. However, this is actually not always true, and in fact, the Fourier transform is a smaller subset of the Laplace transform with the term $\sigma = 0$.

22.1.3 Properties of the Laplace Transform

The Laplace transform has many useful properties that are used throughout this chapter. These properties are summarized below. The Fourier transform, likewise, has many similar properties.

Integration:

$$\boxed{\mathcal{L}\left[\int_0^t dt'\, f(t')\right] = \frac{1}{s}\,\mathcal{L}[f(t)] = \frac{F(s)}{s}.} \tag{22.9}$$

Example: Given $f(t) = a + \int_0^t dt'\, f(t')$, find the solution $f(t)$. Take the Laplace transform to obtain

$$F(s) = \frac{a}{s} + \frac{F(s)}{s} \qquad \text{or} \qquad F(s) = \frac{a}{s-1},$$

from which $f(t) = a\, e^t$.

Differentiation:

$$\boxed{\mathcal{L}\left[\frac{df(t)}{dt}\right] = s\,\mathcal{L}[f(t)] - f(0) = s\,F(s) - f(0).} \tag{22.10}$$

Example: Given $df(t)/dt - af(t) = c$ with $f(0) = 0$, find $f(t)$. Taking the Laplace transform gives

$$sF(s) - f(0) - aF(s) = \frac{c}{s} \qquad \text{or} \qquad F(s) = \frac{c}{s(s-a)} = -\frac{c/a}{s} + \frac{c/a}{s-a}$$

Inversion of this result gives the solution $f(t) = (c/a)[-1 + e^{at}]$.

Higher Order Derivatives:

$$\boxed{\mathcal{L}\left[\frac{d^n f(t)}{dt^n}\right] = s^n F(s) - \sum_{m=1}^{n} s^{n-m} f^{(m)}(0^-),} \tag{22.11}$$

where $f^{(n)}(0^-) \equiv d^n f(t)/dt^n|_{t=0^-}$.

Convolution:

$$\boxed{\mathcal{L}^{-1}[F(s)G(s)] = \int_0^t d\tau\, f(t-\tau)g(\tau) = \int_0^t d\tau\, f(\tau)g(t-\tau)} \tag{22.12}$$

Example: Given $F(s) = \omega/[s(s^2+\omega^2)]$, find $f(t)$. If one lets $G(s) = 1/s$ and $F(s) = \omega/(s^2+\omega^2)$, then $g(t) = 1$ and $f(t) = \sin\omega t$. From this theorem, one then has

$$f(t) = \int_0^t d\tau\, g(t-\tau)f(\tau) = \int_0^t d\tau\, \sin\omega\tau = \frac{1}{\omega}(1-\cos\omega t).$$

Shift Formula:

$$\boxed{\mathcal{L}^{-1}[e^{-as}F(s)] = \begin{cases} f(t-a), & t \geq a \\ 0, & t < a \end{cases}} \tag{22.13}$$

Example: Given $F(s) = e^{-2s}/(s+1)$, what is $f(t)$? Recall that if $G(s) = 1/(s+1)$ then $g(t) = e^{-t}$. By this theorem, one then has

$$f(t) = \begin{cases} e^{-(t-2)}, & t \geq 2 \\ 0, & t < 2 \end{cases}$$

Translation Formula:

$$\boxed{\mathcal{L}[e^{-at}f(t)] = F(s+a)} \tag{22.14}$$

Example: Given $F(s) = s/[(s+a)^2+\omega^2]$, find $f(t)$. One can rewrite $F(s)$ as

$$F(s) = \frac{(s+a)-a}{(s+a)^2+\omega^2} \equiv G(s+a)$$

where

$$G(s) = \frac{s}{s^2+\omega^2} - \frac{a}{s^2+\omega^2} \quad \text{for which} \quad g(t) = \cos\omega t - \frac{a}{\omega}\sin\omega t$$

Then from this theorem, $f(t) = e^{-at}(\cos\omega t - \frac{a}{\omega}\sin\omega t)$.

Initial Value Theorem:

$$\boxed{\lim_{|s|\to\infty}[sF(s)] = \lim_{t\to 0} f(t)} \tag{22.15}$$

Example: If $F(s) = s/(s^2+\omega^2)$, what is $f(0)$? From tables one knows $f(t) = \cos\omega t$ so that $f(0) = 1$. We can get this same result from the theorem, namely,

$$f(0) = \lim_{|s|\to\infty}\left[s\frac{s}{s^2+\omega^2}\right] = 1.$$

Final Value Theorem:

$$\boxed{\lim_{|s|\to 0}[sF(s)] = \lim_{t\to\infty} f(t)} \tag{22.16}$$

Example: If $F(s) = 1/[s(s+2)]$, what is $\lim_{t\to\infty} f(t)$? From tables one finds $f(t) = (1-e^{-2t})/2$ so that $f(\infty) = 1/2$. From this theorem, the same result is obtained, namely

$$f(\infty) = \lim_{|s|\to 0}\left[s\frac{1}{s(s+2)}\right] = \frac{1}{2}.$$

22.1.4 The Transfer Function

The dynamic response (output) $y(t)$ of a *linear* network of components to an input $x(t)$ is generally described by a set of linear coupled differential equations. By taking the Fourier or Laplace transforms of these dynamic equations, they are transformed into a set of algebraic equations involving the transforms $X(s)$ and $Y(s)$ (or $X(\omega)$ and $Y(\omega)$).

The transfer function describes the ratio of two signals, usually the signal output of a circuit divided by a corresponding input signal. Denoting $x(t)$ as the time dependent input signal and $y(t)$ as the time dependent output signal, then the Fourier transfer function is

$$T(\omega) = \frac{Y(\omega)}{X(\omega)} = \frac{\mathcal{F}(y(t))}{\mathcal{F}(x(t))}, \tag{22.17}$$

and the Laplace transfer function is

$$H(s) \equiv \frac{Y(s)}{X(s)} = \frac{\mathcal{L}(y(t))}{\mathcal{L}(x(t))}. \tag{22.18}$$

For the Laplace transfer function, it is usual to assume the initial values $x(0)$ and $y(0)$ are both zero. Values that cause the numerator of Eq. (22.18) to become zero are called *zeros*, and values that cause the denominator to become zero are *poles*. The poles of the transfer function play a key role in the behavior of $y(t)$ when $Y(s)$ is transformed back into the time domain. This behavior and the importance of poles are discussed later in the chapter. A hint of the importance of poles can be seen from the entries in Table 22.1 where the poles in $F(s)$ determine the time and scaling constants in $f(t)$.

Often a dynamic system (here a circuit) is considered that is in steady-state for $t < 0$ and then for $t \geq 0$ some time-dependent input $x(t)$ (or deviation from the steady-state input) is applied to the system so as to produce an output $y(t)$ (or deviation from its steady-state output). The output $y(t)$ could be obtained by solving the differential equations describing the dynamic behavior of the system. However, the same solution can be obtained from the transfer function of Eq. (22.18) as

$$y(t) = \mathcal{L}^{-1}[X(s)H(s)]. \tag{22.19}$$

In particular, if $x(t) = \delta(t)$ the output $h(t)$ produced by this unit impulse input is $h(t) = \mathcal{L}^{-1}H(s)$ since $X(s) = \mathcal{L}[\delta(t)] = 1$. Once the impulse response is known, the output $y(t)$ for any input $x(t)$ can be obtained with the convolution property of Laplace transforms as

$$y(t) = \mathcal{L}^{-1}[H(s)Y(s)] = \int_0^\infty h(\tau)x(t-\tau)\,d\tau. \tag{22.20}$$

The frequency response of electric circuits is important in characterizing the circuit. This response can also be obtained directly from the transfer function. If the input for $t \geq 0$ is $x(t) = x_o \sin\omega t$ the output can be shown to be[2]

$$y(t) = x_o|H(j\omega)|\sin(\omega t + \phi) + \text{ decaying transient terms.} \tag{22.21}$$

Thus, a sinusoidal input produces, asymptotically, a sinusoidal output with a phase shift ϕ. The *gain* $G(\omega)$ of the circuit is the ratio of the amplitude of the asymptotic sinusoidal output to that of the input, i.e.,

$$G(\omega) = |H(j\omega)|, \tag{22.22}$$

and the *phase shift* $\phi(\omega)$ is

$$\phi(\omega) = \arg H(j\omega) = \tan^{-1}\frac{\mathrm{Im}H(j\omega)}{\mathrm{Re}H(j\omega)}. \tag{22.23}$$

[2]If $H(s)$ has a pole at $s = 0$, then a constant shift also appears in the right-hand side of Eq. (22.21).

Example 22.2: What are the zeros and poles of the transfer function?

$$H(s) = \frac{s(s+3)}{(s-2)(4+s)^2}.$$

Solution:
This transfer function has simple zeros at $s = 0$ and $s = -3$. It also has a pole of order 1 at $s = 2$ and a pole of order 2 at $s = -4$.

22.2 Pulse Shaping

The production of induced charge in a radiation detector was described earlier in Chapter 8 where it was seen that the amount of charge created is linearly proportional to the energy deposited by a radiation event in the detector. Signals from a radiation detector usually develop rapidly and are of short duration, mainly because the charge induction continues only while the free charge carriers are in motion inside the detector medium. The goal of a detection system is to measure accurately the charge produced in a detector and to generate an output signal that corresponds linearly to the liberated charge. The method used to measure this charge involves pulse shaping, wherein the input current from the detector is changed to an output voltage pulse with a maximum that is proportional to the initial charge liberated in the detector.

Imperfections with the pulse processing electronics often introduce artifacts into the output stream of pulses as a result of *pulse pile-up*, *ballistic deficit*, and *electronic noise*. Radiation induced pulses arriving at the input of the processing electronics are stochastic, meaning that they arrive at random times. Consider the pulse train shown in Fig. 22.1 generated from monoenergetic radiation interactions. The ideal situation would be to have the processed pulses all have identical heights for identical energies. However, in the case depicted by Fig. 22.1(a), voltage pulses arrive before the electronic tail of previous pulses have relaxed to zero, effectively causing them to appear larger than they really are. In the case depicted by Fig. 22.1(b), the pulse tails have long undershoots, i.e., they extend to negative values before the electronics reset. Consequently, some pulses appear to be smaller than they actually are. Both of these cases are caused by pulse pile-up in which radiation events occur faster than the electronics can respond. Both cases can cause serious deleterious effects on radiation spectroscopy by widening the pulse height spectrum.

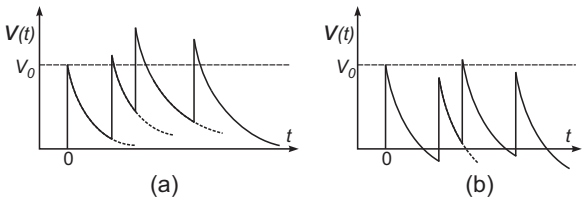

Figure 22.1. The effects of pulse pile-up for (a) tail pulses with relatively long tails and (b) tail pulses with long undershoot. The pulse height without distortions is v_0.

The term "ballistic" deficit refers to the situation in which the output pulses have a lower output amplitude than expected because the processing electronics prematurely ends the signal formation. Unfortunately, this premature pulse termination is often necessary to increase the pulse processing speed in order to accommodate high rates of radiation interactions. Under ideal conditions, the ballistic deficit would be proportional to the amount of induced charge and have little effect on spectroscopic performance. However, gas-filled and semiconductor detectors have induced currents that vary with the trajectory of an ionizing particle and with the interaction location. This effect, thus, broadens the energy resolution of the spectrometer.

Electronic noise produces a variation among ideally identical radiation-induced signals and, thus, causes broadening in the energy resolution of a spectrometer. The average noise voltage should be zero with some standard deviation about zero, or about the root mean square (RMS) voltage. Input pulses have the

randomized noise added, positively or negatively, to the signal so that the energy resolution is broadened. Noise is most problematic in the early stages of amplification. Sources of noise and mitigation methods are discussed in a latter section of this chapter.

22.2.1 Circuit Element Impedances

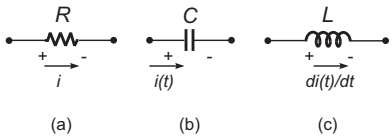

Figure 22.2. Symbols for passive circuit elements, (a) resistor, (b) capacitor, (c) inductor.

There are three main passive elements used in electronic circuits, namely *resistors*, *capacitors*, and *inductors*. The resistor is a passive element that, as the name implies, resists the flow of electrical current in accordance with Ohm's law

$$v(t) = i(t)R = R\frac{dq(t)}{dt}, \tag{22.24}$$

where $v(t)$ is the voltage, $i(t)$ is the current, $q(t)$ is the charge, and R is the resistance with units of ohms (Ω).[3] The symbol for a resistor is a zig-zag line as depicted in Fig. 22.2(a).

A capacitor is a passive device in which two conductors are separated by an insulator (see Sec. 8.3) capable of storing charge when a voltage is applied across the terminals. *Capacitance* C is the ratio of stored charge $q(t)$ to the resulting voltage $v(t)$ (charge per volts) and has units of farads (F), or ampere-second per volt. Thus

$$v(t) = \frac{q(t)}{C}. \tag{22.25}$$

If the stored charge changes with time, then the resulting current is

$$i(t) = \frac{dq(t)}{dt} = C\frac{dv(t)}{dt}. \tag{22.26}$$

An inductor produces a magnetic field when a current flows through it. Further, if the current flowing into the inductor changes with time, an induced voltage is produced that is proportional to the rate of change, namely,

$$v(t) = L\frac{di(t)}{dt} = L\frac{d^2q(t)}{dt^2}, \tag{22.27}$$

where the inductance L is the ratio of change between the induced voltage and the change in current and has units of henries (H), or volt-second per ampere.

Phasors and Impedances

If a circuit contains capacitors and/or inductors, equations for currents and voltages involve time derivatives. So, even for the simplest circuits, transient responses are generally described by ordinary differential equations. Only for circuits composed solely of resistors are the voltage and current transients given by simple algebraic equations. However, there is one important case where the differential equations can be replaced by algebraic equations, namely when the voltages and currents are sinusoidal functions of time.[4] To obtain such a simplification, it is necessary to use the complex plane and introduce complex quantities such as *phasors* and *impedances*.

Sinusoidal voltages and currents can always be written as

$$v(t) = v_o \sin(\omega t + \phi_v) \qquad \text{and} \qquad i(t) = i_o \sin(\omega t + \phi_i), \tag{22.28}$$

[3] Here lowercase v, q, and i are used to denote generally time-dependent quantities, whereas their uppercase counterparts, used for example in Chapter 8, generally denote steady-state values.

[4] The same simplification is obtained with the more complex Laplace transform technique, which is applicable to any type of transient. But the special case of sinusoidal transients is a well-established fixture of circuit analysis.

where v_o and i_o are amplitudes, ϕ_v and ϕ_i are the phase shifts, and ω is the angular frequency. Any complex number z can be written in terms of its real and imaginary parts as $\Re\{z\} + j\Im\{z\}$. Then with Euler's theorem $e^{j\omega t} = \cos\omega t + j\sin\omega t$, the real parts of $v(t)$ and $i(t)$ can be written as

$$v(t) = \Re\{v_o e^{j(\omega t+\phi_v)}\} = \Re\{\mathbf{v}e^{j\omega t}\} \quad \text{and} \quad i(t) = \Re\{i_o e^{j(\omega t+\phi_i)}\} = \Re\{\mathbf{i}e^{j\omega t}\},$$

where the complex numbers $\mathbf{v} \equiv v_o e^{j\phi_v}$ and $\mathbf{i} \equiv i_o e^{j\phi_i}$ are often called *phasors*. Note that the phasors are independent of time. Then the derivatives of the voltage and current can be written as

$$\frac{dv(t)}{dt} = \Re\{j\omega\mathbf{v}e^{j\omega t}\} \qquad \text{and} \qquad \frac{di(t)}{dt} = \Re\{j\omega\mathbf{i}e^{j\omega t}\}. \tag{22.29}$$

Hence, in the complex plane, differentiation with respect to t is the same as multiplication by $j\omega$. In this manner, the differential equations for the analysis of a circuit are converted into algebraic equations. The only difference is that currents and voltages are now phasors and the resistances, capacitances and inductances are replaced by their complex *impedances* defined as the phasor ratio $\mathbf{v}/\mathbf{i}$ with units of *ohms* (Ω).

As an example of an impedance, consider a sinusoidal voltage placed across a capacitor. The complex voltage and current are $\mathbf{v}e^{j\omega t}$ and $\mathbf{i}e^{j\omega t}$, respectively. Then from Eq. (22.26)

$$\mathbf{i}e^{j\omega t} = C\frac{d}{dt}\left(\mathbf{v}e^{j\omega t}\right) \qquad \text{or} \qquad \mathbf{i} = j\omega C\mathbf{v}.$$

The capacitor impedance is thus

$$Z_C = \frac{\mathbf{v}}{\mathbf{i}} = \frac{1}{j\omega C}. \tag{22.30}$$

Equation (22.30) is worth a closer look. At low frequencies, when $\omega \approx 0$, Eq. (22.30) becomes extremely large, i.e., the impedance becomes infinite or equivalent to an open circuit. At high frequencies Eq. (22.30) approaches zero, and the capacitor behaves as a short circuit. The impedances of resistors and inductors can be found in a similar fashion to give,[5]

$$\frac{\mathbf{v}}{\mathbf{i}} = Z_R = R, \quad \text{(resistor)}, \qquad \frac{\mathbf{v}}{\mathbf{i}} = Z_C = \frac{1}{j\omega C} \quad \text{(capacitor)}, \qquad \frac{\mathbf{v}}{\mathbf{i}} = Z_L = j\omega L \quad \text{(inductor)}. \tag{22.31}$$

Note that the impedances of capacitors and inductors change with signal frequency, and lumped circuits must include the complex algebraic manipulations of these terms. Further, opposite of the capacitor, the inductor has high impedance at high frequency and behaves as a short circuit at low frequency. The resistor has no frequency dependence.

Combining Circuit Elements

The impedances of these elements of resistance, capacitance, and inductance generally follow the rules of series and parallel resistive circuits, that is, impedances in series

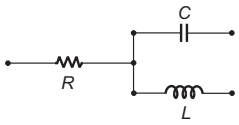
$$Z_{eq} = Z_1 + Z_2 + Z_3 + \ldots + Z_N, \tag{22.32}$$

and impedances in parallel

$$\frac{1}{Z_{eq}} = \frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \ldots + \frac{1}{Z_N}, \tag{22.33}$$

[5]The Laplace transform representations are $Z_C = 1/(sC)$ and $Z_L = sL$, which are also their transfer functions.

where the complex terms remain appropriately separated. The real portion of the impedance is called resistance R (or active component), while the imaginary part is called the reactance X. The magnitude of a complex impedance is



$$|Z| = |R + jX| = \sqrt{(R + jX)(R - jX)} = \sqrt{R^2 + X^2}. \tag{22.34}$$

The phase angle of a complex circuit is

$$\theta = \arctan\left(\frac{X}{R}\right), \tag{22.35}$$

denoted $\angle\theta$ relative to 0°, that is, positive for leading angle and negative for lagging angle with respect to the voltage versus current. Consequently, a purely inductive circuit has voltage phase angle of 90° leading the current, while a purely capacitive circuit has voltage phase angle of -90° lagging the current.

Example 22.3: Find the impedance of the following circuit:

Solution:
First, the parallel combination of the impedance is

$$Z_{\|} = \left[\frac{1}{Z_1} + \frac{1}{Z_2}\right]^{-1} = \frac{Z_1 Z_2}{Z_1 + Z_2} = \frac{(j\omega L)\left(\frac{1}{j\omega C}\right)}{j\omega L + \frac{1}{j\omega C}} = \frac{j\omega L}{1 - \omega^2 LC}$$

Now add the series resistance to find

$$Z_{eq} = R + \frac{j\omega L}{1 - \omega^2 LC} = \frac{R(1 - \omega^2 LC) + j\omega L}{1 - \omega^2 LC}.$$

The magnitude is

$$Z_{eq} = \sqrt{R^2 + \left(\frac{\omega L}{1 - \omega^2 LC}\right)^2},$$

with phase angle

$$\theta = \frac{\omega L}{R(1 - \omega^2 LC)},$$

which, at low frequency ($\omega^2 LC \ll 1$), becomes

$$\theta \approx \frac{\omega L}{R},$$

and at high frequency ($\omega^2 LC \gg 1$)

$$\theta \approx \frac{-1}{\omega RC}.$$

What then does this mean? The phase angle is zero for DC voltage applied to the circuit. At low frequencies, the phase angle is positive, and at high frequencies the phase angle is negative. A resonant frequency appears at $\omega_o^2 = 1/LC$, meaning that the magnitude of the impedance effectively becomes infinite, behaving as a notch (or band-stop) filter at the resonant frequency.

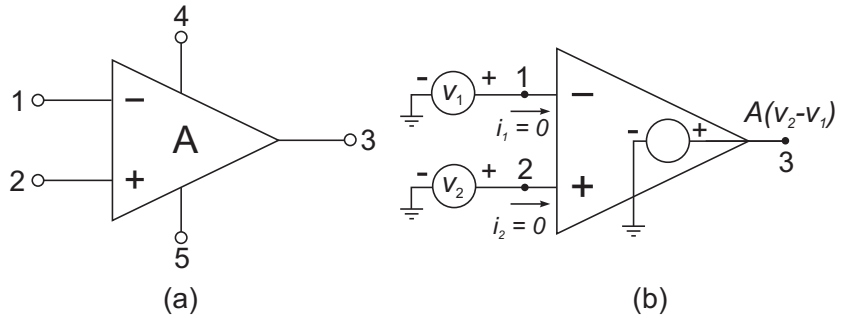


Figure 22.3. Usual depiction of an operational amplifier showing the basic inputs 1 and 2 and output terminal 3. Power is provided at terminals 4 and/or 5.

22.2.2 Operational Amplifier

A basic building block of a preamplifier is often the operational amplifier (or "op amp"), usually depicted as a right pointing triangle with two inputs and one output. This simplistic figure takes the place of a complex network of transistors, resistors, and capacitors that generally make up the actual op amp [Irvine 1981]. For instance, the common 741 op amp has three amplification stages and 20 or so transistors.

The operational amplifier has two input terminals, identified as 1 and 2 in Fig. 22.3(a), and one output terminal, denoted as terminal 3. The devices require power to operate, usually applied at terminal 4 (positive) and 5 (negative). A common operating voltage requirement is ±9 volts, although modern amplifiers may operate on only a few volts. The *open-loop gain* is denoted by A, which is typically very large usually between 10^5 to 10^7 for constant input voltages. An op amp may also have additional terminals designated for special purposes, such as frequency compensation and offset nulling.

The main function of an op amp is to sense the difference between the voltage inputs at terminals 1 (v_1) and 2 (v_2), each referenced to ground, and supply amplification $A(v_2 - v_1)$ at terminal 3. For low frequency inputs, the open-loop gain A has a large value. But at some breakpoint frequency the gain begins to decrease with frequency at -20 db/decade, and where the open-loop gain crosses 0 db is defined as the open-loop bandwidth. The *closed-loop bandwidth* of an op amp is the frequency range over which the gain remains above -3 db of its value at $\omega = 0$. The frequency dependence of the open-loop gain, as discussed in the next sections, is important as it is a major contributor to the non-ideal performance of an op amp circuit. Detailed analysis for op amp performance can be found in a number of references, including Carter and Brown [2016], Carter and Mancini [2017], Jung [2005], and Zumbahlen [2008].

Ideally, an op amp should have an infinite input impedance, thereby eliminating input current. Further, the output impedance at terminal 3 should be zero, such that there is no voltage loss from the ideal gain $A(v_2 - v_1)$. The equivalent circuit is shown in Fig. 22.3(b). Terminal 1 is called the inverting terminal, and terminal 2 is the non-inverting terminal.

Consider the situation of Fig. 22.3(b). If the output at terminal 3 is in fact $A(v_2 - v_1)$, then the following applies for the output voltage at terminal 3

$$\frac{v_3}{A} = (v_2 - v_1). \tag{22.36}$$

Because A is large, and ideally treated as infinite, then it is found that

$$\frac{v_3}{A} = (v_2 - v_1) \simeq 0. \tag{22.37}$$

Consequently, if A is very large, and approaching infinity as in the ideal case, then $v_1 \simeq v_2$, a condition emulating a short circuit between terminals 1 and 2. For this reason, there is a *virtual short circuit* between

terminals 1 and 2. Also, if terminal 2 is connected to ground, then terminal 1 is effectively also connected to ground through the virtual short circuit, and is referred to as a *virtual ground*.

22.2.3 The General Case for Feedback Transfer Function

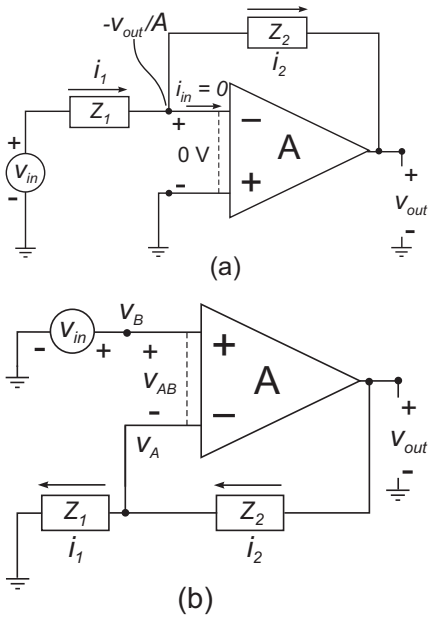

Figure 22.4. The (a) inverting configuration and the (b) non-inverting configuration with generalized impedances.

Consider the op amp configuration of Fig. 22.4(a). There is an input voltage applied across an impedance into the inverting input. Also, another impedance is placed across the inverting input terminal and the output terminal. With the positive terminal grounded, the voltage at the inverting terminal must be $v_{in} = -v_{out}/A$.

The current i_1 is defined as

$$i_1 = \frac{(-v_{out}/A) - v_{in}}{Z_1} = -\frac{1}{Z_1}\left(v_{in} + \frac{v_{out}}{A}\right). \tag{22.38}$$

Because of the high input impedance at the inverting input, the current across the feedback impedance Z_2 is practically the same as that across the impedance Z_1 ($i_2 \approx i_1$). The output voltage v_{out} must be the sum of the voltages at the inverting input terminal and across Z_2

$$v_{out} = -\frac{v_{out}}{A} - \frac{1}{Z_1}\left(v_{in} + \frac{v_{out}}{A}\right) Z_2 \tag{22.39}$$

Rearranging terms yields

$$\frac{v_{out}}{v_{in}} = -\frac{Z_2}{Z_1}\left[\frac{1}{1 + (1 + Z_2/Z_1)/A}\right]. \tag{22.40}$$

Recalling that the value of A is large, Eq. (22.40) reduces to

$$\frac{v_{out}}{v_{in}} \approx -\frac{Z_2}{Z_1}. \tag{22.41}$$

Hence, the transfer function for Fig. 22.4(a) is

$$H(s) = -\frac{Z_2(s)}{Z_1(s)}. \tag{22.42}$$

A similar analysis can be used to show that the non-inverting case of Fig. 22.4(b) results in the following:

$$\frac{v_{out}}{v_{in}} \approx 1 + \frac{Z_2}{Z_1}, \qquad \text{with} \qquad H(s) = \frac{Z_1(s) + Z_2(s)}{Z_1(s)}. \tag{22.43}$$

22.2.4 Passive Low-Pass Filter

A simple low-pass filter is depicted in Fig. 22.5, in which a time dependent input voltage $v_{in}(t)$ is placed across the resistor and the capacitor. As a result the voltage $v_{out}(t)$ is formed across the capacitor and is measured as a function of time. From the figure the voltage across the resistor must equal the difference between the input voltage and the voltage across the capacitor, i.e.,

$$v_{in}(t) - v_{out}(t) = Ri_{in}(t). \tag{22.44}$$

The current flowing to the capacitor is

$$i_{in}(t) = \frac{dQ(t)}{dt} = C\frac{dv_{out}(t)}{dt}, \tag{22.45}$$

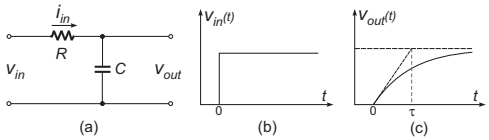

Figure 22.5. The (a) basic low-pass circuit and result from a (b) step function input $v_{in}(t)$ with (c) output response $v_{out}(t)$.

where $Q(t) = Cv_{out}(t)$ is the charge accumulated on the capacitor as a function of time. Substitution of Eq. (22.45) into Eq. (22.44) and rearrangement gives

$$\frac{dv_{out}(t)}{dt} + \frac{1}{\tau}v_{out}(t) = \frac{1}{\tau}v_{in}(t), \tag{22.46}$$

where $\tau = RC$ is the time constant. The most general solution of this linear, first-order, ordinary differential equation is

$$v_{out}(t) = e^{-t/\tau}\left[v_{in}(0^-) + \int_0^t e^{t'/\tau}\frac{v_{in}(t')}{\tau}\right]dt', \tag{22.47}$$

where $v_{in}(0^-)$ is the initial voltage condition. Often it is assumed that $v_{in}(0^-) = 0$ for many solutions.

Step Input

For $V_{in}(0^-) = 0$, or no initial charge, and for the step input shown in Fig. 22.5(b) with $v_{in}(t) = v_{in}^o$ for $t > 0$, this general solution reduces to

$$v_{out}(t) = v_{in}^o\left(1 - e^{-t/\tau}\right), \quad t \geq 0. \tag{22.48}$$

Consequently, the output signal is an increasing exponential function that approaches the input voltage v_{in}^o. Note that the rate of increase is a function of the time constant, which can be altered by changing either C, R, or both. The smaller the time constant, the faster the rise to v_{in}. Depicted in Fig. 22.5(c) is the response to a voltage step input, where the tangent of the initial signal rise intersects the maximum possible output value at $t = \tau$. Stated differently, the difference between $v_{out}(\infty)$ and $v_{out}(\tau)$ equals $v_{out}(\infty)/e \simeq 0.368v_{out}(\infty)$.

Oscillatory Input

To determine the frequency characteristics of this device, first take the Laplace transform of Eq. (22.46) and rearrange to obtain the transfer function

$$H(s) = \frac{1}{1 + sRC} = \frac{1}{1 + s\tau}. \tag{22.49}$$

The voltage gain, defined here by Eq. (22.22), is

$$G(\omega) = |H(j\omega)| = \left|\frac{1}{1 + j\omega\tau}\right| = \left[\left(\frac{1}{1 + j\omega RC}\right)\left(\frac{1}{1 - j\omega RC}\right)\right]^{1/2} = \frac{1}{\sqrt{1 + (\omega RC)^2}} = \frac{1}{\sqrt{1 + \omega^2\tau^2}}, \tag{22.50}$$

which at low frequencies is $G(\omega) \simeq 1$, i.e., the amplitude of the output sine wave equals that of the input sine wave. But at high frequencies $G(\omega) \simeq 1/\omega\tau$ and the output amplitude decreases as $1/\omega$. Because low frequencies of the input pass, without change, to the output while high frequencies are attenuated, the circuit of Fig. 22.5 is called a *low-pass filter*. The cut-off frequency is given by

$$f_c = \frac{1}{2\pi RC} = \frac{1}{2\pi\tau} \qquad \text{or} \qquad 2\pi f_c = \omega_o = \frac{1}{RC} = \frac{1}{\tau}. \tag{22.51}$$

The voltage gain is often expressed in decibels[6] as

$$G_{db}(\omega) = 20 \log_{10} |H(j\omega)|. \tag{22.52}$$

The phase shift is

$$\phi(\omega) = \tan^{-1}\left(\frac{\mathrm{Im}H(j\omega)}{\mathrm{Re}H(j\omega)}\right) = -\tan^{-1}(\omega\tau)\,. \tag{22.53}$$

At the frequency $\omega = 1/\tau$, then $\phi = -45°$.

Example 22.4: Given $R = 1$ MΩ and $C = 10$ pF, what is the cutoff frequency of the low-pass filter?

Solution:

$$f_c = \frac{1}{2\pi CR} = \frac{1}{2\pi(10^6\ \Omega)(10^{-11}\ \mathrm{F})} = 15.916\ \mathrm{kHz}.$$

So the cutoff frequency is 15.916 kHz. To test this result $w_c = 2\pi f_c$ so

$$|G_{db}(\omega)| = 20 \log_{10}\left[\frac{1}{\sqrt{1+(\omega_o RC)^2}}\right] = 20 \log_{10}\left[\frac{1}{\sqrt{2}}\right] = -3\ \mathrm{dB},$$

Hence, at the cutoff frequency, the output magnitude has dropped by 3 dB.

22.2.5 Active Low-Pass Filter

Two simple *active* low-pass filters (inverting configurations) are depicted in Fig. 22.6. In the case depicted by Fig. 22.6(a)

$$i_1(t) = \frac{v_{in}(t)}{R_1}. \tag{22.54}$$

If the initial condition has the voltage across the feedback capacitor C_2 of V_0 then

$$v_{out}(t) = V_0 - \frac{1}{C_2}\int_0^t i_1(t)\,dt = V_0 - \frac{1}{R_1 C_2}\int_0^t v_{in}(t)\,dt. \tag{22.55}$$

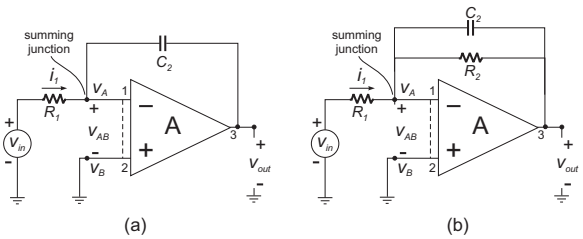

Figure 22.6. Simple low-pass amplification circuits depicting the (a) ideal integrator and the (b) practical integrator.

---

[6] The decibel is actually a logarithmic measure of the ratio of power output to input. The power gain is

$$G\Big|_{\text{power}} = \frac{P_{out}}{P_{in}} = \frac{v_{out}^2/Z_{out}}{v_{in}^2/Z_{in}}$$

where $P = v^2/Z$. Expressed in decibels,

$$G_{db}(\omega)\Big|_{\text{power}} = 10 \log_{10}\left(\frac{v_{out}^2}{v_{in}^2}\right) - 10 \log_{10}\left(\frac{Z_{out}}{Z_{in}}\right).$$

Note that if $Z_{in} = Z_{out}$, then power gain and voltage gain are equivalent when expressed in decibels

$$G_{db}(\omega)\Big|_{\text{power}} = 10 \log_{10}\left(|H(j\omega)|^2\right) = 20 \log_{10}\left(|H(j\omega)|\right) = G_{db}(\omega)\Big|_{\text{voltage}}.$$

Hence, the output is the integral of the input and, thus, the reason this circuit is called an *integrator*. Also, R_1C_2 is the integration time constant. The negative output is a consequence of the inverting op amp configuration. If the input is taken as $v_{in}(t)-V_0$ so as to give a zero initial condition, the closed loop transfer function is

$$H(s) = -\frac{Z_2(s)}{Z_1(s)} = -\frac{\frac{1}{sC_2}}{R_1} = \frac{-1}{sR_1C_2}, \tag{22.56}$$

which has gain

$$G(\omega) = |H(j\omega)| = \frac{1}{\omega R_1 C_2}. \tag{22.57}$$

A positive voltage input produces a negative output, while a negative input produces a positive output. The output voltage remains constant if there is a zero value input. Suppose a series of positive square pulses is applied to the input. With the ideal integrator, every positive pulse produces a progressively increasing negative voltage on the output. This sequential increase occurs because the feedback capacitor C_2 does not discharge, but instead continues to accumulate charge for every pulse. However, this simple integrating circuit has several drawbacks. Eventually the integrator circuit saturates, and the circuit no longer responds to input voltages until the capacitor is discharged. The saturation is a result of a small difference in voltage across the input terminals due to slight transistor mismatching in the amplifier circuit. Over time, this small offset voltage continues to accumulate on the capacitor until, eventually, it changes the baseline V_0 enough to distort the output signal or to saturate the preamplifier. Another difficulty arises because the bandwidth of an ideal integrator is small so that it can be used over only a small input range of frequencies.

These problems can be remedied by placing a feedback resistor R_2 in parallel with C_2, as shown in Fig. 22.6(b), a design traditionally labeled the *practical integrator*. The transfer function for this arrangement is

$$H(s) = \frac{Z_2(s)}{Z_1(s)} = \frac{\left[\frac{1}{R_2} + sC_2\right]^{-1}}{R_1} = \left(\frac{R_2}{R_1}\right)\frac{1}{(1+sR_2C_2)} \tag{22.58}$$

with gain

$$|G(\omega)| = \left(\frac{R_2}{R_1}\right)\left[\frac{1}{(1+(\omega R_2C_2)^2}\right]^{1/2}. \tag{22.59}$$

At low frequency, the gain is R_2/R_1, and the angular cutoff frequency is

$$\omega_o = 2\pi f_c = \frac{1}{R_2C_2}. \tag{22.60}$$

Also with this integrator configuration, capacitor C_2 now discharges with time constant $\tau = R_2C_2$.

22.2.6 Passive High-Pass Filter

A simple passive high-pass filter is depicted in Fig. 22.7, in which a time-dependent input voltage $v_{in}(t)$ is placed across the capacitor and the resistor so that a voltage $v_{out}(t)$ is formed across the resistor. The difference between the input and output voltages is the voltage Q/C developed across the capacitor C, i.e.,

$$v_{in}(t) - v_{out}(t) = \frac{Q(t)}{C}.$$

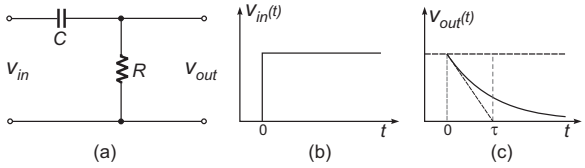

Figure 22.7. The (a) basic high-pass circuit and result from a (b) step function input $v_{in}(t)$ with (c) output response $v_{out}(t)$.

Differentiation with respect to time gives

$$\frac{dv_{in}}{dt} - \frac{dv_{out}(t)}{dt} = \frac{1}{C}\frac{dQ(t)}{dt}. \tag{22.61}$$

But $i(t) = dQ/dt = v_{out}(t)/R$ and, with $\tau = RC$, Eq. (22.61) becomes

$$\frac{dv_{in}(t)}{dt} = \frac{dv_{out}(t)}{dt} + \frac{v_{out}(t)}{\tau}. \tag{22.62}$$

Take the Laplace transform of Eq. (22.62) to obtain the transfer function

$$H(s) = \frac{sRC}{1+sRC} = \frac{s\tau}{1+s\tau}. \tag{22.63}$$

The gain of this circuit is then

$$|G(\omega)| = \left|\frac{v_{out}(t)}{v_{in}(t)}\right| = \left[\left(\frac{j\omega RC}{1+j\omega RC}\right)\left(\frac{-j\omega RC}{1-j\omega RC}\right)\right]^{1/2} = \sqrt{\frac{\omega^2R^2C^2}{1+\omega^2R^2C^2}}. \tag{22.64}$$

From Eq. (22.64), it is seen that at high frequencies $G(\omega) \simeq 1$, i.e., $v_{out} \approx v_{in}$. By contrast, at low frequencies $\omega \ll 1$ $G(\omega) \simeq \omega$ so v_{out} decreases as ω decreases. Thus, the name *high-pass* filter for this device. The low-frequency cutoff is also

$$2\pi f_c = \omega_o = \frac{1}{RC},$$

where $|G(\omega_o)| = -3$ dB.

Step Input to Passive High-Pass Filter

Given a positive step input of height $v_{in}(t=0)$, as depicted in Fig. 22.7(b), there is an instantaneous change in v_{in} at $t = 0$. Otherwise, the input voltage remains constant at v_{in}^o. Thus Eq. (22.62) becomes

$$\frac{dv_{in}(t)}{dt} = 0 = \frac{dv_{out}(t)}{dt} + \frac{v_{out}(t)}{\tau}, \tag{22.65}$$

which, upon integration, gives

$$v_{out}(t) = v_{in}^o e^{-t/\tau}, \qquad t > 0. \tag{22.66}$$

Thus, a step input produces a tail pulse with a decay constant $\tau = RC$.

Rectangular Pulse Input to a Passive High-Pass Filter

If a square wave pulse input $v_{in}(t)$ with width t_p and height v_{in}^o is applied to the passive high-pass filter at $t = 0$, the initial response is the same as the step input. However, at the end of the pulse, the input voltage returns to zero. However, the voltage across the capacitor in the circuit cannot immediately return to zero because the discharge current is limited by the resistor. Consequently, the output must decrease by the pulse input v_{in}^o, or,

$$v_{out}(t_p) = v_{in}^o e^{-t_p/\tau} - v_{in}^o, \tag{22.67}$$

which shows that the output becomes *negative*. Beyond t_p, the pulse exponentially decays back to zero as

$$v_{out}(t) = v_{in}^o\left(e^{-t_p/\tau} - 1\right)e^{-(t-t_p)/\tau}, \qquad t \geq t_p. \tag{22.68}$$

To explore the consequences of this result, consider the cases where $\tau \gg t_p$ and $\tau \ll t_p$. If $\tau \gg t_p$, then the output pulse has decayed very little at time t_p so that the negative undershoot is very small and has little effect on the output. If instead $\tau \ll t_p$, then much decay occurs well before t_p is reached so that the positive output voltage spike and the negative undershoot has the same magnitude as v_{in}^o and appears as a negative spike. Another less obvious result can be found by integrating and comparing both Eqs. (22.66) and (22.68) within their respective operating times, namely

$$\int_0^{t_p} v_{in}^o e^{-t/\tau} = -\tau v_{in}^o e^{-t/\tau}\Big|_0^{t_p} = \tau v_{in}^o \left(1 - e^{-t_p/\tau}\right)$$

and

$$\int_{t_p}^{\infty} v_{in}^o \left(e^{-t_p/\tau} - 1\right) e^{-(t-t_p)/\tau} = v_{in}^o \left(1 - e^{t_p/\tau}\right)\left(-\tau e^{-t/\tau}\right)\Big|_{t_p}^{\infty} = -\tau v_{in}^o \left(1 - e^{-t_p/\tau}\right). \tag{22.69}$$

Hence, the area under the output pulse before t_p and then after t_p are equal (with opposites signs). Consequently, the time it takes to return to zero can be unacceptably long if the circuit has large τ.

Series of Rectangular Pulses to a Passive High-Pass Filter

The natural extension of the analysis for the input of a single rectangular pulse is to consider a series of rectangular pulses. Suppose that the input voltage is a rectangular pulse of duration t_1 and constant voltage v_1 followed by a lower constant voltage v_2 of duration t_2. The total period of a cycle is, therefore, $T = t_1 + t_2$ with a total voltage swing of $V = v_1 - (-v_2) = v_1 + v_2$. This voltage swing can be displaced by a DC voltage shift v_{DC} as shown in Fig. 22.8(a). In other words, the actual high-input voltage is $v_1 + V_{DC}$ and the actual low-input voltage is $V_{DC} - v_2$.

Because the output voltage $v_{out}(t)$ is unaffected by V_{DC} (a high-pass filter does not pass a constant voltage), for the following analyses one can assume any value of V_{DC}. If one chooses $V_{DC} = -v_2$ then Eq. (22.61) for $v_{out}(t)$ can be written as

$$\frac{dv_{out}(t)}{dt} + \frac{1}{\tau} v_{out}(t) = \frac{dv_{in}(t)}{dt}, \tag{22.70}$$

where the input wave form for cycle n is

$$v_{in}(t) = \begin{cases} v_1 - v_2 \equiv v_{in}^o & (n-1)T \le t < (n-1)T + t_1 \\ v_2 - v_2 = 0 & (n-1)T + t_1 \le t < nT \end{cases}. \tag{22.71}$$

The solution of Eq. (22.70) for any $v_{in}(t)$ is

$$v_{out}(t) = e^{-t/\tau}\left[v_{out}(t_o^-) + \int_{t_o^-}^{t} e^{t'/\tau} \frac{dv_{in}(t')}{dt'}\, dt'\right], \qquad t > t_o, \tag{22.72}$$

where t_o^- is the time just before the start of transient calculation.

The output voltage during any cycle has two parts: (1) that during the rectangular pulse when $v_i(t) = v_{in}^o$ and (2) that during the time when $v_{in}(t) = 0$. For the first portion t_o is the time the pulse begins, and for the second portion t_o is the time the pulse ends. The transients for both portions can be calculated from Eq. (22.72) using the appropriate value of $v_{in}(t_o^-)$. Because $v_{in}(t)$ consists of two step functions, dv_{in}/dt consists of two delta functions since the derivative of a step function is a delta function. In particular, for the nth cycle

$$\frac{dv_{in}(t)}{dt} = v_{in}^o \delta(t - [n-1]T)) - v_{in}^o \delta(t - [n-1]T - t_1). \tag{22.73}$$

The output voltage is now calculated cycle by cycle.

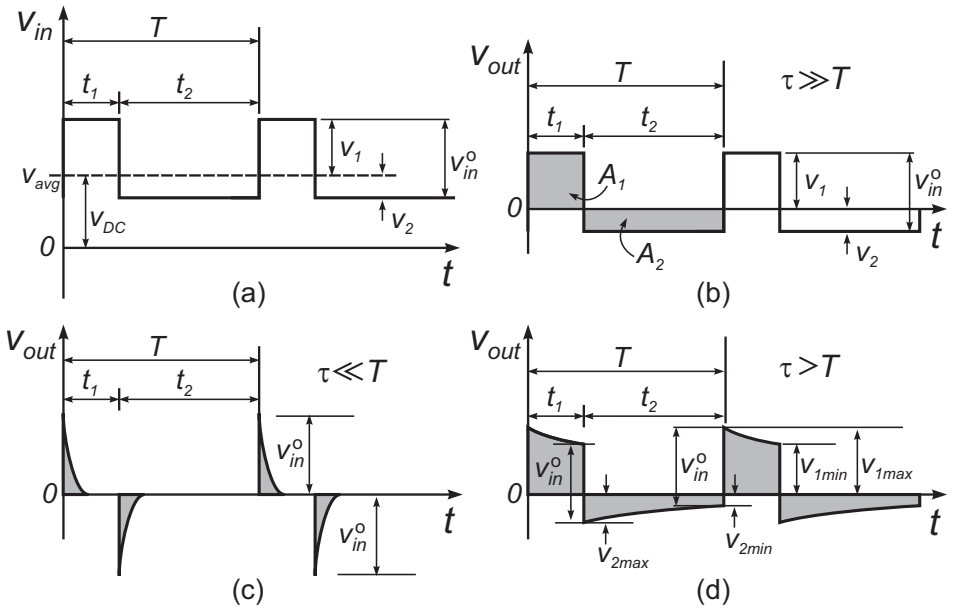

Figure 22.8. (a) Square wave input with a DC offset, (b) output from a passive differentiator circuit with $\tau \gg T$, (c) output from a passive differentiator circuit with $\tau \ll T$, (d) output from a passive differentiator circuit with $\tau > T$. Shown in the output voltage plots are the voltages obtained after a large number of cycles, i.e., when each cycle has the same response.

Cycle 1 ($0 < t < T$): For the first portion of this cycle, $t_o = 0$, $v_{in}(t_o^-) = 0$ and $dv_{in}/dt = v_{in}^o \delta(t)$. Substitution into Eq. (22.72) gives

$$v_{out}(t) = v_{in}^o e^{-t/\tau}, \quad 0 \le t < t_1. \tag{22.74}$$

For the second portion of this cycle, $t_o = t_1$ and $dv_{in}/dt = -v_{in}^o \delta(t - t_1)$. Then from Eq. (22.72) one finds

$$v_{out}(t) = -v_{in}^o \left[1 - e^{-t_1/\tau}\right] e^{-(t-t_1)/\tau}, \quad t_1 \le t < T. \tag{22.75}$$

More compactly the response in the first cycle can be written as

$$\frac{v_{out}(t)}{v_{in}^o} = \begin{cases} e^{-t/\tau}, & 0 \le t < t_1 \\ -\beta e^{-(t-t_1)/\tau}, & t_1 \le t < T \end{cases}, \tag{22.76}$$

where $\beta \equiv 1 - e^{-t_1/\tau} < 1$.

Cycle 2 ($T < t < 2T$): For the first portion of this cycle $t_o = T$, $v_{out}(t_o^-) = -v_{in}^o \beta e^{-(T-t_1)/\tau}$, and $dv_{in}/dt = v_{in}^o \delta(t - T)$. For the second portion of the cycle, $t_o = T + t_1$, $v_{in}(t_o)$ equals the final voltage of the first portion, and $dv_{in}/dt = -v_{in}^o \delta(t - T - t_1)$. Expressions for the transients in both portions of the cycle are obtained from Eq. (22.72).

$$\frac{v_{out}(t)}{v_{in}^o} = \begin{cases} [\alpha + e^{-T/\tau}] e^{-(t-T)/\tau}, & T \le t < T + t_1 \\ -[\beta + \beta e^{-T/\tau}] e^{-(t-T-t_1)/\tau}, & T + t_1 \le t < 2T \end{cases}, \tag{22.77}$$

where $\alpha \equiv 1 - e^{-t_2/\tau} < 1$.

Cycle n ($(n-1)T < t < nT$): One can continue in this fashion cycle after cycle to obtain $v_{in}(t)$ in each successive cycle. By induction, the response for the nth cycle, which begins at $t = t_{n-1} \equiv (n-1)T$, is

$$\frac{v_{out}(t)}{v_{in}^o} = \begin{cases} \left[\alpha \sum_{k=1}^{n-1} e^{-(k-1)T/\tau} + e^{-(n-1)T/\tau}\right] e^{-(t-(n-1)T)/\tau}, & t_{n-1} \le t < t_{n-1} + t_1 \\ -\left[\beta \sum_{k=1}^{n} e^{-(k-1)T/\tau}\right] e^{-(t-(n-1)T-t_1)/\tau}, & t_{n-1} + t_1 \le t < nT \end{cases}. \tag{22.78}$$

Large n: The sums in Eq. (22.78) are a geometric progression

$$S_n = \sum_{k=1}^{n} e^{-(k-1)T/\tau} = 1 + \gamma + \gamma^2 + \ldots \gamma^{n-1} = \frac{1-\gamma^{n-1}}{1-\gamma}, \tag{22.79}$$

where $\gamma \equiv e^{-T/\tau} < 1$. As $n \to \infty$, $S_n \to 1/(1-\gamma)$ and from Eq. (22.78), in the limit of large n,

$$\frac{v_{out}(t)}{v_{in}^o} = \begin{cases} \dfrac{\alpha}{1-\gamma} e^{-t/\tau}, & 0 \le t < t_1 \\ \dfrac{-\beta}{1-\gamma} e^{-(t-t_1)/\tau}, & t_1 \le t < T \end{cases}, \tag{22.80}$$

where t is now measured from the start of a cycle.

The area A_1 under $v_{in}(t)$ during the rectangular pulse is

$$A_1 = v_{in}^o \frac{\alpha}{1-\gamma} \int_0^{t_1} e^{-t/\tau}\, dt = \frac{v_{in}^o \alpha\tau}{1-\gamma}(1 - e^{-t_1/\tau}) = \frac{v_{in}^o \alpha\beta\tau}{1-\gamma}. \tag{22.81}$$

Likewise the area A_2 under $v_{in}(t)$ between t_1 and $t_1 + t_2$ is

$$A_2 = -v_{in}^o \frac{\beta}{1-\gamma} e^{t_1/\tau} \int_{t_1}^{t_1+t_2} e^{-t/\tau}\, dt = -\frac{v_{in}^o \beta\tau}{1-\gamma}(1 - e^{-t_2/\tau}) = -\frac{v_{in}^o \alpha\beta\tau}{1-\gamma}. \tag{22.82}$$

Thus, it is seen that $A_1 = -A_2$, i.e., the two shaded areas in Fig. 22.8 are equal. This equality of the areas for the positive and negative transients is true only for the equilibrium cycle ($n \to \infty$) of Eq. (22.80). For the cycles building up to the equilibrium cycle, $A_1 > -A_2$.

Effect of the Time Constant τ The output response is greatly influenced by the circuit time constant τ. Regardless of the average input voltage (the DC offset), the output signal is averaged about zero (no DC component). For an equilibrium cycle (large n), the maximum positive output from Eq. (22.80) is

$$v_{1max} = \frac{\alpha}{1-\gamma} v_{in}^o \tag{22.83}$$

and the minimum positive voltage is

$$v_{1min} = \frac{\alpha}{1-\gamma} v_{in}^o e^{-t_1/\tau} = v_{1max} e^{-t_1/\tau}. \tag{22.84}$$

At t_{p1}, the polarity switches by $-v_i^o$ (as it does for all cycles), producing the maximum negative voltage

$$v_{2max} = \frac{\beta}{1-\gamma} v_{in}^o \tag{22.85}$$

The negative voltage decays towards zero and reaches a minimum negative voltage at $t = T$ of

$$v_{2min} = \frac{\beta}{1-\gamma} v_{in}^o e^{-(t_2-t_1)/\tau} = |v_{2max}| e^{-(t_2-t_1)/\tau}. \tag{22.86}$$

Then, as expected,

$$v_{1min} + v_{2max} = v_{in}^o \left[\frac{\alpha}{1-\gamma} e^{-t_1/\tau} + \frac{\beta}{1-\gamma} \right] = v_{in}^o \frac{[(1-e^{-t_2/\tau})e^{-t_1/\tau} + (1-e^{-t_1/\tau})]}{1-e^{-(t_1+t_2)/\tau}} = v_{in}^o. \tag{22.87}$$

For small $\tau \ll T$, the output rapidly decays to zero before t_p is reached, causing a flip in polarity equal to v_{in}^o at either t_1 (goes negative) or t_2 (goes positive). Thus a small time constant produces spike peaks of equal magnitudes alternating in polarity, as depicted in Fig. 22.8(c). For long $\tau \gg T$, there is hardly any decay, and the output as a rectangular wave that mimics the input, but one with an average of zero (no DC component). This case is depicted in Fig. 22.8(b). The expected result for cases between these extremes is depicted in Fig. 22.8(d).

Exponential Input to Passive High-Pass Filter

Consider an exponential input to a high-pass filter with the form[7]

$$v_{in}(t) = v_{in}^o \left(1 - e^{-t/\tau_{in}} \right) \tag{22.88}$$

where v_{in}^o is the maximum voltage reached as $t \to \infty$ and τ_{in} is the time constant of the input signal. Substitution of Eq. (22.88) into Eq. (22.62) gives the differential equation

$$\frac{v_{in}^o}{\tau_{in}} e^{-t/\tau_{in}} = \frac{dv_{out}}{dt} + \frac{v_{out}}{\tau}, \tag{22.89}$$

where τ is the time constant RC of the high-pass filter. The solution of this equation is

$$v_{out}(t) = \begin{cases} v_{in}^o \dfrac{\tau}{\tau - \tau_{in}} \left(e^{-t/\tau} - e^{-t/\tau_{in}} \right), & \tau \neq \tau_{in} \\ v_{in}^o \dfrac{t}{\tau} e^{-t/\tau}, & \tau = \tau_{in} \end{cases}. \tag{22.90}$$

Now consider two limiting cases of Eq. (22.90), $\tau \ll \tau_{in}$ and $\tau \gg \tau_{in}$. In the former case, one obtains

$$v_{out}(t) \approx v_{in}^o \frac{\tau}{\tau_{in}} e^{-t/\tau_{in}}. \tag{22.91}$$

Here it is seen that as τ decreases with respect to τ_{in}, the maximum output pulse height diminishes and decays according to the input time constant τ_{in}. Hence, the condition where τ is much smaller than the time constant of the input pulse τ_{in} causes a ballistic deficit with a ratio τ/τ_{in}. For the case in which $\tau \gg \tau_{in}$, Eq. (22.90) reduces to

$$v_{out}(t) \approx v_{in}^o e^{-t/\tau}. \tag{22.92}$$

Note that the dependence of $v_{out}(t)$ on τ_{in} vanishes and the output depends only on the network decay constant and the maximum output voltage equal to v_{in}^o. Actual real high-pass networks are somewhere between the limiting cases of Eqs. (22.91) and (22.92). Generally, the amount of ballistic deficit increases as τ decreases.

[7] Compare this signal input to Eq. (22.48), the output solution of a passive low-pass filter.

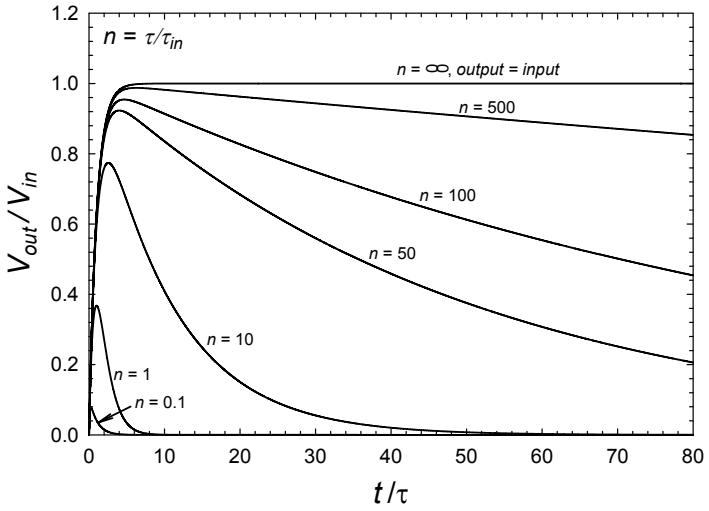

Figure 22.9. Output from a passive high-pass filter from an exponential input described by Eq. (22.89). Shown are normalized outputs to the initial input (v_{out}/v_{in}) as a function of t/τ and τ/τ_{in}. The decrease in the maximum pulse height from unity is the ballistic deficit.

The time to the pulse height maxima is

$$t_{max} = \frac{\tau\tau_{in}}{\tau - \tau_{in}} \ln\left(\frac{\tau}{\tau_{in}}\right). \tag{22.93}$$

This result can then be used to calculate the expected maximum in the output pulse height $v_{out}(t_{max})$. The ballistic deficit is defined as

$$v_{bd} = v_{in}^{o} - v_{out}(t_{max}). \tag{22.94}$$

Examples of normalized output pulses with varying time constants are shown in Fig. 22.9. For large values of τ/τ_{in}, the pulse height maxima is relatively large and approaches the input value of V_{in}^{o}. However, as τ decreases, so does the output pulse height maxima, the difference from unity being the ballistic deficit.

22.2.7 Active High-Pass Filter

Simple *active* high-pass filters (inverting configuration) are depicted in Fig. 22.10. Because terminal 1 is a virtual ground, $V_A = 0$ and the output voltage v_{out} equals the negative of the voltage across the resistor R_2 by the current i_2, i.e.,

$$v_{out}(t) = v_1(t) = -i_2(t)R_2. \tag{22.95}$$

Also because of the high input impedance at terminal 1, the current flowing

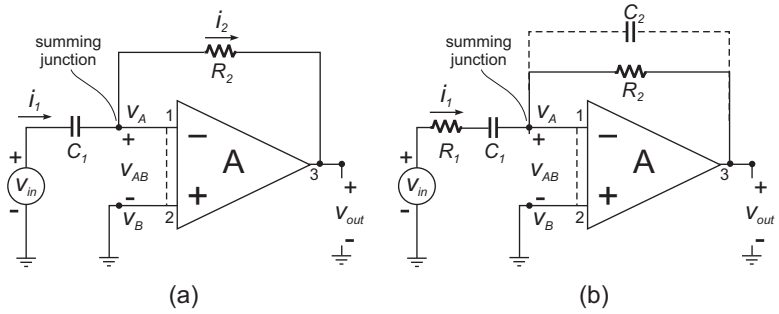

Figure 22.10. Simple high-pass amplification circuits depicting the (a) ideal differentiator and the (b) practical differentiator.

to the capacitor C_1 must be

$$i_2(t) = i_1(t) = \frac{dQ}{dt} = C_1 \frac{dv_{in}(t)}{dt} \tag{22.96}$$

Substitution of Eq. (22.95) into Eq. (22.96) yields,

$$v_{out}(t) = -R_2 C_1 \frac{dv_{in}(t)}{dt}. \tag{22.97}$$

Hence the output $v_{out}(t)$ is the derivative of the input $v_{in}(t)$ so the circuit in Fig. 22.10 is, understandably, called a *differentiator* circuit.

The closed-loop transfer function for the circuit in Fig. 22.10(a) is readily obtained by taking the Laplace transform of Eq. (22.97) to obtain

$$V_{out}(s) = -R_2 C_1 [sV_{in}(s) - v_{in}(0)]. \tag{22.98}$$

If the initial condition is $v_{in}(0) = 0$, then the transfer function is simply

$$H(s) = \frac{V_{out}(s)}{V_{in}(s)} = -sR_2C_1 \qquad \text{with gain} \qquad G(\omega) = |H(j\omega)| = \omega R_2 C_1. \tag{22.99}$$

The simple differentiator circuit in Fig. 22.10(a) tends to magnify noise and is unstable; hence, this simple active differentiator circuit is relatively unpopular and seldom used, mainly due to sharp spikes produced at the output when there is a shape change with the input voltage [Sedra and Smith 1982]. To remedy these problems, there is an improved version of the differentiator, Fig. 22.10(b) where a resistor R_1 has been added in series with C_1, called the *practical differentiator*. The transfer function is now

$$H(s) = -\frac{Z_2}{Z_1} = \frac{-R_2}{R_1 + \dfrac{1}{sC_1}} = \frac{-sR_2C_1}{1 + sR_1C_1} \qquad \text{with gain} \qquad G(\omega) = |H(j\omega)| = \left[\frac{(\omega R_2 C_1)^2}{1 + (\omega R_1 C_1)^2}\right]^{1/2}. \tag{22.100}$$

At low frequency, the circuit of Fig. 22.10(b) becomes a high-pass filter, while at high frequency the circuit becomes an amplifier, with improved noise rejection, with a gain of R_2/R_1. An additional improvement has a parallel feedback capacitor across R_2, which serves to produce a low-pass filter. Ultimately, the circuit can perform as a *bandpass* filter, with transfer function

$$H(s) = -\frac{Z_2}{Z_1} = \frac{-sR_2C_1}{(1 + sR_1C_1)(1 + sR_2C_2)}. \tag{22.101}$$

From Eq. (22.101), there is a zero at $\omega = 0$, and two poles, one at $\omega_1 = (R_1C_1)^{-1}$ (high-pass differentiator circuit), and one at $\omega_2 = (R_2C_2)^{-1}$ (low-pass integrator circuit).

22.2.8 CR-RC Network

The high-pass filters shown in Fig. 22.7 and Fig. 22.10(a) are far from ideal and seldom used alone. They produce sharp output peaks that are difficult to process and, because they pass high frequencies they allow high-frequency noise to pass through the network. These two problems can be effectively mitigated by adding an integration circuit after the operational amplifier, as shown in Fig. 22.11. The differentiator and integrator networks are isolated by the operational amplifier that has a gain of unity at high frequencies.

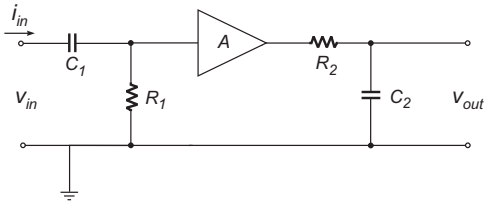

Figure 22.11. Depiction of a *CR-RC* pulse shaping circuit.

In Fig. 22.11 define the time constants $\tau_1 = R_1C_1$ and $\tau_2 = R_2C_2$. Consider the case of a step input $v_{in}(t) = v_{in}^o$ for $t > 0$ into this circuit for which $v_{in} = v_{out} = 0$ for $t \leq 0$. The input to the op amp is described by the output of the high-pass circuit defined by Eq. (22.66), while the output of the low-pass circuit after the op amp is defined by Eq. (22.46). Let the input to the op amp be $v_s(t)$, which is also the output of the op amp because the gain of the op amp is unity for high frequencies. Then

$$\frac{v_s(t)}{\tau_2} = \frac{v_{in}^o}{\tau_2}e^{-t/\tau_1} = \frac{dv_{out}(t)}{dt} + \frac{v_{out}(t)}{\tau_2}. \tag{22.102}$$

Multiply Eq. (22.102) by e^{t/τ_2} to find

$$\frac{v_s(t)e^{t/\tau_2}}{\tau_2} = \frac{dv_{out}(t)}{dt}e^{t/\tau_2} + \frac{v_{out}(t)}{\tau_2}e^{t/\tau_2} = \frac{d}{dt}\left(v_{out}(t)e^{t/\tau_2}\right). \tag{22.103}$$

Substitution of Eq. (22.103) back into Eq. (22.102) leads to

$$\frac{d}{dt}\left(v_{out}(t)e^{t/\tau_2}\right) = \frac{v_{in}^o}{\tau_2}e^{t(1/\tau_2 - 1/\tau_1)}. \tag{22.104}$$

Integration of Eq. (22.104) from $(0, t)$ yields

$$v_{out}(t)e^{t/\tau_2} - v_{out}(0) = \frac{v_{in}^o}{\tau_2}\int_0^t \exp\left[t\left(\frac{\tau_1 - \tau_2}{\tau_2\tau_1}\right)\right] dt, \tag{22.105}$$

which, with $v_{out}(0) = 0$, gives

$$\frac{v_{out}}{v_{in}} = \frac{\tau_1}{\tau_1 - \tau_2}\left(e^{-t/\tau_1} - e^{-t/\tau_2}\right). \tag{22.106}$$

For the case that $\tau_2 \to \tau_1$ Eq. (22.106) becomes indeterminate. But with l'Hôpital's rule one obtains

$$\frac{v_{out}(t)}{v_{in}^o} = \lim_{\tau_2 \to \tau_1} \frac{\tau_1 \dfrac{d}{d\tau_2}\left(\exp[-t/\tau_1] - \exp[-t/\tau_2]\right)}{\dfrac{d}{d\tau_2}(\tau_1 - \tau_2)} = \frac{t}{\tau}e^{-t/\tau}, \tag{22.107}$$

where $\tau_1 = \tau_2 = \tau$. It is notable that the Laplace transform transfer function of the circuit in Fig. 22.11 can be found by simply multiplying the Laplace transform of each stage,

$$H(s) = \frac{\mathcal{L}[V_{out}(t)]}{\mathcal{L}[V_{in}(t)]} = \frac{s\tau_1}{(1 + s\tau_1)(1 + s\tau_2)}. \tag{22.108}$$

The proof that the inverse transform of Eq. (22.108) yields Eq. (22.106) is left as an exercise.

Example results for the shaping network of Fig. 22.11 are shown in Fig. 22.12, from which a few trends can be seen. First, as τ_1 increases, more time is available to measure the induced charge coming from the detector; hence, the total pulse height increases. Second, as τ_2 increases, the pulse height decreases. Third, as τ_2 decreases, the pulse height increases and also returns to

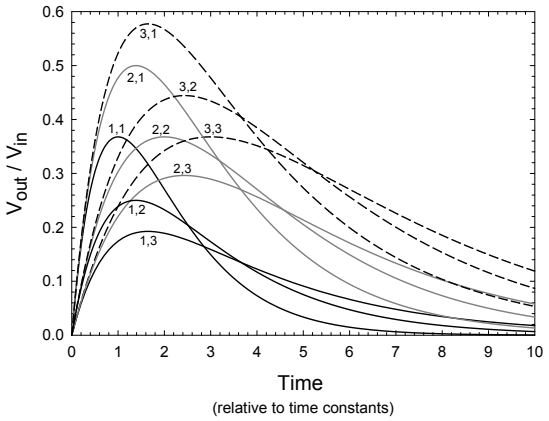

Figure 22.12. Responses of a CR-RC network to a step input voltage. The responses are labeled as τ_1, τ_2 according to Eqs. (22.106) and (22.107).

the baseline faster, thereby producing a faster pulse. To limit problems with pulse pile-up and dead time, these time constants are usually kept short, on the order of a few microseconds.

However, if these time constants are made so short that they are comparable to the rise time of the input signal from the preamplifier, similar to the charge collection time of the detector, then the input to the CR-RC network no longer resembles a step function. Instead it appears as an impulse input with a much different output than that depicted in Fig. 22.7(c). For instance, a square pulse input produces a truncated exponential output that turns negative at the end of the pulse. This unfortunate outcome produces a lower output pulse as a consequence of ballistic deficit. Hence, these time constants are generally designed to be longer than the detector charge collection time. If, however, the time constants are too long, then problems with electronic noise and pulse pile-up arise. As it turns out, for best performance, it is best to optimize the operating system time constants according to the detector type and the radiation measurement environment.

22.2.9 (CR)^2-RC Network

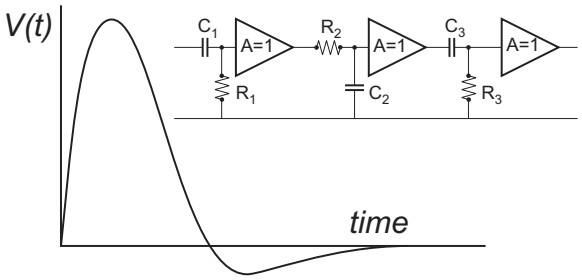

Figure 22.13. Depiction of a (CR)^2-RC circuit and the resulting bi-polar output pulse. Here $\tau_1 = R_1C_1$, $\tau_2 = R_2C_2$, and $\tau_3 = R_3C_3$.

Adding a second differentiator to a CR-RC network, or a double RC differentiator, forms a bipolar output pulse of the shape depicted in Fig. 22.13. The Laplace transform transfer function of this circuit is,

$$H(s) = \frac{s^2\tau_1\tau_3}{(1+s\tau_1)(1+s\tau_2)(1+s\tau_3)}. \tag{22.109}$$

For the fastest return to the baseline, a double differentiator circuit is usually designed with $\tau_1 = \tau_2 = \tau_3$. The advantage of the double differentiator is a reduction in baseline undershoot compared to a unipolar response. However, the bipolar pulse shaper usually has a reduced signal-to-noise ratio and a higher ballistic deficit than those of its unipolar counterpart [Nicholson 1974].

22.2.10 CR-(RC)^n Network

A Gaussian output pulse should theoretically have a shape defined by $e^{-(t/\tau)^2}$ with a nearly optimum signal-to-noise ratio from the symmetric shape. However, such an output is impractical, mainly because the pulse shape would extend to infinity on both sides and, thus, have an infinite time response [Nicholson 1974]. Instead, a network can be devised to approximate a Gaussian output, typically one having several integrator stages beyond the CR stage. The larger the number of integrator stages beyond the high-pass differentiator, the closer the output is to an ideal Gaussian pulse. The Laplace transform transfer function is

$$H(s) = \frac{s\tau_d}{(1+s\tau_d)(1+s\tau_1)(1+s\tau_2)\ldots(1+s\tau_n)}, \tag{22.110}$$

where τ_d is the differentiator (high-pass) time constant and n is the number of integrator (low-pass) stages. If all integrator time constants are equal to τ_i, then

$$H(s) = \frac{s\tau_d}{(1+s\tau_d)(1+s\tau_i)^n}. \tag{22.111}$$

In practice, four integrator stages provide an adequately Gaussian pulse shape [Nicholson 1974]. The output is defined by,

$$V_{out}(t) = \frac{V_{in}}{n!}\left(\frac{t}{\tau}\right)^n e^{-t/\tau}, \tag{22.112}$$

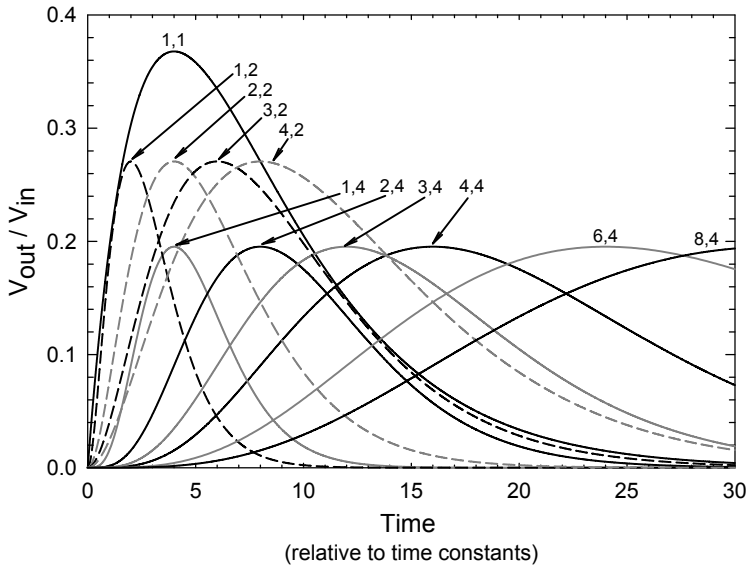

Figure 22.14. Responses of a CR-$(RC)^n$ network to a step input voltage. The responses are labeled as τ, n according to Eq. (22.112).

where n is the number of integrators beyond the low-pass filter. The additional shaping networks prolong the pulse formation by the number n, and for equal values of τ the CR-$(RC)^n$ network is n times longer than a CR-RC network. For instance, given equal values of τ, the CR-$(RC)^4$ network has a pulse duration 4 times that of a CR-RC network. Also, because the shape is not a true Gaussian, the output pulse still has slowly decaying tail. Consequently, pulse pile-up becomes more of an issue than with a CR-RC network. However, if the time constants are adjusted such that the peaking time matches that of an equivalent CR-RC network, the symmetry of the semi-Gaussian pulse enables it to return to the baseline more quickly and, thereby to reduce pulse pile-up at high count rates. Example pulses calculated with Eq. (22.112) are shown in Fig. 22.14. Notably, a practical Gaussian filter design usually incorporates active components (diodes, transistors, op amps) rather than RC filters to produce the desired result [Ortec 2009a].

22.2.11 Delay Line Pulse Shaping

Another method of shaping a voltage pulse is to use two separate signal propagation paths for the input signal. The outputs from each path arrive at different times and, when summed, change the signal. One method used to accomplish this task is depicted in Fig. 22.15. At time t_0, the signal is split between two paths. In the first path, the original signal propagates along the signal cable, such as a coaxial cable, and arrives at the input of an amplifier at some time t_1. Also at time t_0, the signal is diverted through a inverting amplifier with gain of unity,[8] and then propagates along another cable, arriving at the input of the second amplifier at time t_2 slightly delayed behind the other signal. Hence, at time t_2, the second signal is essentially subtracted from the first signal with delay $\Delta t = t_2 - t_1$. The pulse speeds v and arrival times are determined by the cable characteristic properties, where $v = 1/\sqrt{LC}$ (see Sec. 22.6 later in this chapter). The signal delay can be determined by the difference in propagation times of the two transmission line cables.

[8] This gain is at times referred to as a gain of -1. Throughout this text, the gain is the magnitude of the output signal to the input signal, although the sign (negative or positive) of the output may change with respect to the input. Hence, the gain here is 1, while the sign of the output is reversed with respect to the input.

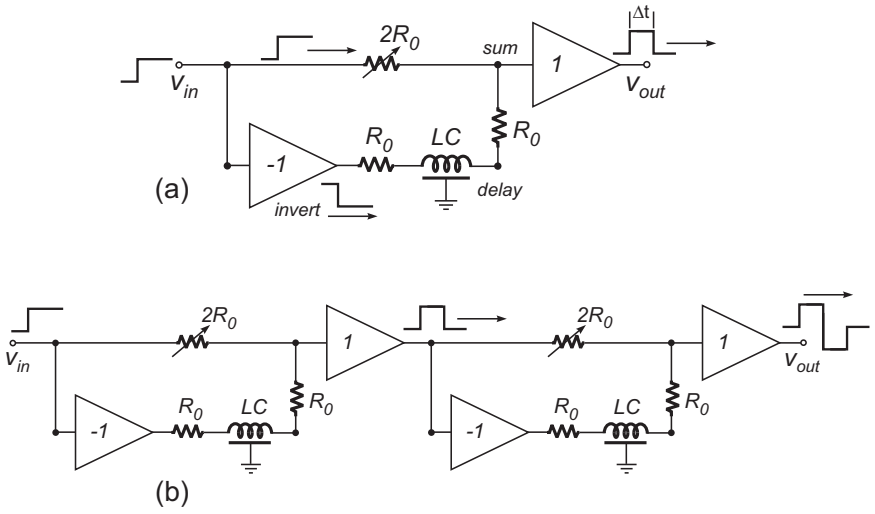

Figure 22.15. Depicted are (a) a single delay line and a (b) double delay line for shaping an input pulse. After Nicholson [1974].

Also, delay line amplifiers are available commercially as nuclear instrument modules (NIM) with a variety of settings and delays. These instruments allow the operator to provide a signal to the module and change the output by simply selecting different delay times and attenuations. The advantage of delay line shaping is the rapid recovery or return to the baseline which cannot be realized with normal Gaussian shaping.

Suppose a step function is applied to the circuit of Fig. 22.15(a) at $t_0 = 0$. One of the signals propagates unaltered, except for attenuation from the cable resistance R_0. The other signal is inverted, attenuated also by $2R_0$, and delayed. When the inverted signal arrives at the summing junction at t_2, with delay of Δt, it is added to the first signal. Because the delayed signal is negative, it causes the step pulse to become a rectangular pulse of width Δt, thereby returning the output pulse to the baseline.

In practice, there is usually some additional attenuation in the delay line, and the added negative signal may not completely restore the output pulse back to the baseline. This effect is especially pronounced for exponential input signals. However, by making the value of $2R_0$ in the first cable adjustable, the signals can be matched to eliminate this problem and properly return the shaped signal back to the baseline.

A bipolar shape can be formed by adding another delay line after the first, as depicted in Fig. 22.15(b). Basically, it adds an inverted shaped pulse directly behind the original shaped pulse. With proper tuning of $2R_0$, this method can also be used for exponential input signals. A disadvantage of the double delay line is that the overall output pulse width is increased.

22.2.12 Pole-Zero Cancellation

The effects of poles and zeros in the transfer function of a circuit can cause the appearance of non-ideal pulse shapes. For instance, the input to a common CR-RC filter usually has an associated input capacitance C_i. The impedance across this capacitance is often regarded as infinite but usually is just very large. Consequently, the input to the filter becomes

$$v_{in}(t) = \frac{Q}{C_i} e^{-t/\tau_i} \tag{22.113}$$

rather than the desired step input.

The equivalent circuit is shown in Fig. 22.16, which has the transfer function

$$H(s) = \frac{s\tau_i\tau_1}{C_i(1+s\tau_i)(1+s\tau_1)(1+s\tau_2)}. \qquad (22.114)$$

Consequently, this additional time constant $\tau_i = R_iC_i$ produces an undershoot in the output pulse.

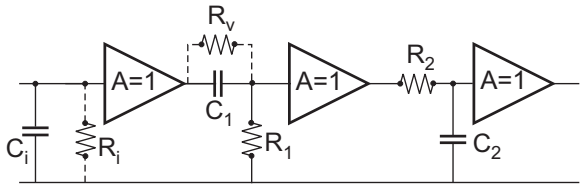

Figure 22.16. Equivalent circuit for a CR-RC filter with input capacitance C_i and pole zero compensation.

At least one method used to counter the effect is to place a variable resistor R_v across the C_1R_1 stage capacitance C_1 [Nowlin and Blankenship 1965]. The new transfer function becomes,

$$H(s) = \frac{\tau_i}{C_i(1+s\tau_i)(1+s\tau_2)} \frac{1}{\left[\dfrac{R_v+R_1}{C_1R_vR_1}+s\right]} \left[\frac{1}{R_vC_1}+s\right]. \qquad (22.115)$$

Equation (22.115) is simplified with the substitutions

$$\tau_a = \frac{C_1R_vR_1}{R_v+R_1} \qquad \text{and} \qquad \tau_b = R_vC_1, \qquad (22.116)$$

in which $\tau_b > \tau_a$, so that

$$H(s) = \frac{\tau_i}{C_i(1+s\tau_i)(1+s\tau_2)} \frac{1}{\left[\dfrac{1}{\tau_a}+s\right]} \left[\frac{1}{\tau_b}+s\right]. \qquad (22.117)$$

By adjusting the values of R_v, R_1, and C_1 such that $\tau_a = \tau_1$ and $\tau_b = \tau_i$, Eq. (22.117) reduces to

$$H(s) = \frac{\tau_1}{C_i(1+s\tau_1)(1+s\tau_2)}, \qquad (22.118)$$

thereby eliminating the undershooting tail. It is common that linear amplifiers come equipped with a pole-zero potentiometer in order to reduce or eliminate undershoot (or overshoot) of the shaped pulse. Note that this compensated result is also achieved with $R_i = R_v = \infty$. Other pole-zero compensation methods for more complicated input pulses are discussed by Blankenship and Nowlin [1966] and Strauss et al. [1967].

22.2.13 Base-Line Shift and Restoration

Amplifiers with AC coupled inputs often produce an output pulse with negative undershoot so the output pulses are not unipolar, but rather have a bipolar characteristic. This effect is described earlier in Sec. 22.2.6 for a series of rectangular wave inputs to a passive high-pass filter. An example of the problem is depicted in Fig. 22.8(b) and (d), in which the RC time constant τ is long compared to the cycle duration T.

The consequence of this undershoot problem is a shift in the base-line of the output pulse. Because the output pulse is measured with respect to the actual zero, the measured amplitude is reduced from its actual value. The problem is worsened in a real counting system because the input pulses arrive at random intervals with random amplitudes. Although a simple counting system can suffer such a difficulty without significant problems, a spectroscopy system suffers reduced energy resolution from the added deviation in pulse heights. The base-line shifting problem increases with count rate, in which T is no longer much greater than τ.

Methods to counteract the base-line shift are described in the literature, including bipolar output, diode clamping, and gated restoration [Nicholson 1974]. The bipolar method uses a circuit fashioned, in general, after the concept shown in Fig. 22.13. Bipolar shapers have positive and negative lobes, and, hence, counteract the problem associated with base-line shifts. If the positive and negative lobes are of equal value, then

the average value is zero and the output baseline remains unaltered. The consequence of bipolar shaping is increased electronic noise and a high ballistic deficit. Many modern pulse shape amplifiers have monopolar and bipolar shaping options, allowing the user to optimize the performance of the system by choosing monopolar shaping for low count rates and bipolar shaping for high count rates.

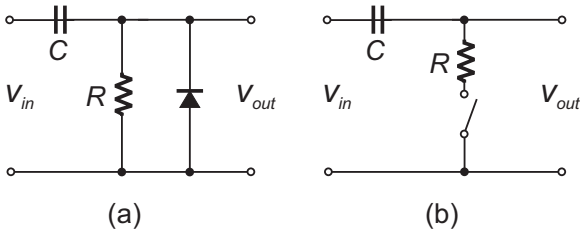

Figure 22.17. Simple base-line restoration circuits with (a) a diode clamp and (b) a gated switch.

The use of a diode in parallel with the resistor, shown in Fig. 22.17(a), acts as a base-line restoration circuit. If at the time the base-line goes negative, t_1 in Fig. 22.8(b), the diode is connected into the circuit and current flows to ground. This flow causes the capacitor to charge up opposite of the held charge and forces the output to return to zero. In reality, the diode has a small forward resistance as does the signal source, both of which combine to produce a small resistance R_s so that complete restoration does not occur. The small negative pulse discharges with time constant RC, and recharge with the next pulse by time constant R_sC. However, if the time constant RC is much greater than T, then the base-line is essentially clamped to zero. In reality, the single diode design is capable of restoring base-line shifts in only one direction. Robinson [1961] and Fairstein [1975] solve this problem by placing two diodes in the circuit to adjust base-line shifts in either direction. Various base-line restoration designs with diode clamps are discussed by Nicholson [1974].

Another method used to restore the base-line is with a gated switch, depicted in Fig. 22.17(b). This configuration eliminates the base-line shift from changing count rates. The switch is open during the input pulse and closed when the output pulse turns negative. By doing so, the CR circuit is active only between pulses, when the voltage is restored to zero. The switch is usually a combination of diodes [Robinson 1961], or more complex circuitry (see references in Nicholson [1974], Karlovac and Blalock [1975] and Fairstein [1975]). The stability of base-line restoration at high counting rates depends on the ability of the gating control circuits to distinguish between the incoming pulses and the base-line. This discrimination can be achieved with a manually adjusted discriminator set slightly above the electronic noise straddling the base-line. Such sophisticated amplifiers include automatic noise discriminators and complicated pulse detection techniques that effectively perform this task [Karlovac and Blalock 1975; Fairstein 1975].

22.3 Components

The main electronic components commonly used in a radiation detection system were introduced in Chapter 2, primarily because many readers using this book to learn about radiation detectors might also need to use some of these components in a laboratory setting as they gain knowledge about the operation of radiation detectors. In the following sections, additional information about these components is provided.

22.3.1 Preamplifiers

A preamplifier unit has two basic purposes, namely (1) to provide a low-noise coupling of the typically high impedance of the detector to a low impedance capable of driving the string of amplifier and readout electronics, and (2) to produce a first stage of signal amplification. This first stage of amplification is usually small. Preamplifiers are designed to be either voltage sensitive, current sensitive, or charge sensitive. Optimum detector performance is obtained when the type of preamplifier is properly matched to the type and characteristics of the detector and the analysis electronics.

Voltage-Sensitive Preamplifiers

Consider the simple preamplifier shown in Fig. 22.18. A resistor R_1 is connected between the input voltage and terminal 1 while terminal 2 is grounded. Also, a feedback resistor R_2 is connected between terminal 1 and terminal 3. The current flowing through R_1 is described by,

$$i_1 = \frac{v_{in} - v_A}{R_1} \tag{22.119}$$

and the current flowing through R_2 is

$$i_2 = \frac{v_A - v_{out}}{R_2}. \tag{22.120}$$

The small voltage appearing between terminals 1 and 2 is,

$$v_{AB} = v_B - v_A, \tag{22.121}$$

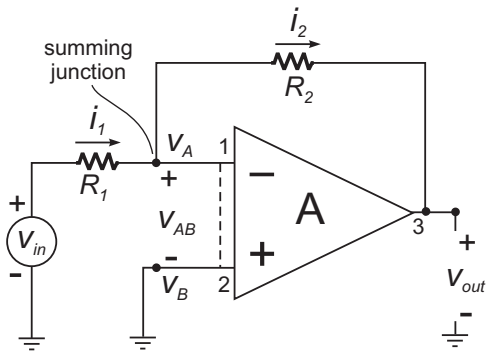

Figure 22.18. Simple voltage sensitive preamplifier with the inverted configuration.

but because terminal 2 is grounded $V_B = 0$ so that

$$v_{AB} = -v_A. \tag{22.122}$$

Because the input impedance into the op amp is large, only an insignificant current flows into terminal 1. Hence, the current flowing through R_1 also flows through R_2, i.e., $i_1 = i_2$, so equating Eqs. (22.119) and (22.120) gives

$$\frac{v_{in} - v_A}{R_1} = \frac{v_A - v_{out}}{R_2}, \tag{22.123}$$

or, upon rearrangement,

$$v_{out}R_1 - v_A(R_1 + R_2) = -v_{in}R_2. \tag{22.124}$$

Equation (22.36) for the present analysis becomes

$$\frac{v_{out}}{A} = v_B - v_A = -v_A \tag{22.125}$$

because here $v_B = 0$. By combining these last two equations, the transfer function of this preamplifier is

$$\frac{v_{out}}{v_{in}} = -\frac{AR_2}{[R_1(A+1) + R_2]}. \tag{22.126}$$

This result can be significantly simplified by recognizing that the open loop gain A is very much larger than unity so that $R_1(A+1) \gg R_2$ and, consequently, Eq. (22.126) reduces to,

$$\frac{v_{out}}{v_{in}} \simeq -\frac{R_2}{R_1}. \tag{22.127}$$

This simple result can also be obtained as follows. Conceptually, one can think of terminal 1 being at virtual ground and causing the input voltage at terminal 1 to also be zero. This means that the current flowing through R_1 must be equal to $i_1 = v_{in}/R_1$. However, the input impedance of the op amp prevents current flow into the device. Instead, the current i_1 must flow through R_2, thereby producing a voltage equivalent to $v_{in}R_2/R_1$. At terminal 3, the output voltage v_{out} is

$$v_{out} = v_1 - i_1R_2 = 0 - v_{in}\frac{R_2}{R_1}, \tag{22.128}$$

which yields the same transfer function as Eq. (22.127).

The gain of Eq. (22.127) is called the *closed loop gain*. First, note that ideally the open loop gain A has no bearing on the closed loop gain.[9] Second, the gain produced has the opposite or inverse sign of the input, hence the name for this circuit is the *inverting configuration*. The inverting configuration is a common circuit used as a voltage sensitive preamplifier, so named because they tend to respond to and linearly amplify the voltage input from the detector into the preamplifier circuit.

As discussed in Chapter 8, the voltage input v_{in} into the preamplifier from the detector is generally an inverse function of the detector capacitance, $v_{in} \approx Q_i/C_d$, where Q_i is the charge induced by the motion of electrons and ions excited in the detector by a radiation interaction event and C_d is the combined capacitance of the detector and coupling cables. Hence, to reduce the capacitance, the preamplifier circuit is usually placed as close as possible to the detector without causing environmental damage to the circuit.

For many detectors, the capacitance remains constant for different applied operating voltages V_o; hence the preamplifier output v_{out} is mostly linear with respect to the charge excited in the detector regardless of the voltage applied to the detector. Examples include gas-filled detectors and scintillation detectors that are coupled to photo-multiplier tubes.

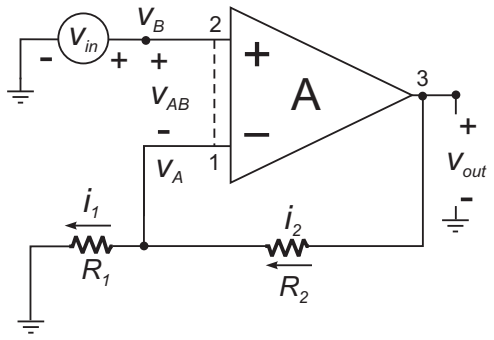

Figure 22.19. Preamplifier in the non-inverting configuration.

Now consider the circuit of Fig. 22.19, referred to as the non-inverting preamplifier configuration. It looks similar to the inverting configuration, except that the voltage input is now at the positive terminal, denoted with the present convention as input 2. As before, the output at terminal 3 is

$$v_{out} = A(v_B - v_A). \tag{22.129}$$

The voltage at input 2 is $v_B = v_{in}$ so that Eq. (22.129) gives

$$\frac{v_{out} + Av_A}{A} = v_{in}. \tag{22.130}$$

From Fig. 22.19 it is seen that

$$v_A = v_{out}\left(\frac{R_1}{R_1 + R_2}\right). \tag{22.131}$$

Substitution of Eq. (22.131) into Eq. (22.130) and rearrangement of terms yields

$$\text{Gain} = \frac{v_{out}}{v_{in}} = \frac{A(R_1 + R_2)}{(A+1)R_1 + R_2}. \tag{22.132}$$

Notice that the output voltage v_{out} retains the same polarity as the input voltage v_{in}. The gain of Eq. (22.132) is often simplified with the assumption that A is very large, so that Eq. (22.132) reduces to

$$\text{Gain} = \frac{v_{out}}{v_{in}} \approx \frac{R_1 + R_2}{R_1} = \frac{R_2}{R_1} + 1. \tag{22.133}$$

However, if the $A + 1$ is not much larger than the ratio $(R_2 + R_1)/R_1$, then considerable error can occur if the approximation of Eq. (22.133) is used.

[9] In reality, the rolloff of the open loop gain has a significant effect on the signal gain of the amplifier. See Carter and Brown [2016], Carter and Mancini [2017], Jung [2005], and Zumbahlen [2008] for more details.

Current-Sensitive Preamplifiers

A current-sensitive preamplifier is designed to measure the instantaneous current flowing from a detector. The practical implementation of the topologies can be identical for charge sensitive and current-sensitive preamplifiers, but they are used for different purposes. The component values are optimized to extract different information. This current sensitive preamplifier is seldom used for most detector applications; however, on rare occasion a preamplifier with a fast rise time for timing applications is needed, and a current sensitive preamplifier is required. Examples in which a current sensitive preamplifier is needed include timing applications with fast photomultipliers and microchannel plates. The current sensitive configuration requires that the input impedance be low and the preamplifier gain A be very large. These conditions can be realized by using the general design of a voltage sensitive preamplifier and reducing the load resistance at the input of the preamplifier.

A simplified current sensitive preamplifier is depicted in Fig. 22.20.[10] The two resistors form a parallel circuit so that the current flowing in R_1 is

$$i_1 = i_{in}\frac{R_2}{R_2 + R_1}. \tag{22.134}$$

If R_1 is much smaller than R_2, then Eq. (22.134) indicates that $i_1 \simeq i_{in}$ so that $v_{out} \simeq -Av_A = -Ai_1R_1$. If the input impedance is 50 Ω, then it can be impedance matched to a common 50 Ω transmission line, thereby eliminating reflection losses. The current sensitive preamplifier converts the input current i_{in} to an output voltage v_{out} described by $v_{out} \simeq Ai_{in}(50\Omega)$.

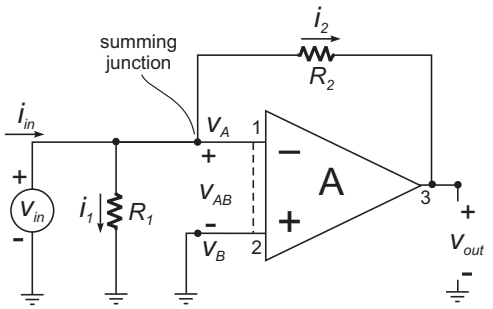

Figure 22.20. Simple current sensitive preamplifier with the inverted configuration.

Because current sensitive preamplifiers are designed to track the detector signal for timing purposes, noise added to the signal causes uncertainty in the actual arrival time of a pulse. This uncertainty is called *jitter*. A preamplifier rise time that is faster than the detector signal really does not help the situation. First, the output signal cannot be faster than the input signal, so a preamplifier rise time that is much faster than the input signal offers no real advantage. Instead, more noise is accepted into the system, thereby causing more jitter. By contrast, if the preamplifier signal is much slower than the detector signal, then the timing resolution suffers. To minimize the effect of jitter, Cova et al. [1991] recommend that the preamplifier rise time be similar to that of the detector input. For practical applications, it is recommended that the preamplifier rise time be within a factor 2 of the detector rise time [Ortec 2009b]. Note that the *Johnson noise* can be high unless the feedback resistor in the preamplifier circuit is $R_2 \geq 10^9$ Ω [Nicholson 1974].

Charge-Sensitive Preamplifiers

There are some detectors that change capacitance as voltage is applied, particularly semiconductor diode detectors. These semiconductor detectors have depletion regions (Chapter 15) that increase with applied operating voltage, which, in turn, causes the capacitance C_d to decrease with increasing voltage. As a result, the preamplifier output changes with a varying operating voltage for identical induced charges q_i. By redesigning the preamplifier feedback circuit, the capacitive component of the detector C_d can be minimized compared to the feedback capacitance C_f of the preamplifier, thereby effectively rendering the preamplifier output almost entirely dependent upon the induced charge q_i.

Consider the amplifier circuit shown in Fig. 22.21. There is a capacitor C_1 connected to input terminal 1 and another capacitor C_2 connected across terminals 1 and 3. The capacitor C_2 is referred to as the feedback

[10] In some cases, the feedback resistor R_2 is missing from an idealized current sensitive preamplifier diagram, implying that it has an infinite feedback resistance.

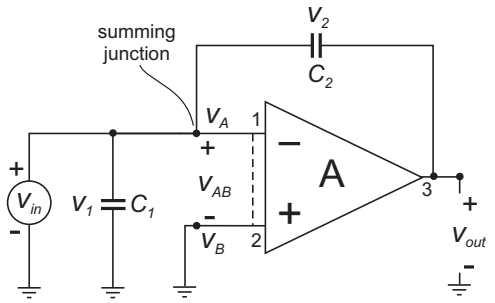

Figure 22.21. Simple charge sensitive preamplifier with the inverted configuration.

capacitor, often denoted C_f. The voltage v_{in} stored on C_1 appears at the summing junction. The voltage at the summing junction is v_{in} and must equal the voltage across C_2 plus v_{out}, i.e.,

$$v_{in} = v_{out} + v_2. \tag{22.135}$$

For an ideal op amp $v_{out} = -Av_{in}$ so that Eq. (22.135) can be written as

$$v_2 = (A+1)v_{in} = -\frac{(A+1)}{A}v_{out}. \tag{22.136}$$

Because $v_2 = q_2/C_2$

$$\frac{q_2}{C_2} = -\frac{(A+1)}{A}v_{out}, \tag{22.137}$$

which upon rearrangement gives

$$v_{out} = -\frac{A}{(A+1)}\frac{q_2}{C_2}. \tag{22.138}$$

Because A is very large and q_2 is the induced charge q_{in} from the detector

$$v_{out} \simeq -\frac{q_{in}}{C_2}. \tag{22.139}$$

The important outcome of Eq. (22.139) is that the output voltage is a function of the feedback capacitor C_2 and the induced change q_i and does not depend on the detector capacitance. Hence, for semiconductor diode detectors, the voltage output v_{out} is largely dependent only upon the induced charge q_i and feedback capacitance C_2, where $v_{out} = -Av_{in} \approx -q_i/C_2$, where A is the preamplifier gain. The *charge gain* is then

$$\frac{v_{out}}{q_{in}} = -\frac{1}{C_2}. \tag{22.140}$$

The goal of the detector system is to measure all of the charge generated in the detector. However, some charge remains on the sensor capacitance, leading to the following ratio for the input charge to the amplifier to the charge remaining on the detector [Spieler 2005],

$$\frac{q_{in}}{q_{in}+q_{det}} = \frac{v_{in}C_{in}}{v_{in}(C_{in}+C_{det})} = \frac{1}{1+\dfrac{C_{det}}{C_{in}}}. \tag{22.141}$$

where C_{in} is the dynamic input capacitance of the preamplifier. For $C_{in} \gg C_{det}$, the ratio $Q_{in}/(Q_{in}+Q_{det})$ approaches 100%.

Commercial charge-sensitive preamplifiers are designed for optimum performance when matched to specific ranges of detector capacitance. Hence, it is advised that the user consult the preamplifier specification sheets to properly match detectors to preamplifiers.

Example 22.5: Consider a silicon surface barrier detector connected to a commercial preamplifier with input capacitance of 10 nF. The detector is circular with diameter of 15 mm. The background doping concentration is 10^{13} cm^{-3} with $V_{bi} = 0.3$ volts. What is the charge ratio measured at self-bias volts? What is it at reverse bias of 150 volts?

Solution:
From Chapter 15, one uses the depletion approximation for the detector self-bias capacitance,

$$C_{det} = \frac{\kappa\epsilon_0 A}{L} = \left[\frac{2\kappa\epsilon_0(V_{bi}-V)}{qN_b}\right]^{-1/2} \kappa\epsilon_0\pi r^2 = \pi r^2 \left[\frac{qN_b\kappa\epsilon_0}{2(V_{bi}-V)}\right]^{1/2}$$

$$= \frac{\pi}{4}(1.5 \text{ cm})^2 \left[\frac{(1.6\times10^{-19}\text{C})(10^{13} \text{ cm}^{-3})(11.9)(8.854\times10^{-14} \text{ F cm}^{-1}}{2(0.3 \text{ V})}\right]^{1/2}$$

$$= 2.962 \text{ nF}.$$

Recalling that the depletion width increases with $\sqrt{V}$, the capacitance at 150 volts reverse bias is,

$$C_{det} = 2.962 \text{ pF}\sqrt{\frac{V_{bi}}{V+V_{bi}}} = 2.962 \text{ pF}\sqrt{\frac{0.3}{150.3}} = 132.34 \text{ pF}.$$

For the self-biased case,

$$\frac{Q_{in}}{Q_{in}+Q_{det}} = \frac{1}{1+\dfrac{C_{det}}{C_{in}}} = \frac{1}{1+\dfrac{2.962 \text{ nF}}{10 \text{ nF}}} = 0.7715 \text{ or } 77.15\%.$$

By the way, the resulting depletion layer width is only 6.29 microns, relatively small compared to alpha particle ranges from most check sources, meaning that the depletion region would be too small to absorb the total particle energy. Consequently, the charge that is deposited in the depletion capacitance is less than the total amount liberated, further diminishing the measured charge.

For the case where the detector is reverse biased at 150 volts,

$$\frac{Q_{in}}{Q_{in}+Q_{det}} = \frac{1}{1+\dfrac{C_{det}}{C_{in}}} = \frac{1}{1+\dfrac{132.34 \text{ pF}}{10 \text{ nF}}} = 0.9869 \text{ or } 98.69\%.$$

Also, the depletion depth would be 140.7 microns, wide enough to absorb alpha particle energies up to approximately 15 MeV.

Charge Sensitive Preamplifier with Resistive Feedback

The charge stored across the feedback capacitor in the charge-sensitive configuration shown in Fig. 22.21 accumulates with successive inputs, and eventually the charge reaches the limiting storage capacity. In order to discharge the capacitor between input pulses, a resistor is attached in parallel across the feedback capacitor so the capacitor discharges exponentially with a decay time constant of $\tau = RC$.[11] These time constants can be relatively long and are often about 50 μs [Ortec 2009a].

Pulse pile-up, depicted in Fig. 22.1, is due to subsequent pulses arriving before a prior pulse has returned to the base-line. Although the circuit ideally does not suffer from dead time losses, the output pulses are distorted. If the pulse decay tail is positive, then the subsequent pulse magnitude is greater than it should be, as shown in Fig. 22.1(a). If the pulse decay tail suffers undershoot, then the subsequent pulse is less than it should be, as shown in Fig. 22.1(b). In either case, the result is a broadening of the pulse height spectrum which reduces the energy resolution of the spectrometer. Further, at high count rates, multiple pulses

[11] Note that the value selected for this resistor is critical to stability of the preamplifier.

contribute to the pile-up problem and the total magnitude of the stored charge can exceed the preamplifier limit to produce a condition called "saturation overload," as shown in Fig. 22.22.

Because preamplifier output pulses are usually sent to the input of a shaping amplifier, the amplifier output can be affected by these pulse height distortions created by the preamplifier. There are several amplifiers designed to address pulse pile-up distortions, a few of which are described in latter sections.

Pulsed-Reset Preamplifiers

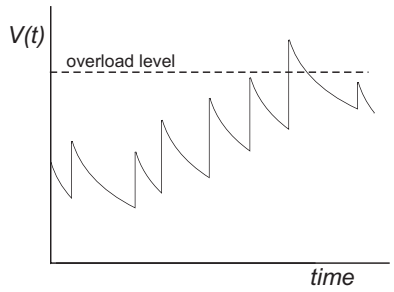

Figure 22.22. Preamplifier pulse pile-up output at high counting rates. Pulses can become distorted if they exceed the preamplifier overload level.

The pulsed-reset preamplifier was designed to reduce noise contributions from the feedback resistor by eliminating it altogether. In other words, R can be regarded as being infinite. Consequently, the decay constant of the feedback capacitor is essentially infinite so the decay tail now becomes a flat step (see Fig. 22.23(a)). Each input to the preamplifier produces a step increase in voltage proportional to the input charge of each pulse. During charge integration, the system does not suffer from dead time, mainly because the preamplifier continues to integrate the input charges that produce the stair-step output. The step inputs are shaped by a shaping amplifier, as described in previous sections. However, if two input pulses occur too close together, a form of pile-up occurs at the shaping amplifier which can cause pulse-height distortions.

A consequence of this preamplifier design is that the feedback capacitance does not discharge the accumulated charge as would occur in a resistive feedback preamplifier. To remedy this problem, an active reset method is incorporated. When the charge accumulated on the feedback resistor reaches a predetermined voltage, labeled V_{ramp}, a reset sequence begins. The design generally replaces a resistor in the feedback loop with either a light emitting diode (LED) or a transistor [Landis et al. 1971; Landis et al. 1982], either one being activated at the end of T_2 to reset the feedback capacitor. First, a short time duration is allowed that passes the last valid input pulse, labeled T_2 in Fig. 22.23(a). The capacitor is rapidly discharged during T_3 using an optical or transistor feedback method. In the case of optical feedback, a light-emitting diode (LED) is triggered that illuminates an optical gate such as a field effect transistor (FET), which opens and discharges the feedback capacitor. Optical feedback has been largely replaced by active FET discharging, in which the gate on the FET is opened to discharge the feedback capacitor when the reset voltage is exceeded.

In either case, the rapid discharge can produce a negative output from the shaping preamplifier. To prevent a negative output, the preamplifier remains disabled for a preset time, designated T_{aol}. During this disabled period, a blocking signal can be supplied to the shaping amplifier for a time T_{inh} to prevent the output of erroneous signals. Although the fractional dead time of the preamplifier would ideally be expressed by the ratio of T_3/T_1 [Britton et al. 1984], the actual fractional deadtime is determined by the time the amplifier cannot accept pulses. Hence, the fractional system deadtime is represented by

$$DT_f = \frac{T_{inh}}{T_1} = \frac{T_{inh}}{\dfrac{V_{ramp}}{(ER)(CG)} + T_2 + T_3}, \tag{22.142}$$

where ER is the input rate of energy into the preamplifier and CG is the conversion gain of the energy to voltage pulse height.

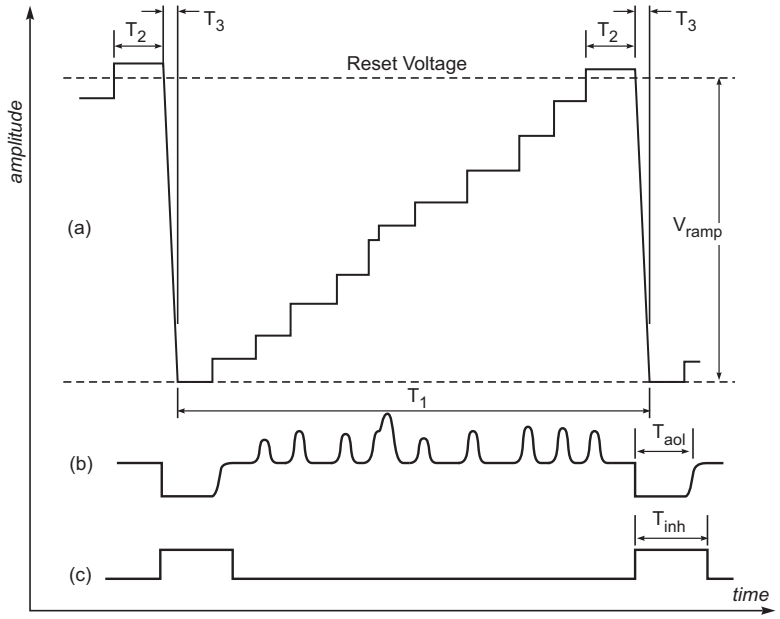

Figure 22.23. Output waveforms from a pulsed-reset preamplifier, where (a) is the output from the preamplifier, (b) are shaped pulses from a Gaussian amplifier, and (c) is the inhibit signal activated to stop data collection during the reset time. After Britton et al. [1984].

22.3.2 Amplifiers

The output pulse from a preamplifier is usually designed to have a short rise time τ_{rise} and a long fall time τ_{fall} so that $\tau_{rise} \ll \tau_{fall}$. Often another radiation interaction occurring in the detector arrives before the tail pulse from the previous radiation interaction is completely discharged. Consequently, subsequent pulses ride atop the tail of prior pulses, as shown in Fig. 22.22. The size of the step increase from a tail pulse contains information about the energy deposited in the detector because it is proportional to charge produced by an interaction and subsequently measured by the preamplifier. Hence, one purpose of the amplifier chain is to measure that signal increment and shape the resulting measured signal into a much shorter pulse signal. Also, because the gain of a preamplifier is usually small in order to prevent overload, the step change is difficult to measure accurately and the small signal can be attenuated significantly over relatively short cable distances. The purpose of the amplifier is to address both of these issues. First, to shape the charge by producing a significantly faster output pulse that still preserves the differential step change of each pulse. Second, to provide additional amplification of the signal. In some cases, fast timing amplifiers allow the preservation of information about the arrival time of different input pulses.

Linear Amplifier

For spectroscopy systems, the preferred amplifier choice is a linear pulse shaping amplifier. The amplifier serves to shape and amplify the input pulses from the preamplifier and produces an output whose amplitude is usually restricted by the maximum 10-volt NIM standard. Thus amplification of a pulse over the maximum limit results in a clipped output with the shaped pulse output being truncated at 10 volts in case of the NIM standard. Users are well advised to adjust the gain such that output pulses for the radiation energy under inspection is well below 10 volts.

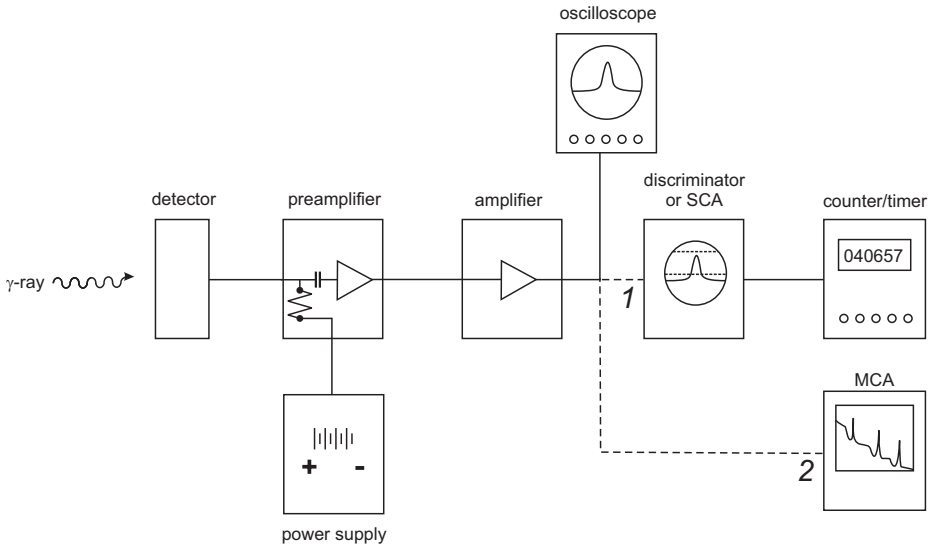

Figure 22.24. Detection system and components for either pulse counting (with SCA) or energy spectroscopy (with MCA).

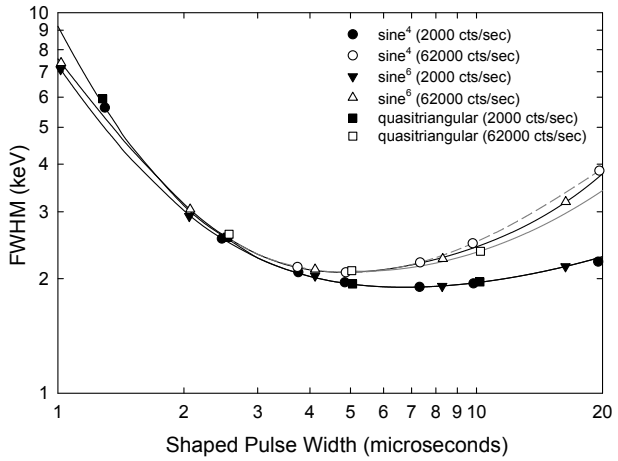

Figure 22.25. The energy resolution as a function of the pulse width for linear amplifiers with three different shaping networks. Also shown are the results from two different counting rates (2000 cps and 62000 cps). Data are from Fairstein [1985].

Most linear amplifiers allow the user to adjust the shaping times, with research units having adjustable independent rise and fall times. This feature allows the user to optimize the energy resolution performance of the system. Gaussian shaping is common with linear shaping amplifiers, although some units offer different shaping outputs such as triangular or quasitriangular as well as variations of Gaussian shaping. Shown in Fig. 22.25 are data obtained for different shaping networks at different count rates for an HPGe detector. As can be seen, the energy resolution changes with shaping time. The minimum FWHM also changes as the count rate changes. From results such as those shown in Fig. 22.25, the shaping times of a linear pulse amplifier can be adjusted to give the best energy resolution. If the shaping times selected are too short, then ballistic deficit losses worsen the energy resolution and the FWHM widens. Also, the contribution from series noise (see Sec. 22.7) increases and consequently decreases the energy resolution. If the shaping time is too long, then parallel noise contributions increase, which also compromises the energy resolution. As the count rate increases, the effects of pulse pile-up also begin to affect detrimentally the energy resolution if long shaping times are used. Consequently, the shaping time should be adjusted for optimum performance at the pulse rate under inspection.

For high-resolution HPGe detectors, the shape of the detector pulse varies depending on the location of the radiation interaction. The induced current entering the preamplifier changes as a function of the

weighting field in the detector, which is a function of position in the detector, so that the rise time of the pulse is also a function of the interaction location (see Sec. 16.4). As a consequence, less charge is integrated per unit time for long rise times, while the opposite is true for short rise times. If the shaping time is adequately long, then this effect is minimal because most of the charge is integrated regardless of the rise time. However, if the shaping time is short relative to the rise times, then there is detrimental increase in the variance of the output pulses from the preamplifier for monoenergetic events. This problem is called the *ballistic deficit* (see Sec. 22.2).[12] For low count rates, the shaping time can be set relatively long (> 6 μs) to reduce the effects of ballistic deficit. At high count rates, short shaping times are preferred in order to reduce pulse pile-up. However, shaping times shorter than 2 μs can cause energy resolution to degrade in high-resolution HPGe detectors [Becker et al. 1981]. Commercially available spectroscopic linear amplifiers quote the spectral broadening for high radiation interaction rates in the detector.[13]

Gated Integrator

Karlovac and Blalock [1975] describe a method for preserving the energy resolution despite a ballistic deficit caused by short shaping times needed for high interaction rates in the detector. The method uses a time-variant amplifier, or "gated integrator," to process the pulse [Radeka 1972]. An output pulse from a semiconductor detector, typically an HPGe detector, is introduced through a preamplifier into a Gaussian shaper. This Gaussian shaper with a short time constant rapidly shapes the input from the preamplifier and delivers the shaped pulse to the gated integrator. The charge leaving the Gaussian shaper is stored on a feedback capacitor across the gated integrator. This charge is the integral (area) of the pulse. At a preset collection time, a shorting gate closes across the feedback capacitor to fully discharge it to ground, while another gate is opened to disconnect the Gaussian shaper from the gated integrator during the discharge process. The time that the gated integrator is active is much longer than the Gaussian shaping time, usually on the order of 10 microseconds. The Gaussian shaper must remain active long enough to measure all charge from the detector.

This gating technique is demonstrated in the modeled results of Fig. 22.26. Here the inputs of three identical charge packets are applied to a fast Gaussian shaper with 0.7 μs shaping time. In one case, the induced current is high from fast charge collection (10 ns) and the Gaussian shaper develops the full Gaussian output with no ballistic deficit. In a slightly slower case, the shaping time and the charge collection time (1 μs) are comparable. Hence, a small amount of ballistic deficit is observed, but the overall integrated output reaches the same level as the faster pulse. In the third case, the charge collection time (10 μs) is much slower than the shaping time. After a short rise, the output fall time causes the input signal to match the output signal, forming a flat top pulse. However, the integral of this slower pulse also reaches the same output as the faster pulses, albeit at a much later time. The integrated charge, shown for all inputs, eventually reaches the same value, despite the rise time differences. The total charge is the same in all cases and is stored on the gated integrator capacitance. Consequently, the output is no longer based on the pulse height as with time-invariant linear amplifiers, but instead the total integrated charge in the pulse. The output is therefore independent of the ballistic deficit perturbations and no longer affects the gated integrator output pulse magnitude, provided that all charge is collected during the processing time and there is no pulse pile-up

[12] Note that ballistic deficit is a consequence of using too short of a shaping time, which results in lost charge integration. For short shaping times, the ballistic deficit can also be affected by specific current induction, which varies as a function of the interaction location, carrier velocity, and the weighting field in the detector [Radeka 1972].

[13] The spectral broadening in terms of percent at a specific high "count rate" is used for this metric. However, this description is somewhat imprecise, because the count rate is the observed response from a system; whereas, it is the input pulse rate that causes the problem. A high input pulse rate is produced by a high radiation interaction rate in the detector and this leads to pulse pile-up. The ballistic deficit is thus exacerbated by short pulse shaping times.

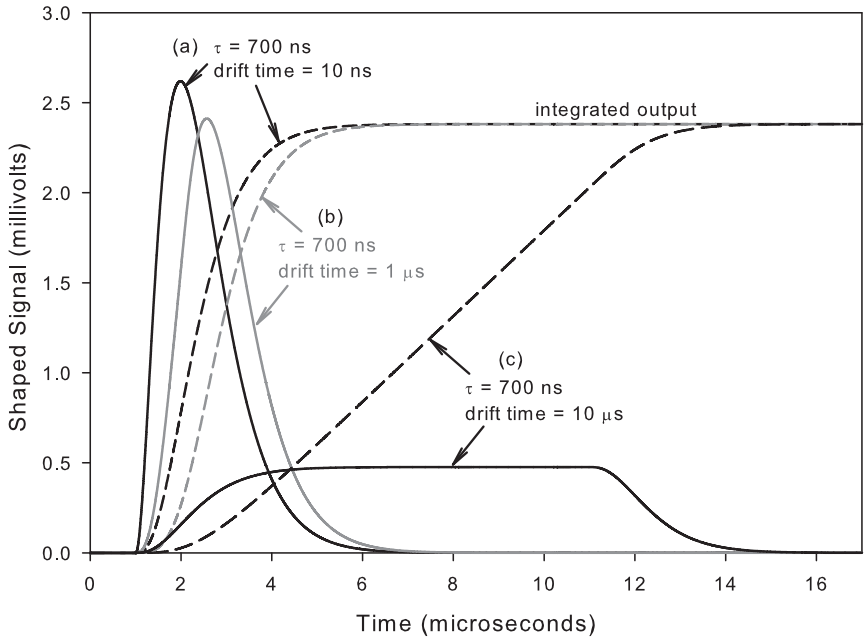

Figure 22.26. Modeled pulses from a Gaussian shaper with $\tau = 0.7\mu$s, showing the effects of different carrier drift times for the same amount of total charge. Also shown is the integrated output, with gain of 500,000, obtained from the shaped signals. In (a), the drift time is 10 ns, yielding a semi-Gaussian output with negligible ballistic deficit. In (b) the drift time is 1 μs and in (c) the drift time is 10 μs. Although the Gaussian peak voltage is different for all cases, the integral of the signals is the same for all cases. Hence, provided that all charge is collected during the processing time and there is no signal pile-up, the integral can be used to preserve the detector spectroscopic information.

during the signal shaping and integration process. Because the circuit is designed to operate under high interaction rates, pile-up rejection is used to reject overlapping pulses.

Two advantages of the gated integrator amplifier circuit are apparent. First, the energy resolution is preserved because ballistic deficit from different rise times is no longer a problem. Second, a shorter time constant allows faster pulse processing; hence more counts are recorded at high rates of gamma-ray interactions. Because the system dead time is largely determined by the processing times of the gated integrator and that of the multichannel analog-to-digital processor, changes in the observed count rate do not necessarily track the interaction rate in the detector [Simpson et al. 1991]. The example spectra in the work of Karlovac and Blalock [1975] shows good energy resolution for an interaction rate of 150,000 gamma-rays per second, but records only (approximately) twice as many counts as observed for a lower count rate of only 5000 interactions per second.[14]

Details for the Common Linear Amplifier

Ideally, a linear pulse amplifier should have the following properties. The output of the amplifier should scale proportionally to the energy input, a condition requiring that any integral and differential non-linearities

[14] The literature states the that input is 150,000 counts per second (150 kcps) [Karlovac and Blalock 1975], but this is a semantics problem. Strictly, the observed count rate is the final tally allowed by the system, which is seriously lower than the gamma-ray interaction rate in the detector. The authors of this text believe that interaction rate, not count rate, is what Karlovac and Blalock actually meant.

should be small. For a linear preamplifier, the minimum output is 0 volts, while the maximum output (NIM rules) is 10 volts. Hence, the minimum input should result in 0 volts output, while the maximum allowed input yields 10 volts output. Ideally the output voltage scales linearly with the input voltage, as depicted in Fig. 22.27. However, there usually is some non-linearity, i.e.,

$$\frac{v_{out}}{v_{in}} = A\,(1+\epsilon_{int})\,, \tag{22.143}$$

or

$$\epsilon_{int} = \frac{v_{out} - Av_{in}}{Av_{in}}, \tag{22.144}$$

where A is the gain and ϵ_{int} is the integral non-linearity [Kowalski 1970]. The differential non-linearity ϵ_{dif} is defined as

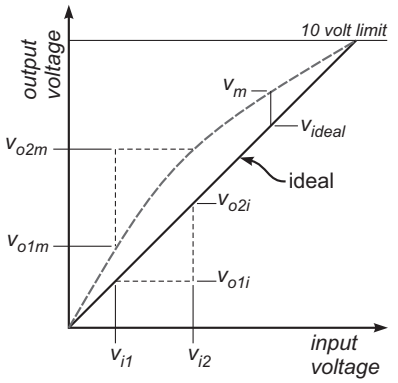

Figure 22.27. Examples of integral and differential non-linearity in an amplifier output.

$$\frac{dv_{out}}{dv_{in}} = A\,(1+\epsilon_{dif})\,, \tag{22.145}$$

or

$$\epsilon_{dif} = \frac{dv_{out}}{dv_{in}}\frac{1}{A} - 1, \tag{22.146}$$

which describes non-linearity between small differences in pulse heights.

Both non-linearities can be measured from a plot of v_{out} versus v_{in} such as shown in Fig. 22.27. For any given input v_{in} the integral non-linearity of Eq. (22.144) is

$$\epsilon_{int} = \frac{v_m - v_{ideal}}{v_{ideal}} \tag{22.147}$$

where v_m is the measured output and v_{ideal} is the predicted linear output.[15] The differential non-linearity can be determined from the ratio of slopes of the measured outputs to linearly predicted outputs at any input voltage, i.e.,

$$\epsilon_{dif} = \left[\lim_{v_{i2}\to v_{i1}} \left(\frac{v_{o2m}-v_{o1m}}{v_{i2}-v_{i1}}\right)\left(\frac{v_{o2i}-v_{o1i}}{v_{i2}-v_{i1}}\right)^{-1}\right] - 1 = \left[\lim_{v_{i2}\to v_{i1}} \left(\frac{v_{o2m}-v_{o1m}}{v_{i2}-v_{i1}}\right)\left(\frac{A\,(v_{i2}-v_{i1})}{v_{i2}-v_{i1}}\right)^{-1}\right] - 1$$

$$= \left[\lim_{v_{i2}\to v_{i1}} \frac{v_{o2m}-v_{o1m}}{A(v_{i2}-v_{i1})}\right] - 1, \tag{22.149}$$

where v_{o2m} and v_{o1m} are measured outputs and v_{o2i} and v_{o1i} are ideal outputs, both corresponding to inputs v_{i2} and v_{i1}, respectively. Usually, these metrics are reported for the highest observed non-linear behavior over the output voltage range. Commercial spectroscopy linear amplifiers usually have an integral non-linearity $\leq \pm 0.025\%$ between 0 to 10 volts, and a differential non-linearity $\leq \pm 0.012\%$ between -9 to 9 volts.

Another problem that can occur with linear amplifiers is in the amplification of small pulses in the presence of large pulses. If sufficient gain is used to distinguish small pulses from large pulses, the processing of a

[15] To provide a uniform measure over the amplifier range, integral non-linearity for commercial units is often reported as,

$$\epsilon_{int} = \frac{v_m - v_{ideal}}{v_{max}}, \tag{22.148}$$

where v_{max} is the 10 volt NIM limit. Usually it is the highest measured value of ϵ_{int} over the amplifier range that is reported.

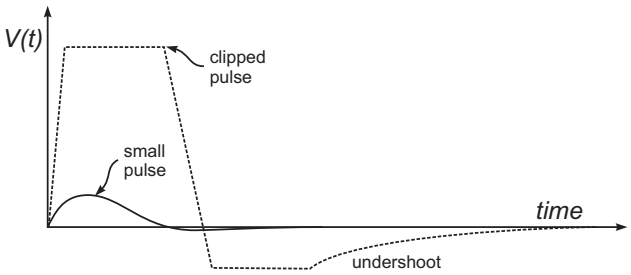

Figure 22.28. Overload pulses can have large undershoot and long recovery time. Small pulses arriving during the recovery time of an overload pulse are distorted.

large pulse may result in a clipped output in which the pulse exceeds the overload setting. Consequently, the pulse undershoot, as shown in Fig. 22.28, of this overload pulse is also large, and the recovery takes excessive time to return to the base-line. During the recovery time, small pulses that arrive are distorted by the negative tail of the overloaded pulse. Modern systems have overload resistant circuits that minimize this effect. Commercial spectroscopy amplifiers usually have the overload recovery specifications reported for maximum gain on the performance sheet.

Thermal stability is important, and the gain should not drift with temperature changes. Commercial units usually have thermal stability of $\leq \pm 0.0075\%$ per °C within a specified temperature range (typically between 0 to 50°C). Also electronic noise must be relatively low to achieve high energy resolution. Hence, the signal-to-noise ratio must be optimized for the device by adjusting the shaping times to coincide with the highest energy resolution (see, for example, Fig. 22.25). The amplifier should respond to high pulse input rates with negligible pile-up effects. Finally, there are some cases where the time correlation of the input pulse must be preserved, and the time trigger method becomes important as explained in the next section.

Amplitude adjustment includes coarse increment changes from 5× up to a maximum gain (usually 2000×). Most units also have a fine adjustment feature, with a continuously adjustable scaling factor between 0.5× to 1.5×. These features allow the user to adjust a pulser input to precise amplitudes for calibration purposes, or to adjust the shaped detector input to fall within the desired range of pulse heights. Detection systems and components for common counting and spectroscopy applications are shown in Fig. 22.24. Other features common to a linear spectroscopy amplifier are pole zero adjustment, automatic base-line restoration, pulse pile-up rejection, and choice of unipolar and bipolar outputs.

Timing Amplifier

For measurements where time correlation is important, the electronic pulse is sent to a timing pick-off gate that uses a threshold method to trigger a time stamp on the pulse. If the pulse height coming from the detector or preamplifier is too low to surmount this threshold, some amplification is then required that does not alter the time signal of the pulse. Common linear amplifiers are not well suited for this purpose, but are instead designed to eliminate high frequency noise while preserving the energy information provided by the detector. Hence, a fast timing preamplifier is needed that mimics the input signal with the added benefit of gain. Timing amplifiers may have rise times in the range of nanoseconds or smaller. Unfortunately, such fast rise times can also detrimentally affect linearity, thermal stability, and electronic noise. Because such amplifiers were designed to process negative output pulses from PMT anodes, the pulse polarity output of commercial units is usually negative to remain compatible with fast timing discriminators.

Earlier it was shown that AC coupling could be used as a DC filter while passing higher frequency signals. Hence, a *wideband amplifier* may be DC coupled to extend the frequency response to zero while still responding to high frequencies. Wideband amplifiers offer no control over the rise time or the decay time of the signal. Also, wideband amplifiers are best used with photomultiplier tube output signals and with silicon diode detectors to preserve timing information [Ortec 2009a]. Pulse shaping adjustment controls are provided with *timing filter amplifiers*, and they also typically have base-line restoration electronics. This type of timing amplifier is generally useful for timing applications with high-resolution HPGe detectors. For timing applications with either type of amplifier, the rise time should be selected to be less than the inherent

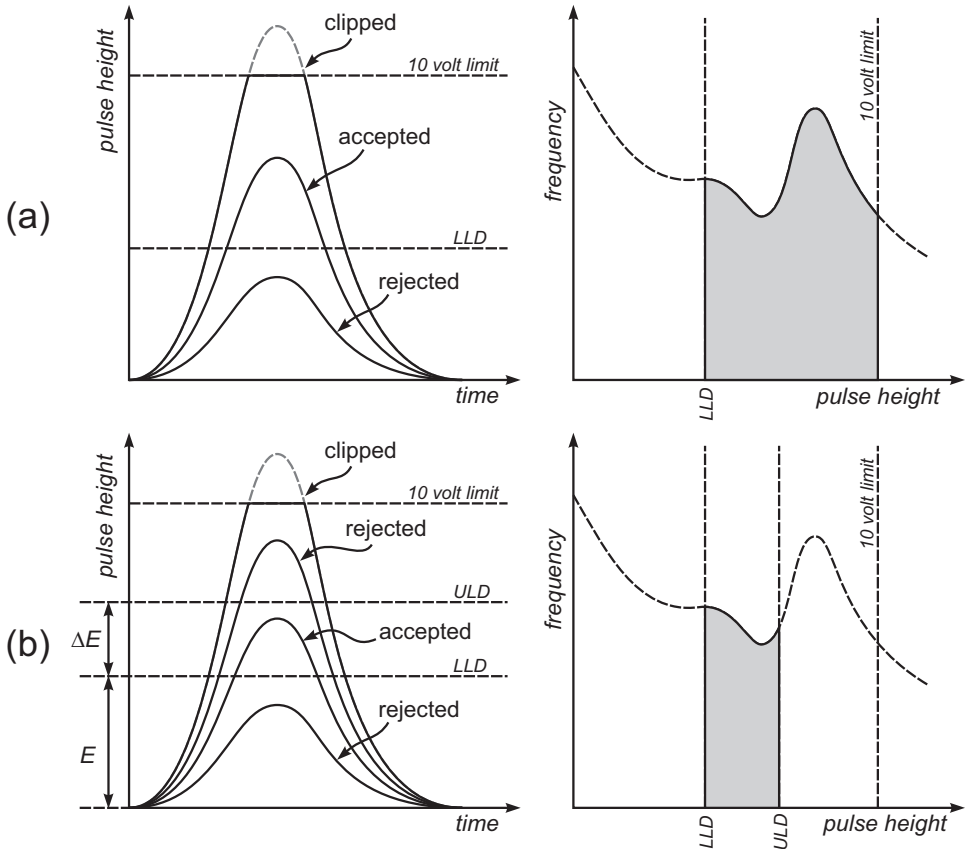

Figure 22.29. The function of an (a) integral discriminator and a (b) single channel analyzer.

rise time of the preamplifier to reduce or eliminate degradation of the signal rise time. As already noted in the discussion on current-sensitive preamplifiers, the rise time should be faster than the input signal rise time, yet not too much faster or electronic noise becomes a problem. Consequently, excessively fast amplifier rise times should be avoided, because they introduce more noise and provide no additional improvement in the signal rise time. The differentiator time constant should be set just large enough to avoid significant loss of the signal amplitude.

22.3.3 Integral Discriminators and Single Channel Analyzers

The electronic pulses emerging from a shaping amplifier are indicative of the energy absorbed within the detector. The amplitude of the pulse varies linearly with the absorbed energy in a well-designed system. Hence, once calibrated, the final signal pulse height is a measure of the energy absorbed in the detector. The main function of both discriminators and single channel analyzers is to reject shaped pulses outside established pulse-amplitude boundaries, thereby passing only pulses whose amplitude voltages are of interest. These systems convert a shaped input pulse into a logic output pulse, usually triggered when the leading edge of the shaped pulse surpasses a preset voltage threshold. Because the output is a logic pulse, energy information is preserved by the electronic boundaries set by the user and not the output pulse amplitude.

Logic pulses are characterized by a binary system, consisting of lows and highs, or alternatively as 0s and 1s. For instance, the Nuclear Instrument Module (NIM) system logic pulse is low (0) at 0 volts and high

(1) for a current of -16 mA through a 50Ω resistor, or a voltage of -0.8 volts.[16] The integral discriminator allows the user to select a signal voltage or energy E defined by a lower level discriminator (LLD) threshold, below which all pulses are rejected (depicted in Fig. 22.29(a)). In most models, any signal above the LLD is passed. However, some systems reject pulses that exceed the nuclear instrument module standard 10-volt upper limit. Because all pulses above the setting E are counted, 10 volt-limit notwithstanding, this device essentially passes all signals above the threshold. Hence, the accumulated pulses during the counting time is the integral of the pulses above E.

Unlike the integral discriminator, the single channel analyzer (SCA) is designed to filter out pulses whose amplitudes are both below a lower level discriminator (LLD) and above an upper level discriminator (ULD) setting. The LLD threshold is designated by E, a relative pulse height energy, while the ULD threshold is designated $E + \Delta E$ where ΔE is the width of the energy channel. Hence, the SCA allows the user to pick a voltage window (or energy window) of interest defined by lower and upper energy thresholds, and pass only those signal pulses that fall within those boundaries, as depicted in Fig. 22.29(b).

One method to accomplish this filtering task is to set two adjustable upper threshold levels in the instrument. The shaped signal input is split and routed through the two threshold circuits. If the signal pulse height is of adequate height to pass through E, then it is routed to an anticoincidence circuit. If the signal is also above the second threshold, it too passes to the anticoincidence circuit, where, upon arriving within a certain time window Δt, the anticoincidence circuit blocks these signals from passing and no logic output pulse is produced. However, if the signal passes above the LLD, but not the ULD, the anticoincidence circuit is not activated, and a logic output pulse is produced. Hence, if the input pulse does not fall within E and $E + \Delta E$ it is rejected. The number of passed signals equals the number of observed counts over a range of energies ΔE to produce a differential result.

Many modern SCA units can be operated as either an integral discriminator or SCA. In integral mode, the device window ΔE is completely opened while the LLD sets the discrimination threshold. When operated as an integral discriminator, the NIM upper 10-volt limit usually applies. Also, many SCA units have two scales, adjusted with a simple switch, with one window that opens to the maximum of 10 volts, and a smaller window with finer resolution that is limited to 1 volt maximum. The reason for the finer window resolution is to allow the experimenter to narrow the energy window with greater precision. A differential pulse height spectrum can be formed by first setting the ΔE window at a desired channel resolution, and subsequently taking measurements at increasing values of E in increments of ΔE from 0 up to 10 volts. Although an educational exercise, the multichannel analyzer (latter section) has made this method of producing a differential pulse height spectrum obsolete.

For most SCA units, the timing information is not accurately correlated to the input time of the pulse. This timing discrepancy occurs, in part, because of the leading-edge timing method usually used to determine when the signal pulse height surmounts the threshold. Unfortunately, this method suffers from so-called "time walk," because the pulse recognition time is dependent on the slope of the input pulse rise time. There are special timing SCAs that use constant-fraction timing, a method that compensates for varying amplitudes and ameliorates this timing shift and gives consistently better timing results. Timing SCAs are designed to minimize timing shift and dead time for a variety of detectors, including NaI:Tl, Si, and HPGe detectors, thereby allowing better system time resolution and higher counting rates.

[16] Other logic systems include resistor-transistor logic (RTL), transistor-resistor logic (TRL), transistor-transistor logic (TTL), complementary metal-oxide-semiconductor (CMOS), and emitter-coupled logic (ECL), all having specific voltage ranges for lows and highs.

22.3.4 Counters (Scalers) and Timers

A counter is used to tally the pulses that emerge from the discriminator or SCA unit. Historically, these units were called "scalers", mainly because their operation required a scaling ratio to tally the number of pulses entering the device. The reason for this operation was that, at one time, electromechanical registers could not keep up with the high rate of delivery from a counting system, capable of recording on average only 60 counts per second [Price 1964]. Instead, a "scale-of-2" was used where one output appears for two inputs. A series of n units gives a dividing factor of 2^n; hence the instrument scales down the number of pulses to manageable levels for the register. The result is an accurate tallying of the counts, giving the scaler the ability to indirectly record thousands of counts per second. The resolving power of these systems determined the count loss rate, manifested as another source of dead time. Other systems with "scale-of-10" were also developed. The period of operation of a scaler was controlled with a separate timer unit. Overall, the name "scaler" is historical, and modern digital electronic registers no longer use this scaling method to record pulses. Instead, the more appropriate name is "counter", and has been adopted as common nomenclature for modern pulse recording units.

High speed counters with rates exceeding 100 MHz are commercially available. These units typically operate with a string of decade counters. Each decade counter can record up to 10 inputs (in binary the number is 1010). Upon reaching the binary number 1010, the counter is reset to zero while a pulse is simultaneously delivered to the next decade counter in the chain, increasing the count by 1. On the second decade counter, a binary number 1010 is then equivalent to 10^2 counts. Hence, a string of n decade counters can register up to 10^n counts before resetting. Commercial units commonly have 8 sequential decade counters (an 8-decade counter).

The timer is used to start and stop the counter at preset time lengths. Usually the timer can be set to count for a certain length of *real* time, where the counter only functions during the preset time interval. Another timing mode feature allows a certain number of counts to be recorded, stopping to show the lapsed time when a preset number of counts is reached. Many timers can be set to scroll, where after a measurement period ends, there is a short delay before the tally is zeroed and another measurement automatically commences.

Timing systems that use the power-line AC frequency as the clock work adequately well and are relatively inexpensive, but they are best suited for use in countries that maintain power-line frequency corrections. However, the actual AC frequency is averaged over a relatively long period of operating time, meaning that short-term timing operations may suffer some inaccuracy. For short measurement time periods, seconds or minutes for instance, a timer based on a crystal-controlled oscillator is preferred.

Depending on the application, counters can be acquired either as independent units, sometimes with more than one counter in a single unit, or as combined counter/timer units having a built-in timer. Display counters have a display for the counting operation, often an 8-digit digital display capable of handling the maximum output from an 8-decade counter. The obvious convenience of a display counter is that the operator can visually monitor the counting process during the operation. Blind counters do not have a counting display, but instead can be interfaced with another display device such as a computer to log the number of counts. In some counter/timer units, there is a display counter, but the timer is blind. Printing counters, as the name implies, have an added capability that they can be connected to a printer to provide an output. Overall, counters and timers can be acquired for various applications, and specification sheets provided by manufacturers supply necessary information on maximum counting rates, display type, and output type.

22.3.5 Ratemeter

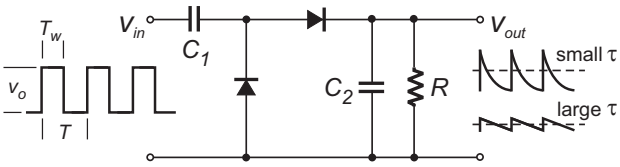

Figure 22.30. The basic diode charge pump ratemeter circuit.

A ratemeter is another type of radiation pulse recording device that produces an output charge (or voltage) proportional to the rate of radiation interactions in the detector. This type of detector was introduced by Gingrich et al. [1936] (see also Evans and Alder [1939]). A ratemeter design in common use is a diode charge pump circuit [Vincent 1960; Vincent and Parker 1970] and is depicted in Fig. 22.30. Consider the input pulse train of square waves as shown in Fig. 22.30. Each pulse has voltage magnitude v_o with width T_w and period T. The capacitor C_1 stores charge q_1 with voltage $v_1 = q_1/C_1$. The pulse input to the diode charge pump causes the capacitor C_2 to accumulate charge q_2, which discharges through the resistor R with a time constant $RC = \tau$. If the capacitance $C_1 \ll C_2$, then the charge passed to C_2 is equivalent to $v_1 C_1$. The instantaneous output on the meter fluctuates in time, although it can be assumed that there is an average input value. The amount of fluctuation about an average is a function of the time constant τ, where a large value of τ decreases the fluctuation (less discharge) while a small τ has greater fluctuation (more discharge).

In reality, radiation pulses arrive at sporadic intervals with varying amplitudes. Instead of a wave train, what is actually observed are fluctuations in stochastic arrivals which contribute to the uncertainty in the measurement. The total charge measured on C_2 is q_2 while each pulse produces an average charge of $\bar{q}$. For instance, recall that a Geiger-Müller counter produces pulses of nearly the same amplitude regardless of the original particle type or energy. Given a fixed measurement time interval, the number of interacting particles within that time period can be found from

$$N = \frac{q_2}{\bar{q}}, \tag{22.150}$$

with fractional standard deviation,

$$\frac{\sigma_N}{N} = \frac{\sqrt{N}}{N} = \frac{1}{\sqrt{N}} = \sqrt{\frac{\bar{q}}{q_2}}. \tag{22.151}$$

The standard deviation of the measured q_2 is thus

$$\sigma_{q_2} = q_2 \frac{\sigma_N}{N} = \sqrt{\bar{q} q_2}. \tag{22.152}$$

The amount of charge on the capacitor C_2 at t_0 is the remaining amount after the prior charge input. For an average charge $\bar{q} r dt$ produced between times t and $t + dt$, the amount of remaining charge on C_2 is

$$q_2(t)dt = \bar{q} r \exp\left[-\frac{t_0 - t}{RC_2}\right] dt \tag{22.153}$$

where r is the average rate of particle interactions. The standard deviation of the charge is

$$\sigma_{q_2} = \bar{q}\sqrt{r dt}, \tag{22.154}$$

and, therefore, the contribution to the standard deviation at t_0 is

$$\sigma_{q_2} = \bar{q}\sqrt{r dt}\ \exp\left[-\frac{t_0 - t}{RC_2}\right]. \tag{22.155}$$

For all charge packages delivered to the circuit from the detector, the separate variances can be summed to determine the total standard deviation

$$\sigma_{q_2}^2 = \int_{-\infty}^{t_0} \bar{q}^2 r \ \exp\left[\frac{-2(t_0 - t)}{RC_2}\right] dt = \frac{\bar{q}^2 r RC_2}{2}. \tag{22.156}$$

The average output current from the device is

$$\bar{i} = \bar{q}r, \tag{22.157}$$

while the instantaneous output current is

$$i(t) = \frac{q_2(t)}{RC_2}. \tag{22.158}$$

Hence, with error propagation on Eq. (22.158) and substitution of Eq. (22.157) into Eq. (22.156), the variance of the current is

$$\sigma_i = \frac{\sigma_{q_2}}{RC_2} = \bar{q}\sqrt{\frac{r}{2RC_2}}, \tag{22.159}$$

or the fractional standard deviation with respect to the average current (and also the counting rate) is

$$\frac{\sigma_i}{\bar{i}} = \frac{\sigma_r}{r} = \sqrt{\frac{1}{2rRC_2}}. \tag{22.160}$$

The average output signal is a function of the RC_2 time constant. To understand this outcome, consider the net rate of change on the capacitor C_2, where $r\bar{q}$ is the charge rate and q_2/RC is the discharge rate

$$\frac{dq_2(t)}{dt} = \bar{q}r - \frac{q_2(t)}{RC_2}. \tag{22.161}$$

Assuming at $t_0 = 0$ there is no charge on C_2, then

$$q_2(t) = r\bar{q}RC_2\left[1 - \exp\left(\frac{-t}{RC_2}\right)\right]. \tag{22.162}$$

Notice that as t becomes large ($t \gg RC_2$)

$$q_2(t) \simeq r\bar{q}RC_2, \tag{22.163}$$

which occurs at equilibrium. Hence, Eq. (22.156) and Eq. (22.163) are combined to find the average charge output with standard error,

$$q_2 \simeq \bar{q}rRC_2 \pm \bar{q}\sqrt{\frac{rRC_2}{2}} \tag{22.164}$$

or in terms of voltage

$$v_{out} = \frac{q_2}{C_2} \simeq \bar{q}rR \pm \bar{q}\sqrt{\frac{rR}{2C_2}}. \tag{22.165}$$

The output from a ratemeter can be altered by changing the RC_2 time constant. A long time constant RC_2 provides a relatively steady output reading. However, the device takes longer to reach the equilibrium condition and does not respond quickly to rapid changes in the count rate. Ratemeters accommodate different count rates by making R adjustable. Modern instruments often have automatic meter ranging. To handle large ranges of count rates, some ratemeters produce an output proportional to the log of the interaction rate [for example, see Cooke-Yarborough and Pulsford 1951; Fraser 1974a, 1974b].

22.3.6 Multichannel Analyzers

A multichannel analyzer (MCA) sorts shaped pulses from a linear amplifier according to their amplitudes. The instrument operates by changing the analog signals from the amplifier into digitized outputs. By digitizing and binning the pulse magnitudes, the resulting pulse height histogram produces a digitized image of the differential pulse height spectrum. If analog signals are supplied to the MCA, then the instrument must also incorporate an analog-to-digital converter (ADC). The analog-to-digital conversion architecture affects both the speed and linearity of the system. Some types of ADCs are discussed below.

The ADC outputs are sorted by magnitude and assigned to channels divided equally by 2^n over specific voltage range, usually limited by the NIM maximum standard of 10 volts. For instance, the 10 volts may be divided by 2^9 channels, yielding 512 consecutive channels each 19.53 mV wide. Most modern multichannel analyzers allow the user to change the number of channels 2^n from 256 up to 8192 by changing the value of n. Hence, the multichannel analyzer[17] operates, in some respect, as several SCAs sequentially scaled and operating concurrently.

The MCA evolved over the last 70 years by incorporating many improvements. Early models used vacuum tubes and, consequently, were quite large and were usually floor models. With solid-state electronics, these devices were reduced to table top models with cathode ray tube screens and a pin-fed dot-matrix printer readout. In the 1990s, the table top models were largely replaced by computer cards that would plug into a PC bus. Although the computer card MCAs are still available through resale outfits, they have been largely replaced by compact stand-alone units. Today, MCA instruments can be acquired as nuclear instrument modules that insert into a NIM bin, or as independent portable units. User interface software allows the operator to control the MCA and display the output on a personal computer or other electronic graphical user interface.

The Analog-to-Digital Conversion

An analog-to-digital converter (ADC) is an electronic system that converts a continuous time and amplitude signal into a quantized digital signal. For an MCA, the ADC converts an input analog voltage into a digital output representative of the magnitude of the input pulse. An ADC system is limited by its bandwidth, i.e., by the maximum number of conversions per unit time that can be achieved. This limitation is a consequence of the small time an ADC requires to process a conversion, a time in which additional signals cannot be processed. Factors that affect ADC performance include sampling rate, aliasing, signal-to-noise ratio, jitter, dither, linearity, and resolution, each of which is briefly described here.

The ADC resolution is determined by the number of discrete divisions spread over the analog voltage range (or voltage span). These divisions are determined by the number of bits n. For example, an ADC with n bit resolution over voltage span of V_m has channel resolution of,

$$\Delta E = \frac{V_m}{2^n}. \tag{22.166}$$

The actual resolution is limited by the signal-to-noise ratio, in which the noise consists of noise on the analog signal and quantization noise. Electronic noise appearing with the input signal is also incorporated into the digitized signal. Quantization noise appears as a consequence of the roundoff error between the analog signal and the digitized result.

Linearity is important in spectroscopy measurements for accurate energy identification. The non-linearity of an ADC is defined by either differential non-linearity or integral non-linearity. Differential non-linearity

[17] At one time, multichannel analyzers were called "kick-sorters", a term dating back to an electro-mechanical version of the device that would project small spheres by way of an electromechanical plunger. The magnitude of the kick was proportional to the pulse input, and the balls would land in a linear array of adjacent grooves to produce a histogram as the balls were stacked. The device of Frank et al. [1951] had 30 channels (grooves), each capable of holding 100 balls.

refers to the uniformity of channel widths ΔE defined by Eq. (22.166). The deviation in the width of MCA channels is usually less than $\pm 1\%$ differential non-linearity for modern commercial instruments. Using a linear fit for the channel assignment, the integral non-linearity refers to the maximum difference between the original analog signal pulse height and the assigned digital channel as measured over the entire signal range. For modern MCAs, integral non-linearity is usually on the order of or less than $\pm 0.25\%$ over the top 99% of the dynamic range.

Dither refers to the process of adding white noise to the analog signal before digitization. The reason for adding white noise is to improve the randomization of the quantization error, although such addition increases the system noise. This method slightly extends the range of the ADC while smoothing the quantization error over several noise values. Consequently, hard changes in digitized signals become smoother. Dither is widely used in digital processing of audio and image data.

In many cases, the analog signal is continuous. Consequently, a method is required to measure the signal and hold that specific value constant for a sufficient time to allow the ADC to produce a digitized output. The process of holding the sampled signal constant is performed with a sample-and-hold circuit, in which the sampled signal is used to charge a capacitor to store the charge. This capacitor is then temporarily disconnected from the input while the signal is being digitized. The *sampling rate* is the average speed at which an ADC can measure an analog signal (called sampling) to convert it into a digital output. This speed is usually reported as "samples per second."

To measure a periodic function, it is important that the sampling rate should be high enough to reproduce an accurate representation of the original signal. Typically the sampling rate should be at least greater than twice the analog signal bandwidth. A sampling rate that is too small can result in a problem called *aliasing* in which the reconstructed input is no longer representative of the original periodic input frequency. Usually a lower frequency digitized output is produced. The time between radiation pulses is stochastic, and the task of the ADC is to measure and digitize the peak voltage of the shaped input signal. Related to sampling time is the conversion time, defined as the time that it takes the ADC to sample an analog signal and process a digital output. The ADC is essentially inactive to additional incoming pulses during the conversion process. Hence, it is possible that these shaped pulses arrive at the ADC input faster than the ADC can process them, which ultimately contributes to lost counts.

Jitter refers to the temporal uncertainty in significant events in the ADC process and is observed as a deviation from the ideal timing interval between sampled signals. When the sample-and-hold circuit is opened, the capacitor is connected to the input circuit and stores the signal. The clock closes the circuit after some time Δt, while the ADC converts the stored voltage into a digital output. Jitter is the variation in the time at which the switch is opened. Jitter contributes to uncertainty in the sampled voltage, and is proportional to the amplitude and the rising edge of the input signal. Jitter problems increase with frequency and pulse amplitude.

Stacked Discriminator

An ADC can be realized by combining a series of simultaneously operated SCAs. In this architecture, multiple SCAs are arranged in parallel, each simultaneously accepting the shaped input pulse. Each separate SCA defines a range ΔE, sequentially stacked over the entire acceptable input voltage range. This stack of SCAs feeds a logic circuit that generates a code for each input channel. Ultimately, the stacked discriminator is a fast method to digitize pulses, mainly because the output is routed to the correct accumulator in a single step. Consequently, these ADCs are also called flash ADCs for their high speed capability. However, this architecture is too expensive for modern MCAs with large numbers of channels. For instance, the number of ADCs is equal to the digital resolution, which for an MCA with n-bit resolution requires 2^n comparators. Flash ADCs are usually restricted to 8 bit or to MCAs with only 256 channels. Also, the differential non-linearity is sometimes a problem because the independent threshold values of voltage for each channel have

their own associated error and, thus, add variance to the channel widths. Other problems include higher input capacitance than other architectures, higher power consumption, and generally lower energy resolution because of the restricted number of channels.

Wilkinson ADC

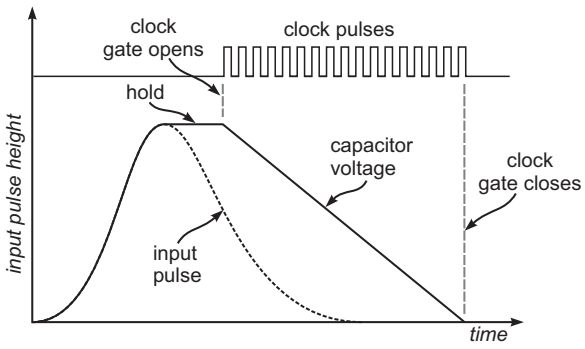

Figure 22.31. Principle of the Wilkinson ADC operation. After Nicholson [1974].

Introduced in 1950 [Wilkinson 1950], the Wilkinson ADC is still one of the most popular architectures used in MCAs. An input voltage into the Wilkinson ADC charges a capacitor while a voltage comparator is used to monitor the charge. When the input capacitor voltage is equivalent to the magnitude of the input voltage, the capacitor is discharged at constant current through a linear network. Hence, the capacitor voltage decreases in time with a constant slope as shown in Fig. 22.31. By measuring the time it takes to fully discharge the capacitor, a relative measure of the original voltage is found. This discharge time is determined by introducing a gate pulse when the capacitor begins to discharge. The gate pulse opens a linear gate that passes pulses produced by a precision oscillator to act as a clocking timer. The gate closes when the capacitor is fully discharged. While the gate is open, a discrete number of pulses is allowed to pass; hence the number of clock cycles that pass through the gate is a digitized indication of the initial input pulse. These clock cycles are counted on a digital address register. To prevent ambiguities in channel assignment, steps are taken to prevent the discharge process from starting in the middle of a clock cycle [Nicholson 1974]. Because the ADC method relies on a time-correlation, it becomes clear that large input pulses take longer to process than small input pulses. Further, the processing time, which depends on the clock frequency, becomes smaller as the clock frequency is increased. Commercial MCAs can be acquired that operate linearly with clock frequencies on the order of 100 MHz.

Successive Approximation ADC

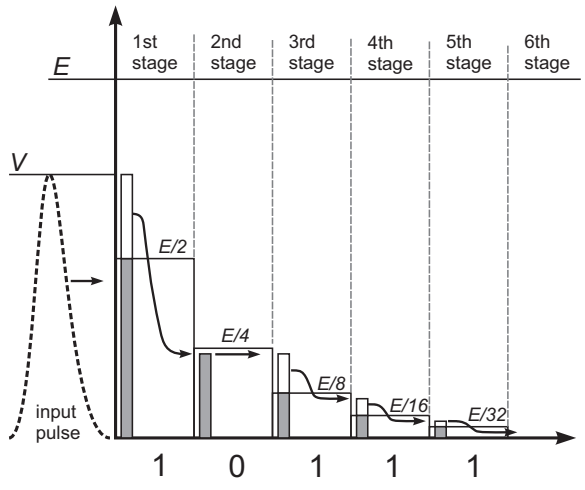

Figure 22.32. Principle of the successive approximation ADC operation. After Nicholson [1974].

A successive approximation ADC uses a comparator and a successive binary approximation method (see Fig. 22.32). An input shaped voltage pulse is initially compared to a range determined by $E/2$, where E is the maximum range of interest. For example, E might correspond to the NIM standard of 10 volts. If the input voltage V is larger than $E/2$, then a '1' is generated in the output, and the difference $V - E/2 = V_1$ is passed to the next stage. If, instead, V is less than $E/2$, then a '0' is assigned and $V = V_1$ is passed to the second stage unaltered. At the second stage, the process is repeated, except the comparison is now performed between V_1 and $E/4$. Hence, if V_1 is greater than $E/4$, then another '1' is assigned and $V_1 - E/4$ is passed. If V_1 is instead less than $E/4$, a '0' is assigned and the unaltered signal is passed. This process continues through a series of binary comparisons until the channel limit is reached. Hence, with 2^n channels for

the MCA there are n comparison stages. Each result is stored in a successive approximation register. The final output is the binary number representative of the digital conversion of the analog signal. The main advantage of the successive approximation register is that each input pulse takes essentially the same amount of time to process, which is usually less than that required for large pulses in a Wilkinson ADC in an MCA having a large number of channels. Hence, the successive approximation ADC is potentially faster than the Wilkinson ADC.

Ramp-Compare ADC

The ramp-compare or digital ramp ADC introduces a saw-tooth ramp input signal that is incremented by a counter. The ramp is produced by initiating a digital counter that has its output tied to the input of a digital-to-analog converter (DAC). This DAC ramp output is compared sequentially at each step to the amplitude of the shaped input voltage. The first comparison is performed with the ramp voltage at zero. If the input voltage is higher than the DAC signal, then the comparator produces a '1' which signals the counter to increment by one. The DAC output is therefore also incremented by one voltage division and the comparison is repeated. When the DAC output signal matches the shaped input signal, within a set division tolerance, the counter transfers the binary number to a shift register, and the comparator indicates a match and resets the counter to '0'. The shift register transfers the binary count to the ADC circuit output. Unfortunately, these ADCs are relatively slow and sensitive to the thermal changes. Further, their output speed is a function of the initial input pulse height because it takes longer to process the signal as the pulse height increases.

Sliding Scale Smoothing

A problem arises from the variance in channel widths of an MCA, where some channels are given more weight than others. This variation in channel width ultimately skews the digitized pulses that accumulate in each channel. For instance, pulses of a particular range falls between two levels that mark a channel width. If that channel width is wider or narrower than the average, then the number of pulses assigned to that channel is greater or smaller than the average. The variance and linearity of an ADC can be improved by a technique introduced by Cottini et al. [1963], known as *sliding scale smoothing*. The method alters the shaped input pulse before digitization, returning to its former value afterwards by the following sequence. The analog input pulse V has an analog value E_i added to it. After running through the ADC, the digital value of E_i is subtracted, ultimately returning to the digital value of V. However, the value of E_i is randomized over various i, meaning that the assigned values after digitization also vary. With subtraction of E_i, the process produces an average value spread over a few channels and, thereby it ameliorates the influence of channel width variance.

22.3.7 Pulse Generators

An important electronic component that assists with calibration of the radiation counting system is the pulse generator, which is commonly referred to as a *pulser*. Pulsers provide accurate voltage test pulses into the radiation detection system. The pulses can be set to have different shapes (a tail pulse being the most common), decay times, pulse frequencies, and amplitudes in order to calibrate an amplifier, MCA, SCA, or counter/timer. The test pulses can also be used to help determine system dead times and system electronic noise. Although not necessary to operate a radiation counting system, they are quite valuable when first configuring the system and calibrating it for radiation measurements. Further, a pulser is usually operated during a spectroscopic measurement in order to have a comparison peak with which the system noise can be determined. Typically the pulser peak is set to an MCA channel that does not interfere with the accumulated radiation spectrum. Some vendors offer digital pulsers with multiple pulser outputs.

22.3.8 Power Supplies

Detectors that operate with the NIM system typically produce an electronic output and, therefore, require a power supply of their own. Traditionally, the majority of such NIM power supplies for detectors apply a high voltage to the detectors. Stability of the supply voltage is of particular importance in high-resolution spectroscopic systems. High-voltage power supplies are used to operate detectors that do not suffer changes in capacitance as a function of voltage, such as gas-filled and scintillation detectors. High-voltage bias power supplies are usually used for semiconductor detectors, in which the operating voltage can affect the detector capacitance.

High-Voltage Power Supply

The high-voltage power supply, as the name implies, supplies high voltage to the detection device, and can supply it with either positive or negative polarity. The voltage is applied to the detector across a load resistor with the connection routed through the preamplifier unit. Typically, a power supply has a meter indicating the applied voltage and it is reasonably accurate because the detector resistance is usually much greater than the preamplifier load resistance. HV power supplies are available with the maximum voltages exceeding 3.5 kV. Such units are commonly used with PMTs and gas-filled detectors, neither having capacitance changes as the applied voltage is varied. As discussed in Sec. 14.1.6, a small change in output voltage can produce a large change in a PMT output. Consequently, power supplies used for scintillation spectrometers require high-voltage regulation to prevent voltage drift. Commercial units quote stability specifications as usually less than 0.03% variation over a 24-hour period. Also, because PMTs require high voltage to operate and often with current in the mA range, a HV power supply is usually connected directly into an AC receptacle. For convenience, many models have rails that allow the unit to slip into a NIM bin compartment.

High-Voltage Bias Supply

For semiconductor detectors, the power supply is generally referred to as a "bias supply." As with a HV power supply, the bias supply provides a choice of positive or negative high voltage to the detector. However, this type of power supply usually does not have a meter, but rather only a dial indicator indicating the total applied voltage to the system. Because the system includes load resistances in series with the detector, there is a voltage drop across this resistance, which reduces that applied to the detector. Thus, a meter indicating total voltage would be misleading. Instead jacks are often provided that allow determination of the bias current. Because the series' load resistance is known, the voltage applied to the detector, which is less than the total, can also be determined by subtracting iR from the overall applied voltage. Bias supplies are available for which the maximum allowable voltages can exceed 5 kV. Because typical detectors are highly resistive and draw little current, the power requirement of the bias supply is low and, consequently, most bias supplies are connected directly into the NIM bus for power, unlike HV power supplies. Stability in commercial units is commonly quoted as less than 0.1% variation per hour.

NIM Power Supply

A power supply is attached behind a NIM bin to supply power to the modules. This unit provides ±6 volts DC, ±12 volts DC, and ±24 volts DC to the NIM sockets and voltage jacks,[18] as well as 117 volts AC. Power is commonly rated between 150 and 160 W for the larger power supplies, although lower power models rated at about 95 W are available (usually for models that do not offer the ±6 volt DC option). The NIM bin sockets and pin assignments conform to the specifications outlined in DOE/ER-0457T. Test jacks in the front of the NIM bin provide convenient access to monitor the DC voltage, and can also be used to conveniently supply power to custom electronics. Modern power supplies are filtered from electromagnetic interference (EMI), are short-circuit proofed, thermally protected, and provide stable power required for

[18] Some models do not provide ±6 VDC.

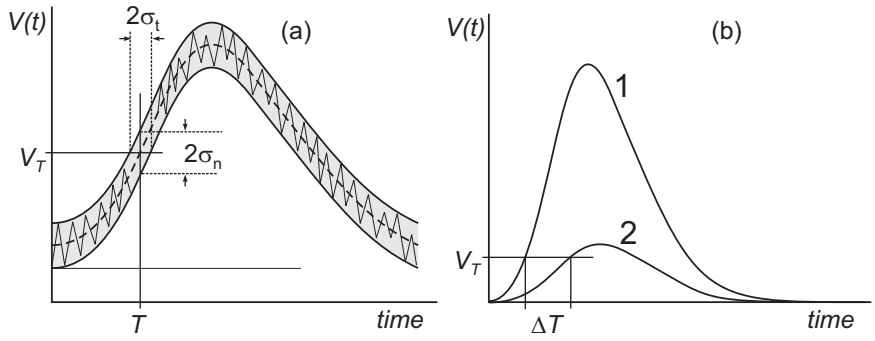

Figure 22.33. The effects of (a) time jitter and (b) time walk on the timing uncertainty, where V_T is the timing trigger threshold.

NIM components. Usually NIM bins have warning indicators that inform the operator if the power supply is approaching the temperature limit.

22.4 Timing

Sometimes it is important to know the time a radiation pulse occurs. Examples where such timing information is needed include coincidence measurements, anticoincidence measurements, and time-of-flight measurements. Timing systems use comparator circuits to determine the time at which a pulse amplitude reaches a preset threshold and then produce a logic pulse at the moment the pulse crosses the threshold. This logic pulse can then be used as a synchronization signal for timing measurements.

22.4.1 Jitter and Time Walk

Jitter refers to noise variations on the input signal as shown in Fig. 22.33(a). Consider a threshold voltage denoted V_T used to trigger a time stamp on an incoming pulse. The average value of an input pulse $v(t)$ is depicted as the dotted line in Fig. 22.33(a). However, electronic noise causes a variance in the time dependent input signal at V_T. This variance is quantified by the standard deviation σ_n of the noise. This variance in noise causes a variance in the actual time that the signal passes the threshold V_T and is quantified by the standard deviation σ_t. Because of these variances, there is uncertainly in the time stamp due to the jitter. Note that σ_n is simply the voltage amplitude of the noise. The contribution of the noise to the timing jitter is represented by [Spieler 2005]

$$\sigma_t = \sigma_n \Big/ \left.\frac{dV}{dt}\right|_{V_T} . \tag{22.167}$$

If the noise cannot be reduced, the jitter can still be minimized by setting the threshold V_T at the point of the maximum slope of the input pulse.

For some timing methods, the amplitude of the input pulse causes changes in the trigger time. Consider the leading edge of two analog pulses of different amplitude as depicted in Fig. 22.33(b). Both pulses start at the same time and are triggered at the same threshold V_T. For the larger amplitude pulse (1), the pulse crosses V_T before the smaller pulse (2). The difference ΔT in the trigger time is called *time walk*. The trigger timing of pulses shifts with pulse height and, thus, contributes to the uncertainty of the trigger time. Time walk can also appear as a consequence of different rise times, even if the pulse amplitudes are identical. For instance, the pulse output is a function of the location of radiation interaction in a HPGe detector (see Sec. 16.4.2), and these different rise times cause the trigger time to change. Time walk exacerbates the effects of jitter on the timing uncertainty. Some systems may partially compensate for time walk by making

appropriate corrections from the slope of the pulse. However, such methods reportedly fail if the input pulses suffer time walk from both amplitude and rise time variances [Spieler 2005]. Otherwise, time walk can be reduced by setting V_T at the lowest possible setting without being triggered by noise. Unfortunately, the optimum settings for time walk and jitter are usually not at the same V_T.

22.4.2 Common Timing Methods

There are many methods for recording the arrival time of pulses, and choosing the appropriate method should include consideration of the required timing resolution and type of detector in use. Briefly outlined in the following sections are a few popular methods of recording pulse arrival times.

Leading-Edge Timing

The leading-edge triggering method is relatively straightforward, and used when timing information is needed with somewhat relaxed timing resolution. The operator can set a threshold V_T and a comparator circuit identifies when the time dependent input pulse matches this preset threshold, at which point a logic pulse is generated. Some units provide a preset logic pulse length, while other units may terminate the logic pulse when the falling slope of the pulse once again matches V_T. However, leading edge timing is susceptible to resolution degradation from time walk and jitter. Nicholson [1974] reviews a few select designs for leading edge timing trigger circuits.

Zero-Crossover Timing

If the input signal is converted into a bipolar pulse, then the zero point crossing of pulses with varied amplitudes is time-invariant as shown in Fig. 22.34. Consider the result of a CR-RC shaping network from Eq. (22.107). Adding a differentiator (as in Fig. 22.13) produces a bipolar output

$$V_{bp} = \frac{d}{dt}V_{out} = V_{in}\frac{d}{dt}\frac{t}{\tau}e^{-t/\tau} = V_{in}\left[\frac{\tau - t}{\tau^2}\right]e^{-t/\tau}. \tag{22.168}$$

From this result it is seen that the output becomes zero when $t = \tau$. Note that the zero crossing is only a function of the shaping time and not the amplitude. Zero-crossover timing is best used for detectors that produce a wide range of pulse amplitudes.

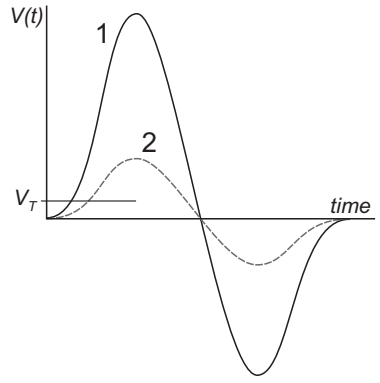

Figure 22.34. The zero-crossover timing method.

Such a system can be set to trigger when the zero-crossover condition is met, ideally eliminating problems with time walk. Noise can also trigger the timing circuit when noise pulses cross the zero point. To prevent confusion between noise and radiation pulses, a leading edge threshold comparator is often included to discriminate against noise. The original pulse is split and passed through both the threshold comparator and the zero crossover network. If the original pulse triggers the threshold comparator, indicating that the pulse is real and not noise, a signal is sent to an AND gate[19] that temporarily allows signals to pass. If both signals arrive in coincidence at the output gate, then a logic pulse is generated. Otherwise, the zero crossover pulse is blocked. The circuits are generally engineered such that the discriminator comparator signal is stretched and arrives at the gate before the zero crossover signal, thereby synchronizing the time signal with the arrival of the zero crossover time signal.

There are a few problems associated with the zero crossover method. First, with any timing circuit, there is a small delay from the time that the trigger condition is met and

[19] An AND gate is a digital logic gate that produces a "high" output (or 1) only when all inputs are also "high". Otherwise, the output is "low" (0).

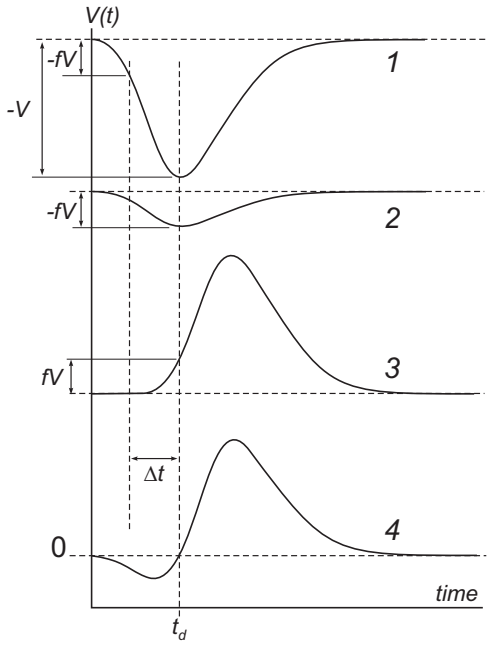

Figure 22.35. Constant fraction timing method. The inverted negative input (1) is reduced by fraction f (2). The input pulse is inverted and delayed by Δt such that a fraction of the input pulse fV equals the attenuated pulse maximum (3). Adding (2) and (3) together causes (4) the summed pulse to cross zero at the delay time t_d.

when the comparator initiates the trigger. Hence, there is a small amount of time walk. Second, the zero crossover point can shift with pulses of different rise times and shapes, such as those produced by HPGe detectors. Finally, jitter can be worse for zero crossover timing than leading-edge timing [Nicholson 1974]. For detector measurements where the pulse amplitudes are similar, the time walk may be less of an issue than jitter, and leading-edge timing may be a better choice.

Constant Fraction Timing

Another method developed to reduce the effect of pulse height time walk is constant fraction timing, which also uses a zero crossover method [Gedcke and McDonald 1967; 1968]. The input pulse V is split and one branch is attenuated by a fraction f of the pulse amplitude, while the other branch is inverted and delayed. The fraction f can be chosen to minimize jitter.

The delay time Δt is chosen to shift the rising edge of the inverted input pulse, the location at fV, to align with the maximum of the attenuated pulse, which is also fV (see Fig. 22.35). The delayed inverted pulse is added to the attenuated pulse, which produces a bipolar pulse that crosses zero at the time denoted t_d. A logic pulse is generated when the bipolar pulse matches the zero condition. The end result is a timing method that no longer suffers from amplitude time walk. This method is also less affected by time walk due to variations in rise time than is the leading edge method [Ortec 2009c]. Further, for relatively low values of f (less than 0.4), the timing resolution remains relatively constant.

ARC Timing

The amplitude and rise time compensated (ARC) timing method was developed for detectors that produce pulses that vary in rise time and pulse amplitude, which is particularly true for HPGe detectors [Chase 1968;

Cho and Chase 1972]. From the explanation for time-dependent pulse height formation in a planar HPGe detector given in Sec. 16.4.2 and shown in Fig. 16.31, the pulse rise takes on various shapes as also shown in Fig. 22.36.

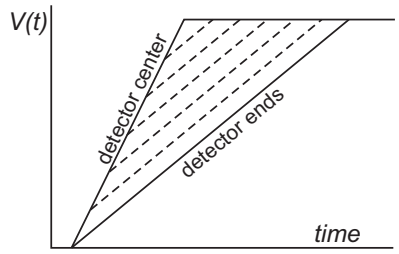

Figure 22.36. Position-dependent pulse shapes for a planar semiconductor detector. If the charge speeds are equal, the shortest rise time is for events occurring at the center of the detector because both electrons and holes are collected at the same time. The longest rise times occur when events take place at the ends of the detector.

The ARC timing method has some similarities to the constant fraction timing methods. The input pulse V is split, where one branch is inverted and attenuated by a fraction f of the pulse amplitude, and the other branch is delayed by Δt and then added to the attenuated pulse. The summed signals produce a bipolar pulse with a zero crossover that triggers a logic pulse. The main difference from constant fraction timing is that the delay Δt is chosen to be small. From Fig. 22.36, pulses from a planar semiconductor detector are initially linear. Once one type of charge carrier is collected (holes or electrons), the pulse shape changes to have a slower rise. ARC timing has time walk if the slope changes before the zero time crossing. By choosing a small Δt to delay the pulse, the zero crossover occurs before the pulse becomes non-linear, and consequently is independent of the overall rise time and pulse amplitude (see Fig. 22.37). As with the bipolar and constant fraction timing methods, a threshold comparator is used to remove zero crossings caused by noise pulses.

The ARC timing method has been shown to work well with coaxial HPGe detectors [Cho and Chase 1972]. However, the slope of pulse shapes from coaxial detectors is non-linear, changing between a mix of convex and concave shapes depending on interaction location (see Fig. 16.32). Consequently, ARC timing does not completely eliminate time walk with coaxial detectors, although it does show better performance than most other timing methods.

Some coaxial HPGe detector pulses can have relatively long rise times, generally caused by the excitation of electron-hole pairs in a region with low electric field, thereby initially producing low carrier speeds. If the discriminating comparator fires relatively late because of a slow rising pulse, then the gate is closed when the zero crossover signal arrives. Instead, the gate is opened late, corresponding to the arrival of the leading edge trigger instead of the zero crossover time. Consequently, these pulses can cause time walk that severely distorts the time spectrum. To counter the effect, slow rise time (SRT) rejection can be used to block the timing output if the zero crossover signal arrives before that of the leading edge discriminator signal [Bedwell and Paulus 1976].

22.5 Coincidence and Anti-Coincidence

There are many applications that require the measurement of coinciding events that occur in two or more separate detectors within a specified time interval. Examples include identification of the simultaneous arrival of photon-photon or photon-particle events, applications involving positron decay, and determination of radioactive decay schemes. Such measurements are commonly referred to as *coincidence measurements*, in which two or more events are considered coincident if they arrive at the coincidence discriminating unit within a preset time window of width τ. Accuracy of these measurements depends on the time correlation of the events that depends on a time window which must be set large enough to identify coincident events while being narrow enough to exclude uncorrelated events.

For example, positron emission tomography (PET) seeks to correlate annihilation photons from a single positron decay event and usually is based on the photons entering separate pairs of detectors arranged 180° about the source. Coincidence measurements can also be used to characterize light yield in scintillators, as explored by Rooney and Valentine [1996]. Coincidence counting is also used to distinguish between radiation

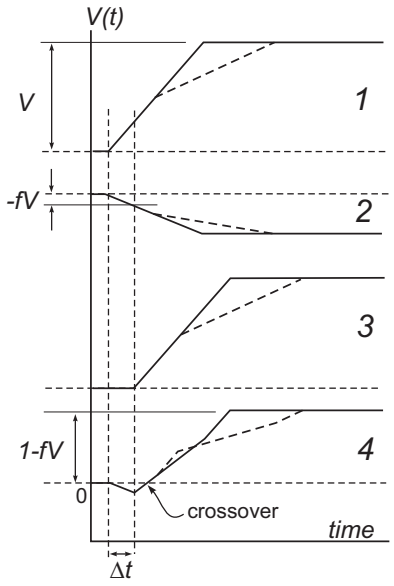

Figure 22.37. The ARC timing method. The input pulses (1) may have different rise times, depending on the interaction location. An input pulse is split into two signals, where one input pulse is inverted and reduced by fraction f (2). The other input pulse (3) is delayed by Δt, starting at only a small fraction of the rising pulse. Adding (2) and (3) together causes the summed pulse (4) to cross zero at the same delay time, regardless of rise time or pulse height.

types, for example the selective imaging of beta particles that are coincident with gamma-ray emissions [NCRP 1985; Dewaraja et al. 1994].

By contrast, there are some measurements that require the opposite condition, i.e., when two radiation events are recorded within time interval τ are rejected. Such measurements are referred to as *anticoincidence* measurements. For example, Compton suppression spectroscopy is a measurement method that uses the technique of anti-coincidence [Lindblad 1978; Bender et al. 2015] to reduce the Compton plateau in a pulse-height spectrum.

22.5.1 Coincidence Analyzers

The main function of a coincidence analyzer is to discern the arrival of two or more radiation particles in separate detectors within some preset time interval τ. In practice, it is not possible to analyze coincidence events with 100% confidence due to the uncertainties associated with the statistical nature of radiation emissions. Statistical timing errors may occur from the detection process and uncertainties in the electronics resulting from timing jitter, amplitude walk and noise, all of which lead to statistically variable time delays between processed events.

A coincidence analyzer accepts the time stamped inputs from two or more detectors, each connected to a separate port. Input signals are converted into stretched logic pulses, where the time duration is set to τ. A simple coincidence circuit solves this problem by essentially summing the two input pulses, passing the resultant sum pulse through a discriminator level, and generating an output pulse when the summed input pulses exceed the discriminator setting.

The period of time in which the two input pulses can be accepted is defined as the coincidence resolving time τ. Commercial coincidence modules allow the user to set τ within limits, usually between tens of ns up

to a few μs. A time-stamped pulse enters one port of the unit. If during the set resolving time another pulse enters another port of the unit, it is considered coincident. It does not matter which signal arrives first. If both signals overlap, then the coincidence analyzer produces an output logic pulse. Commercial units also often have an anti-coincidence feature in which, by either flipping a switch or connecting an input to an anti-coincidence port, logic pulses are generated at the output only if pulses are not coincident.

Suppose an input pulse arrives at a random time t_1. It is possible that a pulse already arrived at port 2 between time $t_1 - \tau$, causing a coincidence. It is also possible that a pulse arrives at port 2 between time $t_1 + \tau$, also capable of producing a coincidence signal. Consequently, the actual window for possible coincidence is the sum of these two intervals, namely 2τ. Because detector events occur at random times, accidental coincidences can occur between two pulses which produce background in the coincidence counting. Suppose that two counting rates are recorded by two separate detectors. The experimenter would observe, on average, g_1 cps from detector 1, about which for any single count a coincidence may arrive within $\pm\tau$. The average number of counts recorded from detector 2 within the time window is $g_2(2\tau)$ so that the average rate of accidental or random coincidences is

$$g_a = g_1 g_2(2\tau). \tag{22.169}$$

For N-fold detectors, the accidental coincidence rate is determined as [Jánossy 1950],

$$g_a = N g_1 g_2 \dots g_N \tau^{N-1} + \text{higher order terms}. \tag{22.170}$$

For the case where $n_i \ll \tau$, Jánossy [1950] shows that the higher order terms are negligible, yielding [Fenyves and Haiman 1969],

$$g_a \simeq N g_1 g_2 \dots g_N \tau^{N-1}. \tag{22.171}$$

Consider a two-fold coincidence system where detectors 1 and 2 have counting rates g_1 and g_2, respectively. If the source activity S is known and the source is relatively small, the count rates recorded by each detector are

$$g_i = S\epsilon_i \Omega_{fi} B_i \qquad i = 1, 2, \tag{22.172}$$

where for the ith detector B_i represents correction factors (such as the source branching ratio), Ω_{fi} is the fractional solid angle subtended by the detector from the source, and ϵ_i is the detector counting efficiency for the radiation of interest and source location. The rate of true coincidences depends upon the source activity S and the probability that concurrent emissions arrive at the detectors with respect to the source-to-detector solid angles,

$$g_t = S(\epsilon_1 \Omega_{f1} B_1)(\epsilon_2 \Omega_{f2} B_2). \tag{22.173}$$

The accidental coincidence rate is the detection rate of uncorrelated emissions. From Eq. (22.171), the accidental coincidence rate is

$$g_a = 2\tau S^2 (\epsilon_1 \Omega_{f1} B_1)(\epsilon_2 \Omega_{f2} B_2). \tag{22.174}$$

The ratio of Eq. (22.174) to Eq. (22.173) yields

$$\frac{g_a}{g_t} = 2\tau S, \tag{22.175}$$

which shows that the ratio of accidental to true coincidences increases linearly with source activity and resolving time. Note also that the source activity can be determined by dividing Eq. (22.175) by the value of 2τ.

The number of counts recorded by the detectors depends upon the experimental geometry and the detectors used. A good method to reduce accidental coincidences is to make the resolving time as small as

possible. However, the resolving time cannot be better than the system time resolution, which is affected by jitter and time walk. Consequently, the timing methods and detector types together determine the limitations on the resolving time. The limited resolution is depicted in Fig. 22.38(top), where the coincidence count rate is shown as a function of count rate (a differential time spectrum). Given identical equipment with identical delay times between the detectors and the coincidence analyzer inputs, both pulses should arrive at the coincidence analyzer at identical times. In other words, if one pulse arrives at t_1, then the other pulse should also arrive at t_1, although the arrival times may instead be slightly different because of jitter, time walk, and perhaps other effects. Without this deviation, the coincidence peak would be represented by a single channel; however, in reality it is statistically spread out over several channels.

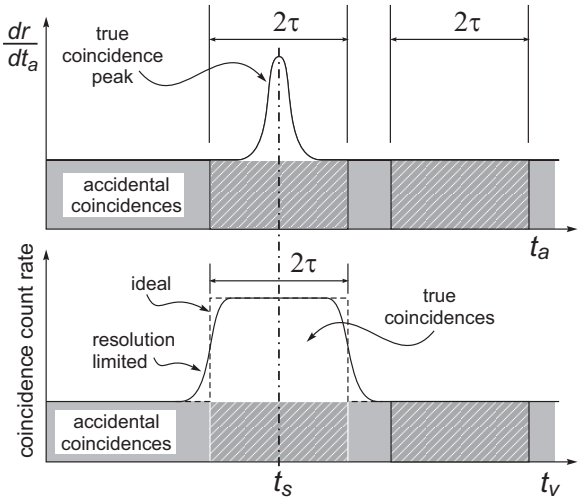

Figure 22.38. (top) The expected differential time spectrum for coincidences, where r is the coincidence count rate, t_s is the set arrival time at one input, and t_a is the variable arrival time at the other input. (bottom) The coincidence count rate observed from a coincidence analyzer with resolving time τ and variable delay input t_v.

Typically, the detectors and electronics for each detector branch are different. Suppose that a resolving time τ is selected that is wider than the actual coincidence peak, as depicted in Fig. 22.38. If the arrival time of one coincidence pulse arrives at time t_s, then a coincidence from the other pulse is logged provided that it arrives within $t_s \pm \tau$. A delay line on each branch of the circuit, depicted in Fig. 22.40, allows the user to set one delay time t_s while also varying the other delay time, denoted by t_v. The operator can then take coincidence measurements at different values of t_v, thereby producing an output response as shown in Fig. 22.38(bottom). If the delay is too small, such that $t_v < t_s - \tau$, or if it is too large, such that $t_v > t_s + \tau$, then any coincidence measured is accidental. If the delayed pulse arrives such that $t_s - \tau < t_v < t_s + \tau$, then real coincidences are tallied along with accidental coincidences. Hence, by setting the variable time delay t_v in the center of the delay curve spectrum, the operator measures the sum of true and accidental coincidences. The true coincidence rate is determined by subtracting the accidental count rate of Eq. (22.169).

The coincidence count rate increases as τ is increased, mainly because the accidental coincidence rate increases. The coincidence analyzer output can be optimized by measuring the delay curve response as a function of both τ and t_v, as depicted in Fig. 22.39 [Nicholson 1974]. If τ is longer than needed, the delay curve has a flat top response, shown as (1) and (2) in Fig. 22.39. If τ is too narrow, true coincidences are rejected and the count rate maximum incorrectly reports the coincidence rate, depicted as (4) in Fig. 22.39. However, at the optimized τ setting, there is no flat top to the delay curve ((3) in Fig. 22.39), and the peak location correctly indicates the sum of the true and accidental coincidence rates. Notably, the delay t_v must equal t_s for the optimized condition. The advantage of narrowing τ to the optimum value is the reduction of background accidental coincidences.

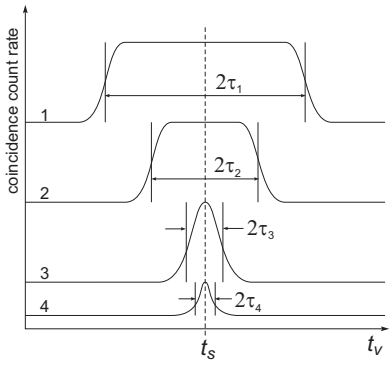

Figure 22.39. Depiction of delay curves for various values of the coincidence resolving time τ, showing the sum of real and accidental coincidences.

Consider the timing analysis system depicted in Fig. 22.40. Two detectors are positioned to measure coincident events from a radiation source. These coincidences may include, for example, positron annihi-

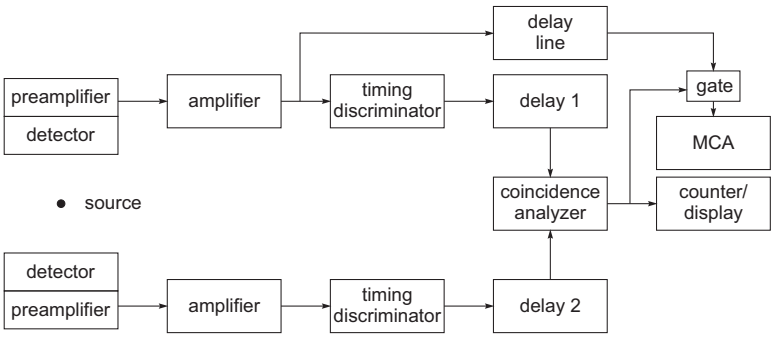

Figure 22.40. A method of using a coincidence analyzer for measuring coincident events.

lation photons, dual gamma-ray emissions such as those from ^{60}Co, and beta particle/gamma-ray coincident events. The selected detectors should detect the radiation emissions of interest with good efficiency and/or energy resolution. They need not be the same type of detector. For instance one detector may be a NaI:Tl detector. while the other is an HPGe detector. The HPGe detector can be used for its excellent energy resolution while the highly efficient scintillator provides the coincidence signal. The signals are passed through preamplifiers and amplifiers compatible with the timing requirements. The time stamps for pulses from either detector are produced by a timing discriminator that uses one of the timing measurement methods previously discussed. The pulse processing chain from the separate detectors may cause coincident events to emerge from the timing discriminators at different times. If so, this problem is remedied by placing a variable delay instrument after the timing discriminator. Although Fig. 22.40 depicts a delay after each timing discriminator, often one delay line or delay amplifier placed on the faster processing chain is adequate to synchronize the pulses as they converge on the coincidence analyzer. If counting coincident events is all that is required, the signals from the coincident analyzer can be routed to a counting system. If the goal is to produce a pulse height spectrum from the high resolution detector only of the coincident events, then the signal from the amplifier can be split and routed to the coincidence analyzer and also into another delay module. If a coincidence is triggered, the logic pulse opens a gate that allows the high-resolution detector pulse to be logged by a multichannel analyzer. The delay on the high resolution pulse is set to arrive within the time that gate is open.

22.5.2 Time-to-Amplitude Converter

The time-to-amplitude converter (TAC) is a measurement module that converts the difference in arrival times between events into a histogram, much like a pulse height spectrum. However, the abscissa is in units of time rather than energy. The timing resolution is defined as the full width at half maximum (FWHM) of the pulse height spectrum. The device operates by accepting a start signal and a small time later accepting a stop signal. Unlike the coincidence analyzer, the order that pulses arrive at the input does matter. A delay is at times employed to ensure that the stop signal arrives at some time Δt behind the start signal. These signals can be provided by separate detectors whose pulses have passed through a timing discriminator, perhaps timed with one of the methods previously described.

The circuit is arranged with a constant current source supply that is routed through start and stop switches. These switches are initially in the closed position, which normally routes the current to ground. The start switch is also in parallel with a converter capacitor that is tied to an amplifier input. When the leading edge of the start signal arrives, the start switch is opened which then allows the constant current source to charge the converter capacitor. When the leading edge of the stop signal arrives, the stop switch

is opened to disconnect the constant current source from the circuit. The charging current produces the voltage

$$V = \frac{i\Delta t}{C}, \tag{22.176}$$

where i is the constant current, Δt is the time spacing between the start switch opening and the stop switch opening, and C is the converter capacitance. Hence, the stored voltage is a linear measurement of Δt. Shortly after the stop switch opens, the voltage in the form of a square wave is passed through a linear gate to an amplifier and to the TAC output. The amplitude of the output is indicative of time Δt, which can be supplied to a tallying unit such as a multichannel analyzer. Shortly thereafter, the switches are closed and the converter capacitor is discharged to ground, thereby resetting the circuit for the next timing measurement.

The use of a TAC can greatly simplify a coincidence measurement system. The TAC timing method eliminates the need to produce a delay curve, and there is no need to set a resolving time. The logic signal amplitudes produce a pulse height spectrum in which the pulse height is a function of Δt. Hence, the spectrum directly yields the time resolution of the system. The channels have units of time so the channel resolution (time per channel) can be changed by varying the conversion gain of the MCA. A TAC coincidence spectrum is depicted in Fig. 22.41. The time resolution is measured by the FWHM of the true coincidence peak. Shown is a window about the coincidence spectrum where the total counts in the window are the sum of true and accidental coincidences. The net true counts can be determined by setting a window of equal width (channels) away from the peak, and subtracting the counts in the second window from the counts in the first window.

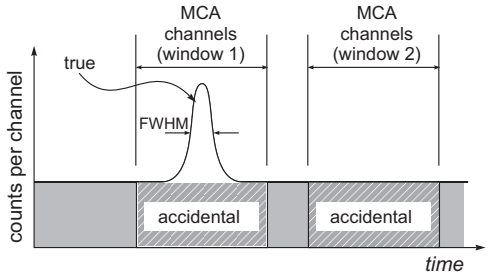

Figure 22.41. Depiction of an MCA spectrum provided by a TAC coincidence system.

One possible arrangement using a TAC is depicted in Fig. 22.42. The system is fundamentally similar to the system of Fig. 22.40, but a single delay line is used to ensure that the stop signal arrives after the start signal. The output of the TAC is a function of the time difference, thereby delivering a differential time spectrum to the MCA. Because the logic pulse amplitudes from the TAC are a function of the Δt, the difference between the start and stop times, the MCA produces a histogram of pulse height frequency as a function of Δt.

Without noise or jitter, the TAC output would deliver a Δt output that is exactly the same for each true coincident event. Hence, the differential time spectrum would fall into a single channel. Yet, this ideal behavior does not occur. Because of timing variations due to jitter and time walk, there is an inherent

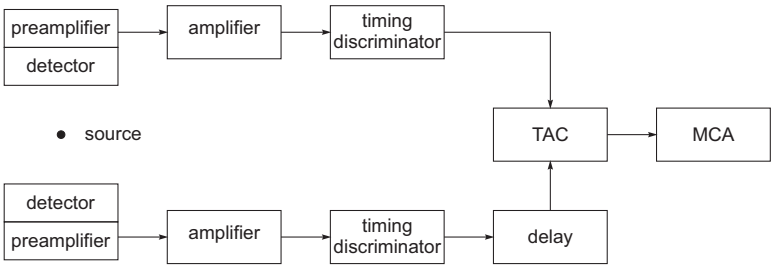

Figure 22.42. A method of using a TAC for measuring coincident events.

limitation to the time resolution. This resolution can be measured by connecting the TAC inputs to a single detector or to a pulse generator. If the signal is split and routed through the two system branches and into the TAC, it is expected that the output would have constant amplitude at some time T. The distribution of pulses about this value of T renders a spectrum that includes the variance in Δt about T. The FWHM of this differential time spectrum is commonly called the *timing resolution*. It is worth noting that the delay shown in Fig. 22.42 is important. Without the delay, the true coincidence spectrum would be centered about T equal to zero. pulses occurring at $T - \Delta t$ would yield a negative output and thus not be counted.

22.6 Instrumentation Standards

Early nuclear instruments used vacuum tube circuits within a standardized 19-inch wide chassis. The components each had their own DC power supply connected directly to AC power. These components, which were easily installed in a standard 19-inch wide instrument rack, could be easily interchanged because each unit operated independently.

The invention of the transistor in 1948 led to more compact electronics, which generated far less heat than vacuum-tube components. Yet, these early transistorized nuclear instruments were built in a similar fashion to their vacuum-tube counterparts and were still designed for large 19-inch wide racks. It was eventually realized, however, that these transistorized electronic components could be built as smaller and more efficient modular units, thereby eliminating the need for a single 19-inch wide chassis. Many independent laboratories and commercial companies began to design and construct systems of various modular electronic components.

Two such systems, advanced at the time, were the systems developed by the European Organization for Nuclear Research (CERN) and the United Kingdom Atomic Energy Research Establishment. The European Standards community on Nuclear Electronics (ESONE), founded in 1961, also began development of a new standardized modular system. Along with these systems, numerous commercial companies began working on various systems of modular nuclear electronics. Further, the independent U.S. national laboratories began developing modular nuclear electronics systems for their own purposes. As a result, numerous different nuclear electronics systems were under development, none of which was compatible with any of the other systems. Overall, research at nuclear laboratories was seriously limited by the compatibility of instruments, and researchers were forced to invest in numerous different modular nuclear components.

22.6.1 NIM Standard

To remedy this divergent development of nuclear modules, the U.S. National Bureau of Standards (NBS),[20] in a 1963 report to the U.S. Atomic Energy Commission (AEC), recommended that the U.S. national laboratories develop a modular system to be duplicated by commercial manufacturers. The U.S. AEC convened a meeting of representatives from several national laboratories on Feb. 26, 1964 to determine if such standardization was of interest to the laboratories. In agreement, the AEC Committee on Nuclear Instrument Modules (NIM) was established and composed of members from all AEC national laboratories and a few other prominent nuclear laboratories.

The first NIM Committee meeting was held on March 17, 1964, with follow-up meetings over several ensuing months. The committee studied the advantages and shortcomings of the existing modular systems, and a system similar to the CERN design was eventually developed. The prototype bins were manufactured by Oak Ridge National Laboratory (ORNL), Lawrence Radiation Laboratory in Berkeley, and Lawrence Radiation Laboratory in Livermore.[21] These early prototypes were studied at later meetings of the NIM Committee and eventually led to a recommended design. Final details were resolved by the NIM Executive

[20] The National Bureau of Standards is now the National Institute of Standards and Technology (NIST).

[21] The Lawrence Radiation Laboratory in Berkeley is now the Lawrence-Berkeley National Laboratory and the Lawrence Radiation Laboratory in Livermore is now the Lawrence-Livermore National Laboratory.

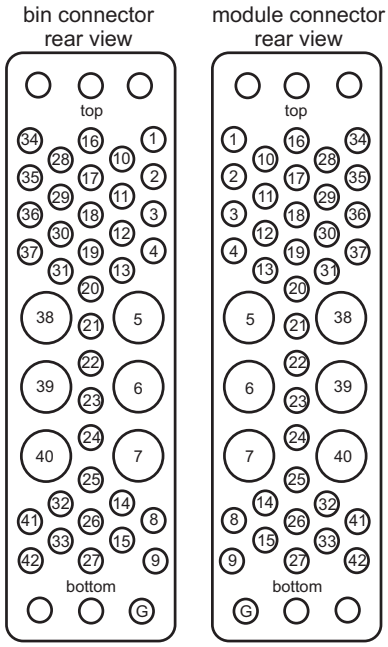

Figure 22.43. Pinout designations for the connectors of nuclear instrument modules and bins. From DOE/ER-0457T.

Committee with representatives from the U.S. NBS, ORNL, Lawrence Radiation Laboratory in Berkeley, and with later added members from Princeton-Pennsylvania Accelerator and Brookhaven National Laboratory (BNL). The final specifications were published in July 1964, and later updated versions of the specifications were published in 1966, 1968, 1969, and 1974. The standard was well received, with the first commercial NIM components made available by November 1964 (see AEC report TID-20893 [1964]). During 1965, numerous other NIM instruments became available, and NIM components accounted for over 95% of all modular nuclear instruments produced in the U.S. in the immediate years following 1967. The NIM standard was again revised in 1990, to make the standard compatible with existent technology and manufacturing processes, as described in Department of Energy (DOE) document DOE/ER-0457T, where detailed information on power, signal, connector, and size dimensions are provided in detail. A few of these specifications are outlined below. Additional information is provided in ORTEC Technical Note 010308 [2008].

Dimensions

A Nuclear Instrument Module (NIM) conforms to a nominal 8.75 inches (22.23 cm) panel height and a basic width such that a standard size NIM Bin accommodates 12 single-width NIMs or any combination of single- and multiple-width NIMs with a total of 12 or less unit widths. A unit width for a single Module is 1.32 inches (3.35 cm).[22] The Module design permits vertical air flow past the components in a NIM Bin which is required to provide an open area (reasonably distributed) of not less than 10% of the total horizontal projection of the Module. Ventilation holes less than 7/64 inch (2.8 mm) diameter are not considered to abide by the recommended 10% condition and do not apply. The connector pin assignments are designated as shown in Fig. 22.43 and listed in Table 22.2.

[22] A limited number of Modules with nominal 5.25-inch panel height have been constructed, along with accompanying NIM Bins with similar reduced dimensions. They are not very popular.

NIM Bins mount in standard EIA or EC 19-inch racks and are designed to accommodate the size and pinout of NIMs. Each standard Bin includes 12 sets of guides and 12 Bin Connectors so as to accommodate up to 12 single-width Modules or any combination of single-width and/or multiple-width Modules with a total of 12 or less unit widths.[23] NIM Bins provide power to the Modules through bussed Bin Connectors that mate with the Module Connectors. Ample air flow through Bins and power supplies is essential to provide adequate cooling for both single Bin and stacked Bin systems. This may necessitate the use of fans, spacers, deflectors, or similar devices. Power at the standard voltages of ±6.00, ±12.00, and ±24.00 DC as well as 117 volts AC is provided at the Bin busses, as shown in Fig. 22.43 and Table 22.2. The ±6 volt option is not available on some NIM bins.

Table 22.2. Pinout designations for NIM components. From DOE/ER-0457T.

Pin	Function	Pin	Function	Pin	Function
1	reserved	15	reserved	29	−24 volts
2	reserved	16	+12 volts	30	spare
3	spare	17	−12 volts	31	spare
4	reserved	18	spare	32	spare
5		19	reserved	33	117 V AC (hot)
6		20	spare	34	power return ground
7		21	spare	35	reset
8	+200 V DC	22	reserved	36	gate
9	spare	23	reserved	37	spare
10	+6 volts	24	reserved	38	
11	−6 volts	25	reserved	39	
12	reserved	26	spare	40	
13	spare	27	spare	41	117 V AC (neutral)
14	spare	28	+24 volts	42	high quality ground
				G	ground guide pin

Coaxial Connectors

Signal connectors shall be either of two standards. One standard is 50 Ω BNC type in accordance with the American National Standards Institute (ANSI) Standard N544, "Signal Connectors for Nuclear Instruments." This standard is also defined in the International Electrotechnical Commission (IEC) Publication 313, "Coaxial Cable Connectors used in Nuclear Instrumentation." The other allowed standard is type 50CM in accordance with Section 4.2.5 of ANSI/IEEE Std 583-1982, "Modular Instrumentation and Digital Interface System (CAMAC)." Connectors for high-voltage applications up to 5 kV shall be the SHV type in accordance with ANSI Standard N42.4, "High Voltage Connectors for Nuclear Instruments," also defined as Type B Connector in IEC Publication 498, "High-Voltage Coaxial Connectors used in Nuclear Instrumentation." Signal and high-voltage connectors may be mounted on the front and rear of the Nuclear Instrument Modules, with stipulation that they shall not be mounted on the bottom 3.00 inches (7.62 cm) of the rear of the Modules.

Logic and Analog Signals

The NIM standard states that the reset and slow gate signals, including those on pins 35 and 36 (see Fig. 22.43 and Table 22.2), shall conform to the levels specified by Table 22.3. In addition, the rise and fall

[23] There are also mini NIM Bins that are designed to hold 4 single-width bins and that, at times, can be quite useful. Also the Bin frame around the NIM connectors is inconveniently oversized and blocks the AC power cords and heat sinks on some HV power supplies.

Table 22.3. NIM standard logic levels for transmission of digital data.

	Nominal Signal Level	Output (shall deliver)	Input (shall respond to)
Logic 1	+4 V	+4.0 V Min	+3.0 V Min
Logic 0	0 V	+1.0 V Max	+1.5 V Max

Table 22.4. NIM standard fast logic levels and characteristics (preferred practice).

	Ouput Driver Current mA into 50 Ω	Receiver Input Voltage Response
Logic 1	−14 to −18	−0.6 max to −1.8 min (or −12 mA to −36 mA)
Logic 0	−1.0 to +1.0	−0.2 min to +1.0 max (or −4 mA to +20 mA)

times of signals on all busses shall be limited so as not to produce excessive cross-talk. Fast signals that can cause cross-talk problems shall not be applied to these busses but may be routed to or from the Modules by external cables.

In Table 22.3, the term "shall deliver" means shall deliver to any load impedance of 1 kΩ or greater. The term "shall respond to" means shall respond fully within specifications. To avoid damage to the circuitry, the NIM standard states that no positive signal (logic level) voltage shall exceed 12 volts and no negative signal voltage shall exceed 2 volts.

According to the NIM-standard, a fast negative logic signal is normally used when rise time or repetition rate requirements exceed the capability of the positive logic pulse standard. The NIM provisions define this signal as one that is furnished into a 50 Ω impedance with the characteristics described in Table 22.4. In Table 22.4, the receiver response to input voltages more positive than +1.0 V or more negative than −1.8 V is not specified. Further, the "Response" means shall respond fully within specifications to any voltage within this range. Circuit designers are alerted to the overdrive required in many receiver circuits to assure "full specification performance," and the need, therefore, to set the receiver trigger threshold accordingly.

For microsecond analog signals, the preferred open-circuit output range is 0 to +10 volts. For fast (submicrosecond) signals, the preferred amplitude ranges are 0 to −1 volt and 0 to −5 volts into a 50 Ω load.

22.6.2 CAMAC Standard

For complex detection systems, such as those encountered at large research facilities and high-energy accelerator centers, there is another international standard for modularized electronics, namely, Computer Automated Measurement And Control, or CAMAC, which defines a standard bus for data acquisition and control [Leo 1994]. The interface system, upon which this standard is based, was developed by the ESONE Committee of European Laboratories with the collaboration of the NIM Committee of the US Department of Energy (DOE) [ESONE 1964; CAMAC 1972]. This standard is based on ERDA Reports TID-25875, July 1972 (corresponding to ESONE Report EUR 4100e) and TID-25877. The standard defines the mechanical construction and electrical dataway for the modules. The CAMAC also includes the IEEE standards of 583 (the basic CAMAC design), 595 (serial highway system), 596 (parallel branch highway system), 675 (auxiliary crate controller), 683 (block transfer specifications), 726 (real-time BASIC computer language subroutines) and 758 (FORTRAN computer language subroutines for CAMAC).

The container for instrumentation modules is referred to as a 'crate' or 'CAMAC crate.' The CAMAC bus allows data exchange between plug-in modules (up to 24 in a single crate) and a crate controller, which

then interfaces to a PC or to a VME-CAMAC interface. The original standard was capable of one 24-bit data transfer every μs. Later a revision to the standard was released to support shorter cycles which allow a datum transfer every 450 ns. A follow-on upwardly compatible standard, Fast CAMAC, allows the crate cycle time to be tuned to the capabilities of the modules in each slot. Typically, CAMAC components are significantly more costly than NIM components, and are best used when computer automation is necessary.

Table 22.5. Pinout designations for normal CAMAC modules, from top to bottom viewed from the front of the crate. Here BL stands for "bus-line" and PBL for "power bus-line". From IEEE [1982a].

Description / Function	Pin	Pin	Description / Function

*previously reserved for +200 DC volts.

Dimensions

The basic single-width CAMAC module conforms to a nominal 8.72 inches (22.15 cm) panel height with depth of 12 inches (30.5 cm) [Leo 1994]. The width of a single-width CAMAC module is half that of a NIM, or 0.67 inches (1.70 cm). CAMAC modules may have widths corresponding to integer multiples of the single-width standard. A CAMAC crate is typically 19 inches (48.3 cm) wide with 25 module slots, usually referred to as stations. Of those stations, 24 are considered 'normal stations' while the 25th is a 'control station'.

A CAMAC module plugs into the CAMAC crate by way of an 86-pin PC card connector, with the pins arranged in parallel as 43 pins on each side. It is noted that these connectors are not as robust as the NIM pin connectors, and a greater amount of caution is recommended when inserting and removing CAMAC modules from the crate [Leo 1994]. The connector pin assignments are arranged in a double row and are designated as listed in Table 22.5.

Electrical and Communications

The CAMAC crate is connected to a host computer, and the computer communicates with CAMAC modules through a crate control module. The CAMAC crate must have this control module in order to operate and is inserted into slot 25 (furthest to the right). Usually the CAMAC control module is double-wide so the practical number of available CAMAC module slots is reduced to only 23. The CAMAC crate controller module acts as the crate communication center and manages all information signals on the crate dataway. Commands originating at the computer or at a module in the crate must pass through the crate controller.[24] Ultimately, the crate controller is the *master* and the CAMAC modules are *slaves*. If necessary, multiple crates can be connected to the computer through a branch highway, but each crate must still have a crate controller. Multiple CAMAC crates may be connected in series or parallel configurations. Further, if connected in parallel, the data is managed with a branch driver to control the information flow between the CAMAC crates and the computer.

Table 22.6. CAMAC dataway signal levels.

	Logic 0	Logic 1
Input must accept	+2.0 to 5.5 V	0 to +0.8 V
Output must generate	+3.5 to 5.5 V	0 to +0.5 V

Signal transmission along the dataway is performed with TTL logic with the signals requirements listed in Table 22.6. Notice that, opposite NIM signals, the lower voltages produce a 1 and the higher voltages produce a 0. Communications between the modules are conducted over the dataway through the controller. The dataway is a network of parallel wires that connect the pins at the slots and facilitate communication between the modules and controller. Power lines are designated for the bottom 14 pins, which include ±6 VDC, ±12 VDC, ±24 VDC, as well as 117 VAC and, in some systems, 200 VDC lines. Bussed signals constitute most of pins and are used to transfer data, commands, addresses, and other control signals. Two module pins are reserved for point to point lines that connect the modules to the crate controller, mainly the N (address) and L (look-at-me or LAM) lines. Each bus line has a specific function, as outlined by IEEE [1982a], at locations indicated in Table 22.5. Although most signal transfers are conducted over the dataway, there are some operations that may still require external input. For these external inputs, the IEEE standard [1982a] recommends type 50CM subminiature coaxial connectors. A brief explanation of the listed connector functions is given in Table 22.7.

Three common control signals are available at all stations, namely, one to Initialize (Z) all units (typically after switch-on) in the dataway, one to Clear (C) data registers, and one to Inhibit (I) features such as data recording. The Z signal has priority over all other signals and is always accompanied by signals from I, S2, and B. The same conditions hold for the C signals that are used to clear registers and bistables. The module designer is allowed to determine which registers and bistables are cleared with the C signal, but the signal must also initiate a sequence that includes the S2 and B signals. The I signal inhibits the feature to which it is connected in a module.

[24] There are stand-alone units where the computer microprocessor is incorporated in the crate controller.

Table 22.7. A brief description of the functions for the connector pins of the CAMAC module listed in Table 22.5.

Pin	Description
Ai	($i = 1, 2, 4, 8$): Subaddress, selects a specific section of the module.
B	Busy, indicates that a dataway operation is in progress.
C	Clear, clears registers, accompanied by S2 and B.
E	Clean earth, reference for circuits requiring a clean earth.
Fi	($i = 1, 2, 4, 8, 16$): Function, defines the command function code to be executed by the module.
I	Inhibit, disables features for the duration of the signal.
L	Look-at-me (LAM), indicates request for service. Dedicated point-to-point line from a module to the crate controller.
N	Station number, dedicated point-to-point line that selects a module in the crate for communication.
Pi	($i = 1, 2$): Free bus lines, for unspecified uses.
Pi	($i = 3, 4, 5$): Patch contacts, for unspecified interconnections, no dataway lines.
Q	Response, Indicates status of feature selected by command.
Ri	$i = 1, ..., 24$: Read, i.e., take information from the module.
S1	Strobe 1, controls the first phase of a dataway operation. Dataway signals must not change.
S2	Strobe 2, controls the second phase of a dataway operation. Dataway signals may change.
Wi	$i = 1, ...24$: Write, i.e., bring information to the module.
X	Command accepted, indicates that module is able to perform action required by the command.
Y1	Supplementary, provides supplementary -6 volts.
Y2	Supplementary, provides supplementary $+6$ volts.
Z	Initialize, sets module to a defined initial state, accompanied by S2 and B.

Status signals come from locations B, L, Q, and X. The busy signal (B) indicates that a dataway operation is in progress. The Busy (B) signal is used to interlock various aspects of a system that can compete for the use of the dataway. The signal B = 1 indicates to all units that an operation is in progress. The Look-at-Me (L) signal is a request from a module indicating the need for attention. The Response (Q) signal is a no/yes answer to command operations, where an output of 0 indicates "no" and an output of 1 indicates "yes". Whenever a module is addressed during a command operation, it generates a signal of 1 on the Command Accepted (X) output if it recognizes the command as valid for the instrument, either within the module or in association with external equipment. If the output from X is 0, this indicates a serious malfunction. Examples for a 0 output may include a missing module, no power, bad connections, or improper equipment for the function. The controller may indicate the need for intervention by the operator if a 0 is generated.

Data operations are conducted on the Read (R) and Write (W) lines. Up to 24 bits may be transferred in parallel between the controller and the selected module. Independent lines are provided for the read and write directions of transfer. Read and write lines are activated by command operations.

The state of the signals on the Station Number (N) lines, the Subaddress lines (A), and the Function (F) lines constitute various commands. These command signals are maintained for the full duration of a dataway operation. They are accompanied by a signal on the busy (B) line to indicate that an operation is underway. The Station Number (N) is used to select a module in the crate. The stations are labeled from the front of the CAMAC crate starting with N1 from the left-hand side. The signals for N originate from the

controller module. Different sections of a module are addressed by four subaddresses (A1, A2, A4, A8) that specify a subsection of the module. With four locations, there are 16 possible binary codes that are identified as A(0) to A(15). The subaddress codes are defined as A(i) to distinguish them from the subaddresses Ai. Function signals define the function code to be performed at the five F subaddresses (F1, F2, F4, F8, F16) of a module. With five locations, there are 32 possible binary codes, identified and numbered from F(0) to F(31). Note that the type of code F(i) should not be confused with subaddress Fi. The details of each specific F function are provided in the IEEE Std 583-1982.

During each command operation, the controller generates two Strobe signals S1 and S2 in sequence on separate bus lines. In response to these timing signals, the modules initiate various actions appropriate to the dataway command. Only Strobe S2 is mandatory during unaddressed operations, but S1 may also be generated. The timing signals S1 and S2 are used to synchronize events during an operation.

Example 22.6: For the input subaddresses A, what code is selected for A1 = 1, A2 = 0, A4 = 1, and A8 = 0? Also, determine the code for the Function input where F1 = 1, F2 = 0, F4 = 1, F8 = 0, and F16 = 1.

Solution:

From the binary code, the A input is 0101,

$$0101 = 1(1) + 0(2) + 1(4) + 0(8) = 5$$

which is equivalent to 5 in base ten numbers; hence the identifying code is A(5).

From the binary code, the F input is 10101,

$$10101 = 1(1) + 0(2) + 1(4) + 0(8) + 1(16) = 21$$

which is equivalent to 21 in base ten numbers; hence the identifying code is F(21).

22.6.3 VMEbus Standard

The Versa Module Europa bus (VMEbus) is a computer bus standard described in IEEE 1014-1987. The system was originally created in 1971 by Kister and Black for the Motorola MC68000 CPU, receiving upgrades from a larger engineering team in the following few years [Wiener, undated]. It was released in 1981 with standard described in the IEC 821 document and now by ANSI/IEEE 1014-1987. Upgrade standards to 64-bit data paths can be found in ANSI/VITA 1-1994 (or VME64), and also the superset to the VME64 standard called the VME64 Extensions (or VME64x). In both upgrades, the data handling capabilities were greatly improved and many other features were enhanced. Overall, the VMEbus is a scalable and flexible computer backplane bus interface intended to support computer intensive operations [Wiener, undated].

The bus includes four sub-buses on the backplane, identified as the arbitration bus, the data transfer bus, the priority interrupt bus, and the utility bus [IEEE 1987]. The arbitration bus allows an arbiter module and several requester modules to coordinate use of the data transfer bus. The data transfer bus allows master modules to direct the transfer of binary data between themselves and slaves. The data transfer bus supports 8-, 16-, and 32-bit transfers over a non-multiplexed 32-bit data and address highway. The priority interrupt bus allows interrupter modules to send interrupt requests to the various interrupt handlers. The utility bus includes signals that provide periodic timing and coordinates the power-up and power-down of VMEbus systems.

The mechanical specifications of boards, backplanes, subracks, and enclosures are based on the Eurocard form factor, although it has a different signaling system. Each VME card is 20.3 mm wide and 21 of these cards can fit into a 19-inch rack mounted VME crate. The connection between the module and the backplane is made by two 96-pin DIN 41612 connectors. The number of connectors used determines the address space of the card and the card size. Uncommitted pins on the connectors provide support for application specific busses and rear transition modules. 9-U modules[25] may provide a third connector for application specific use.

There are three sizes of VME cards, namely the 3U $\times$ 160 mm cards, 6U $\times$ 160 mm cards (the most common), and the larger 9U $\times$ 400 mm cards. The smaller 3U $\times$ 16.0 cm cards have only one backplane connector, labeled J1, with a 24-bit/16-bit address space. Both the 6U $\times$ 16.0 cm cards and 9U $\times$ 40.0 cm cards have two backplane connectors, labeled J1 and J2, with a 32-bit address/data space. The VME cards are inserted into the slots of a VME crate, which serves as the power supply for the backplane. The actual circuit board should not be greater than 1.8 mm thick in order to slide into the slot. Standard VME voltages are 5 V and $\pm$12 V. The crate is outfitted with a cooling fan or a fan tray.

The VME bus has 31 address lines. The first 23 lines are present on J1 and the remainder being on J2. The lowest address bit (A0) is implied by the transfer cycle and is not present on the backplane. The VME bus has 32 data lines. The low order 16 data lines are on J1, the high order 16 on J2. Hence, the smaller VME modules with only J1 can only perform 16-bit transfers, while larger modules can perform 32-bit transfers. The communications are handled with TTL logic, with the highs between 2.4 to 5 V and lows between 0 to 0.6 V.

Data handling was increased by the newer VME64 and VME64x standards, allowing 32-bit data and 40-bit addressing in the 3U modules, and 64-bit data and addressing on the 6U modules. VME64 can multiplex address and data lines allowing 31 address bits on J1 and an additional 32 address bits on J2. VME64 also has an additional 3.3 volt supply. The bandwidth was increased by the newer standards. The VME64x also describes different connector pins than the VMEbus. Regardless, the older VME modules are compatible with the newer standards, meaning that older modules can be inserted into the newer system. Further, modules designed to the VME64x standard are backward compatible with older backplanes and subracks.

Similar to the CAMAC system, the VMEbus has a controller module, called a crate manager, but it is placed in the left-most crate slot. The VMEbus system also has various modules that perform specific functions, much like the NIM and CAMAC systems.

There are commercial modules available that can perform the familiar standard functions of NIM or CAMAC modules. Modules perform as master, slave, interrupter, interrupter handler, or arbiter. The master can initiate transfers, while the slave module(s) responds to these commands. The bus allows multiple masters and, to enable proper operation, it contains a powerful interrupt scheme which is managed by a crate manager. This managing arbiter is located in slot 1 of the crate. The slave can send an interrupt signal to request an action, for example a signal that data has arrived or an error notification. The interrupt handler is a module that can receive and process interrupt signals, usually a slave module. Data transfer on the VME Bus is asynchronous, thereby enabling modules with a broad variety of response times to be supported.

Module functions are controlled by a computer rather than turn knobs, although some modules may allow direct input lines. Any of the modules can act as a master module or slave module. Master actions send communications through the bus to the crate manager module, which arbitrates the signals and allows access to the bus one module at a time. Once a module assumes the identity as master, it drives the bus

[25] The notation 'U' is defined as a *rack unit*, with a single U being 1.75 inches (4.45 cm) high. Cards that are fit into a slot should be 1.313 inches (3.335 cm) shorter than the slot height. Hence, a 3U card is 10.0 cm high, a 6U card is 23.34 cm high, and a 9U card is 36.67 cm high.

lines to identify a slave module and data transfer to take place. The slave then responds over the data bus lines. After the data transfer, the master relinquishes the bus. Note that slave units, through an interrupt communication over one of the seven interrupt bus lines, can also signal a master module.

Overall, the VMEbus is able to provide high speed of operation combined with a flexible modular system. It is also possible to develop specially designed hardware to operate with the VMEbus for specific functions and requirements.

22.7 Electronic Noise

A biased radiation detector connected to output electronics, such as a preamplifier, randomly produces output signals even though there are no radiation interactions occurring in the device. This noise is generated at the output even when there is no input signal at all. There are numerous sources for these random signals that produce an output voltage [Ambrózy 1982], the important ones of which are described in this section. It is important to understand this electronic noise as it tends to increase the minimum discrimination level as well as increase the variance in the output signal.

Typically the average noise signal is centered about zero. For instance, the average output noise voltage sampled over a long time period is

$$\langle v_{out} \rangle = \lim_{T \to \infty} \frac{1}{T} \int_0^T v_{out}(t) dt = 0. \tag{22.177}$$

This means that the average magnitude of positive pulses equals the average magnitude of negative pulses. The average of the noise provides little information about the noise spectrum because the outcome is (nearly) always zero, regardless of the circuit. To obtain a more meaningful description of the noise, it is the average square of the noise voltage that is usually reported, i.e.,

$$\langle v_{out}^2 \rangle = \lim_{T \to \infty} \frac{1}{T} \int_0^T v_{out}^2(t) dt, \tag{22.178}$$

or, equivalently, the *root mean square* or *rms* of the noise deviation

$$\sigma_n = \langle v_{rms} \rangle = \sqrt{\langle v_{out}^2 \rangle}. \tag{22.179}$$

Electronic noise is superimposed upon radiation induced signals, thereby adding to the total signal variance. It is common to represent the noise signal in terms of the average charge from the detector to produce the same signal, or the current needed at the input of the amplifier to produce an output equivalent to the rms noise voltage. This is called the *input referred noise* and is very valuable in comparing different processing methods as it removes gain and bandwidth effects. The equivalent noise charge q_n can be described in units of coulombs, but it is more commonly normalized by the unit charge q_e and described by the number of equivalent electrons. The equivalent noise charge q_n can then be directly compared to the average number of charges produced by a radiation event. The signal-to-noise ratio is defined as the ratio of the mean signal pulse height v_m to that of the RMS noise voltage

$$\text{SNR} = \frac{v_m}{\langle v_{rms} \rangle}. \tag{22.180}$$

For a given radiation quantum of energy E, the SNR is

$$\text{SNR} = \frac{E}{w q_n} = \frac{Q}{q_n}, \tag{22.181}$$

where w is the average energy required to produce a charge pair. One important goal of the measurement electronics is to reduce the rms electronic noise to values well below the standard deviation of radiation induced signals.

Electronic noise affects the performance of both counters and spectrometers. For counters, q_n greatly affects where the LLD must be set to discriminate between radiation counts and electronic noise. If the LLD is set too low, then noise pulses are included with actual radiation induced pulses, ultimately leading to an enhanced count rate and, often enough, serious system dead time. If the pulses produced in a counter are large, the LLD can be set above the noise and the count rate remains unaffected. However, if the detector pulses are of similar magnitude as the rms noise, then setting the discriminator to remove noise also removes valid radiation counts. If the LLD is set too low, noise is included along with counts and, thus, falsely increases the count rate while also increasing the detector system dead time. The same problem holds true for spectrometers, along with the added inconvenience of spectral broadening manifested as poorer energy resolution.

As an example, consider a planar semiconductor with contacts at the ends. The average density of free charges is a function of temperature. If a bias is applied to the semiconductor, then some current flows

$$i = \frac{q_e N v_c}{d}, \tag{22.182}$$

where q_e is the unit charge, N is the number of charges in motion, v_c is the charge speed, and W_d is the width of the detector between the contacts. The average differential change in current due to fluctuations in the number of charge carriers produced is

$$di_N = \frac{q_e v_c}{W_d}\langle dN\rangle, \tag{22.183}$$

and due to fluctuations in the charge carrier speed is

$$di_v = \frac{q_e N}{W_d}\langle dv_c\rangle. \tag{22.184}$$

The total current fluctuation, or variance, is thus

$$\sigma_n^2 = \langle di\rangle^2 = \left[\left(\frac{q_e v_v}{W_d}\langle dN\rangle\right)^2 + \left(\frac{q_e N}{W_d}\langle dv_c\rangle\right)^2\right]. \tag{22.185}$$

Speed fluctuations arise from the thermal motion of charge carriers. Number fluctuations can result from various sources, including the statistical spread in the average number of charge pairs in motion, thermionic emission past contact barriers, and recombination and generation current.

The variance in the noise signal σ_n^2 must be added to the detector signal variance σ_d^2 to yield the observed standard deviation. For a Gaussian pulse height spectrum, the standard deviation of a full energy peak can be estimated as

$$\sigma = \sqrt{\sigma_d^2 + \sigma_n^2}, \tag{22.186}$$

as depicted in Fig. 22.44.

Note that detectors with severe trapping do not produce Gaussian distributions, but instead can be severely skewed, usually towards the low energy portion of the spectrum. Consequently, the simplicity of Eq. (22.186) yields inaccurate results.

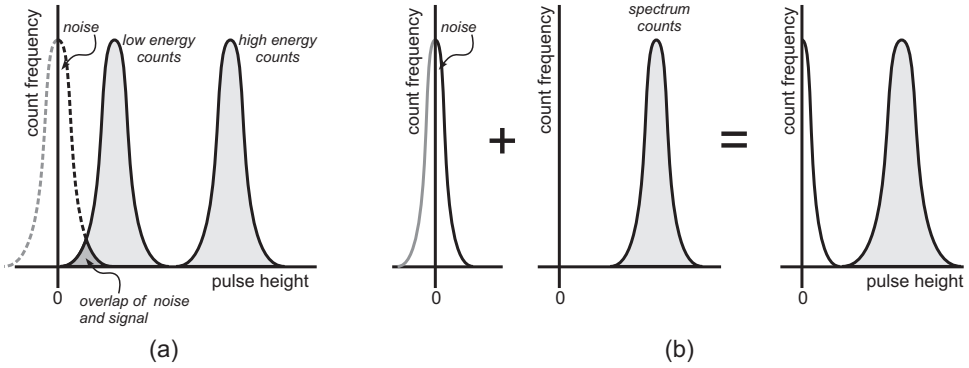

Figure 22.44. The effects of electronic noise: (a) noise floor affects where the LLD must be set to eliminate false counts, and (b) noise fluctuations broaden the energy resolution.

22.7.1 Thermal or Johnson Noise

Thermal or Johnson noise is generated by the thermal motion of charge carriers in a conductive medium, usually electrons in electrical circuits. Thermal agitation causes local fluctuations in the current and also fluctuations in voltage at the conductor contacts. These fluctuations are present even when the component is not connected in a circuit and without applied voltage. If measured over an infinite time period, both the current and voltage must average to zero.

The so-called *spectral power density* (actually power per unit frequency) of the thermal noise is an oft quoted value used to describe noise [Gillespie 1953]

$$\frac{dP}{df} = 4kT, \tag{22.187}$$

where f is the frequency. However, it is usually voltage or current that is being measured; hence, it is convenient to quote noise in terms of voltage or current. From

$$P = iv = \frac{v^2}{R} = i^2 R, \tag{22.188}$$

the noise spectral density in terms of voltage and current, expressed as noise per unit bandwidth, are

$$\frac{d\langle v_j^2\rangle}{df} = 4kTR \qquad \text{and} \qquad \frac{d\langle i_j^2\rangle}{df} = \frac{4kT}{R}. \tag{22.189}$$

Of note, for a constant value of R in Eqs. (22.189), the spectral power density is independent of the frequency. To determine the total voltage or current noise contribution, Eqs. (22.189) must be multiplied by the noise bandwidth[26] Δf to give

$$v_j = \sqrt{4kTR(\Delta f)} \qquad \text{and} \qquad i_j = \sqrt{\frac{4kT(\Delta f)}{R}}. \tag{22.190}$$

[26] A common approximation for the noise bandwidth is $\pi/2$ times the system 3 db frequency.

22.7.2 Shot Noise

Pure shot noise is a consequence of fluctuations in the number of charge carriers comprising a current. In other words, there is a variance in the number of charges flowing in a circuit at any time, which affects the current in metals, semiconductors, gases, and through contacts and barriers. There are multiple sources of this form of noise, including thermionic emission, generation-recombination current, and charge carrier trapping. The spectral noise density is [Gillespie 1953]

$$\frac{d\langle i_s^2\rangle}{df} = 2q\langle i_{dc}\rangle, \tag{22.191}$$

where $\langle i_{dc}\rangle$ is the average current. As with Johnson noise, the spectral noise density of Shot noise is also independent of frequency. For these reasons, both Johnson and Shot noise are often called *white noise*,[27] because the power spectral density is nearly constant over a wide frequency spectrum. The total noise contribution is determined by multiplying Eq. (22.191) by the noise bandwidth

$$i_s = \sqrt{2q\langle i_{dc}\rangle(\Delta f)}. \tag{22.192}$$

22.7.3 Flicker or 1/f Noise

Flicker noise is believed to be a consequence of surface effects and structural defect changes on electrodes. It is most important at low frequencies. Although flicker noise is not completely understood, the properties are well documented [Gillespie 1953; Nicholson 1974], and as described by [Kowalski 1970]

$$\frac{d\langle v_F^2\rangle}{df} = \frac{A_F}{f^m}, \tag{22.193}$$

where the parameter m ranges between 0.8 to 1.5 and A_F is a proportionality constant. If m is unity, then the flicker noise can be described by [Spieler 2005],

$$\langle v_F^2\rangle = \int_{f_1}^{f_2} \frac{A_F}{f} df = A \ln\left(\frac{f_2}{f_1}\right). \tag{22.194}$$

where f_1 and f_2 define the low to high frequency range. Consequently, flicker noise is a function of the ratio of the system high and low cutoff frequencies.

Example 22.7: Consider the non-inverting preamplifier configuration of Fig. 22.19 with a bandwidth of 250 kHz operated at room temperature and for which $R_1 = 10$ kΩ, $R_2 = 100$ kΩ, $A = 6000$, and $\langle I_{dc}\rangle = 130$ nA. Determine the zero input electronic noise contribution at the amplifier output. Assume that flicker noise is minimal. The input voltage is terminated to ground with a 5 kΩ resistor.

Solution:
The shot noise is found from Eq. (22.192) as

$$i_s = \sqrt{2q\langle i_{dc}\rangle(\Delta f)} = \sqrt{2(1.6\times10^{-19}\text{ C})(130\times10^{-9}\text{ A})(2.5\times10^5\text{ Hz})} = 102\text{ pA rms}.$$

This shot noise current appears on the feedback resistor R_2 to produce,

$$v_{so} = i_s R_2 = (102\text{ pA rms})(10^5\ \Omega) = 10.2\ \mu\text{V rms}.$$

[27] Named so, because much like white light is made up of the different color frequencies, white noise is a combination of multiple noise frequencies each of equal intensity.

The Johnson noise at the input is found from Eq. (22.190),

$$v_j = \sqrt{4kTR(\Delta f)} = \sqrt{4(1.38 \times 10^{-23}\ \text{J/K})(293\ \text{K})(5000\ \Omega)(2.5 \times 10^5\ \text{Hz})} = 4.5\ \mu\text{V rms}.$$

The resulting Johnson noise is amplified at the output to produce,

$$v_{jo} = V_j \left[\frac{R_2}{R_1} + 1\right] = 4.5\ \mu\text{V rms} \left[\frac{10^5\ \Omega}{10^4\ \Omega} + 1\right] = 49.46\ \mu\text{V rms}.$$

The shot and Johnson noise contributions are combined to determine the zero input rms noise voltage from the preamplifier output, namely,

$$v_{no} = \sqrt{v_{so}^2 + v_{jo}^2} = \sqrt{(10.2\ \mu\text{V rms})^2 + (49.46\ \mu\text{V rms})^2} = 50.5\ \mu\text{V rms}.$$

22.7.4 Detector Performance

In radiation spectroscopy, the system noise can be of particular concern. The noise originates partly in the detector and partly in the first stage of a preamplifier circuit. Generally, the optimal performance of the system is obtained by reducing the input capacitance C_i to a minimum while increasing the input resistance R to be as high as is practical. In this way, the input can be approximated by the step input voltage of Q/C_i. The input noise takes the form [Baldinger and Franzen 1956],

$$d\langle v^2\rangle = \left[2\pi a^2 + \frac{b^2}{2\pi f^2} + \frac{c^2}{f}\right] df = \left[a^2 + \frac{b^2}{\omega^2} + \frac{c^2}{\omega}\right] d\omega. \tag{22.195}$$

The term proportional to a^2 is called 'A noise' or *series noise*, the term proportional to b^2 is called 'B noise' or *parallel noise*, and the term proportional to c^2 represents flicker noise. Series noise is usually a consequence of shot noise in the preamplifier FET. The parallel noise is usually thermal or Johnson noise from the detector leakage current or the current flowing in the amplifier feedback resistor.

As an example, consider a simple CR-RC network with a transfer function described by Eq. (22.108). The mean square noise voltage is

$$\langle v_n^2\rangle = \int_0^\infty \left(a^2 + \frac{b^2}{\omega^2} + \frac{c^2}{\omega}\right) \left(\frac{\omega^2\tau_1^2}{(1+\omega^2\tau_1^2)\,(1+\omega^2\tau_2^2)}\right) d\omega, \tag{22.196}$$

which upon integration gives [Nicholson 1974]

$$\langle v_n^2\rangle = \frac{\pi a^2}{2K_1(K_1+1)\tau_1} + \frac{\pi b^2\tau_1}{2(K_1+1)} + \frac{c^2}{K_1^2-1}\ln K_1, \tag{22.197}$$

where $K_1 = \tau_2/\tau_1$. Baldinger and Franzen [1956] show that the lowest noise is achieved when $K_1 = 1$, for which Eq. (22.197) reduces to

$$\langle v_n^2\rangle = \frac{\pi a^2}{4\tau} + \frac{\pi b^2\tau}{4} + \frac{c^2}{2}. \tag{22.198}$$

From the result of Eq. (22.107) for a CR-RC network, the maximum pulse voltage from a radiation quantum is seen to occur at $t = \tau$ so that

$$v_{max} = v_{in}e^{-1} = \frac{E}{wC_i}e^{-1} = \frac{Q}{C_i}e^{-1}, \tag{22.199}$$

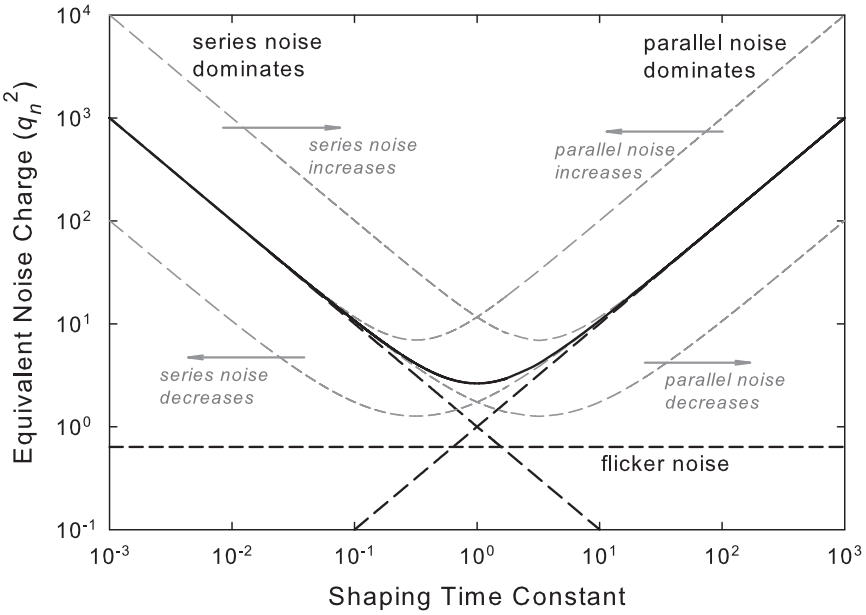

Figure 22.45. Dependence of q_n^2 on the shaping time constant for an CR-RC circuit in which $\tau_1 = \tau_2$. As described in the text, the conditions shown here are for $a = b = c = 1$ and $e^2 C_i^2 = 4/\pi$.

where E is the radiation particle energy, w is the average energy required to produce an ion pair, and C_i is the input capacitance. Hence, the equivalent noise charge q_n is represented by,

$$q_n^2 = e^2 C_i^2 \left(\frac{\pi a^2}{4\tau} + \frac{\pi b^2 \tau}{4} + \frac{c^2}{2} \right). \tag{22.200}$$

Consider the result of Eq. (22.200), where the series noise has a τ^{-1} dependence, parallel noise has a τ dependence, and flicker noise has no dependence on the shaping time constant. To illustrate the dependence of q_n on the shaping time, several simplifications are introduced. First assume a special case in which $a = b = c = 1$ is considered. Then assume the unlikely happenstance that $e^2 C_i^2 = 4/\pi$. For such simplifying assumptions Eq. (22.200) reduces to

$$q_n^2 = \left(\frac{1}{\tau} + \tau + \frac{2}{\pi} \right), \tag{22.201}$$

and the results of this idealized case are shown in Fig. 22.45. At relatively small time constants, the series noise is dominant, while at relatively long shaping times the parallel noise is dominant. In this example there is an optimum τ where the noise equivalent charge is minimized, which turns out to be the general optimizing condition for a semi-Gaussian pulse shaper. Hence, for a spectroscopic measurement, one should adjust the shaping time constant to minimize the electronic noise. If the series noise is decreased, the optimized time constant reduces as does the minimum noise level. If instead, the parallel noise is decreased, the optimized time constant increases while the total noise decreases. The opposite effects are found if either the series or parallel noise contributions are increased.

For high-resolution spectroscopy systems, such as with HPGe detectors, performance is improved by decreasing the coupling capacitance while increasing the input resistance. Typically, the first stage field effect

transistor (FET) in the preamplifier is placed close to the detector to reduce the total input capacitance. The sources of noise include shot noise from the detector leakage current, Johnson noise from both parallel and series resistances, and noise from the input FET. Van der Ziel [1962; 1963] shows that the electronic noise for a FET can be described by

$$\frac{d\langle i_{F1}^2\rangle}{df} \simeq \frac{2}{3}\, 4kTg_m, \tag{22.202}$$

where g_m is the transconductance (or mutual conductance), with $g_m = dI_{out}/dV_{in}$ of the FET. Hence, the transconductance has units of inverse ohms, or mhos ($1/\Omega$). The output current is the *drain* current, and the input voltage is applied across the *gate* to the *source*.[28] The channel current in the FET is another source of noise, which causes fluctuations in the current across the gate to the source capacitance C_{gs} and can be described by

$$\frac{d\langle i_{F2}^2\rangle}{df} = \frac{kT\omega^2 C_{gs}^2}{g_m}. \tag{22.203}$$

The gate leakage current I_g also produces shot noise as

$$\frac{d\langle i_{F3}^2\rangle}{df} = 2qI_g. \tag{22.204}$$

Leakage current through the detector also contributes to shot noise

$$\frac{d\langle i_{D1}^2\rangle}{df} = 2qI_d, \tag{22.205}$$

while the load resistance contributes to the Johnson noise

$$\frac{d\langle i_{D2}^2\rangle}{df} = \frac{4kT}{R_L}. \tag{22.206}$$

Usually, the load resistor is very high, on the order of $10^9\ \Omega$, so that the noise contribution of Eq. (22.206) is negligible.

The total input impedance Z_L is

$$Z_L = \frac{R_S}{1 + j\omega C_i R_S}, \tag{22.207}$$

where R_S is the sum of all resistances at the input, and has the magnitude

$$|Z_L| = \left[\frac{R^2}{1 + \omega^2 C_i^2 R_S^2}\right]^{1/2}. \tag{22.208}$$

If R is large, which is usually the case required to reduce thermal noise at the input, then the impedance can be approximated by

$$|Z_L| \approx \frac{1}{\omega C_i}. \tag{22.209}$$

The series noise is formed by the combination of Eq. (22.202) and Eq. (22.203),

$$\frac{d\langle i_S^2\rangle}{df} = \frac{2}{3}\, 4kTg_m + \frac{kT\omega^2 C_{gs}^2}{g_m}. \tag{22.210}$$

[28] The authors refer to Sze [1981] for a detailed discussion on FET operation.

Equation (22.209) can be rewritten as voltage noise by multiplying by the resistance, namely by selectively applying g_m^{-1} and Z_L (Eq. (22.209)),

$$\frac{d\langle v_S^2\rangle}{df} = \frac{8kT}{3g_m} + \frac{kTC_{gs}^2}{g_m C_i^2}, \tag{22.211}$$

which is the term $2\pi a^2$ in Eq. (22.200). Substitution into Eq. (22.200) produces the series equivalent noise charge contribution to a CR-RC pulse shaping circuit, where the series equivalent noise charge q_{sn} becomes,

$$q_{sn}^2 = e^2 C_i^2 \frac{1}{8\tau}\left(\frac{8kT}{3g_m} + \frac{kTC_{gs}^2}{g_m C_i^2}\right) = e^2 \frac{kT}{g_m \tau}\left(\frac{C_i^2}{3} + \frac{C_{gs}^2}{8}\right). \tag{22.212}$$

A similar process can be used to describe the parallel noise

$$\frac{d\langle v_p^2\rangle}{df} = Z_L^2\left(2qI_d + 2qI_g + \frac{4kT}{R_L}\right) = \frac{1}{\omega^2 C_i^2}\left(2qI_d + 2qI_g + \frac{4kT}{R_L}\right), \tag{22.213}$$

and is the term $2\pi b^2/\omega^2$ in Eq. (22.200). Substitution into Eq. (22.200) produces the parallel equivalent noise charge q_{pn}

$$q_{pn}^2 = e^2 C_i^2 \frac{\omega^2\tau}{8}\frac{1}{\omega^2 C_i^2}\left(2qI_d + 2qI_g + \frac{4kT}{R_L}\right) = \frac{e^2\tau}{8}\left(2q(I_d + I_g) + \frac{4kT}{R_L}\right). \tag{22.214}$$

Finally, the flicker noise is described by

$$\frac{d\langle i_{F1}^2\rangle}{df} = \frac{A_f}{f}, \tag{22.215}$$

where A_f is c^2 in Eq. (22.200).

From Eq. (22.212) the input capacitance and the FET capacitance increase the series noise equivalent charge q_{sn}. Consequently, it is important to reduce the input capacitance as much as possible. From Eq. (22.214), parallel noise equivalent charge q_{pn} is not affected by the input capacitance. Note also that both the series and parallel noise can be decreased by cooling the system. The detector shot and Johnson noise decrease as the temperature is lowered, and the series noise in the FET also decreases with lower temperature. Hence, high-resolution detectors are often cooled to reduce noise and improve energy resolution. Finally, the load resistance R_L should be large to reduce the parallel Johnson noise.

22.8 Coaxial Cables

Cables and connectors were introduced in Chapter 2, with descriptions on types and uses. Presented here, with a modest increase in detail, are some of the more common cables used in radiation detection and measurement.

Perhaps the most used cable configuration, in some form or other, is the coaxial cable, invented in 1880 by Oliver Heaviside [Nahin 2002]. The cable consists of a central core electrical conductor surrounded by a concentric insulating layer that is further surrounded by another conducting layer shield as shown in Fig. 22.46. Usually coaxial cables have an outer insulating layer covering the conducting shield. The inner conductive core is usually held at potential with the conducting shield connected to ground. The potential may be applied by the user or may be a signal voltage transmitted by the detector or electronics. This same conducting shield operates as a Faraday cage to divert electromagnetic noise to ground, thereby effectively reducing or eliminating noise pickup.

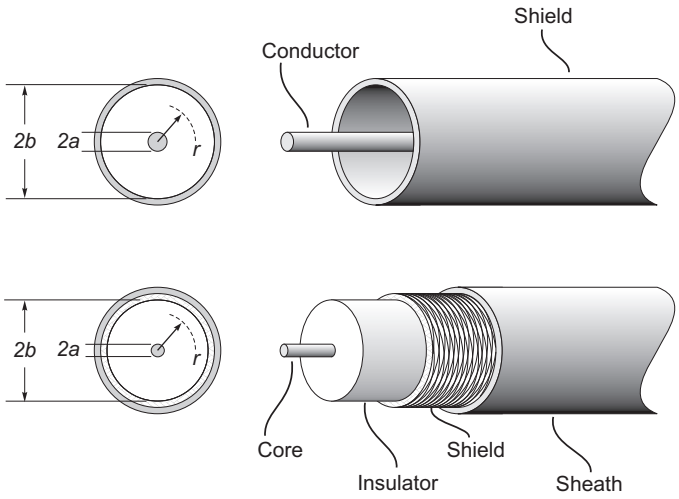

Figure 22.46. (top) Basic coaxial conductor. (bottom) Components of a flexible coaxial cable.

22.8.1 Basic Characteristics

With the notation of Fig. 22.46 and the results derived in Sections 10.2 and 10.3, the electric field in a coaxial device is

$$E(r) = \frac{V_0}{r}\left[\ln\left(\frac{b}{a}\right)\right]^{-1}, \tag{22.216}$$

where V_0 is the applied voltage on the conductive core. The capacitance, per unit length (farads per meter), is

$$C = 2\pi\epsilon_0\kappa\left[\ln\left(\frac{b}{a}\right)\right]^{-1}, \tag{22.217}$$

where ϵ_0 and κ have their usual meanings. The inductance, per unit length (henrys per meter), is

$$L = \frac{\epsilon_0\kappa\mu_0\mu_r}{C} = \frac{\mu_0\mu_r}{2\pi}\ln\left(\frac{b}{a}\right), \tag{22.218}$$

where μ_0 is the permeability of free space ($4\pi \times 10^{-7}$ H m^{-1}) and μ_r is the relative permeability (μ/μ_0) of the insulating material. The conductance, per unit length (siemens per meter), is

$$G = \frac{\sigma}{\epsilon_0\kappa\mu_0\mu_r}C = 2\pi\sigma\left[\ln\left(\frac{b}{a}\right)\right]^{-1}, \tag{22.219}$$

where σ is the usual symbol for electrical conductivity, and $1/\sigma = \rho$, the resistivity (SI unit Ω m).

The complex frequency dependent characteristic impedance of a coaxial cable is defined by

$$Z(j\omega) = \left[\frac{R + j\omega L}{G + j\omega C}\right]^{1/2}. \tag{22.220}$$

At low frequency, the characteristic impedance reduces to

$$Z(0) = \left[\frac{R}{G}\right]^{1/2} = R. \tag{22.221}$$

At high frequency, the characteristic impedance becomes

$$Z_0 \approx \left[\frac{j\omega L}{j\omega C}\right]^{1/2} = \frac{1}{2\pi}\left[\frac{\mu_0\mu_r}{\epsilon_0\kappa}\right]^{1/2} \ln\left(\frac{b}{a}\right). \tag{22.222}$$

It is this impedance that is usually quoted for a coaxial cable. Most quality insulators have a relative permeability of 1, so Eq. (22.222) reduces to

$$Z_0 \approx 60\Omega\left[\frac{1}{\kappa}\right]^{1/2} \ln\left(\frac{b}{a}\right). \tag{22.223}$$

The signal velocity in the coaxial cable is defined by,

$$v_s = \frac{1}{\sqrt{\mu_0\mu_r\epsilon_0\kappa}} = \frac{c}{\sqrt{\mu_r\kappa}}. \tag{22.224}$$

Example 22.8: Given a Cu core diameter of 0.5 mm and insulator diameter of 3.0 mm, what is the characteristic impedance of a cable if the insulator is HDPE? Also, what is the signal velocity?

Solution:
The relative permittivity κ for HDPE is 2.26 and the relative permeability is approximately equal to 1. From Eq. (22.223), the characteristic impedance is,

$$Z_0 \approx 60\Omega\left[\frac{1}{\kappa}\right]^{1/2} \ln\left(\frac{b}{a}\right) = 60\Omega\left[\frac{1}{2.26}\right]^{1/2} \ln\left(\frac{3}{0.5}\right) = 71.5\ \Omega.$$

The signal velocity is found from Eq. (22.224),

$$v_s = \frac{c}{\sqrt{\mu_r\kappa}} = \frac{2.9979\times10^{10}\ \text{cm s}^{-1}}{\sqrt{2.26}} = 1.9942\times10^{10}\text{cm s}^{-1} = 0.6652\ c.$$

Characteristics of a few of the hundreds of commercially available coaxial cables are given in Table 22.8. The maximum voltage that can be applied is a function of the insulator material and not necessarily determined by the cable type. For example, RG-58/U cable, a common choice for radiation detection measurements, may have a limiting voltage of 300 volts with a foam polyethylene insulator, but can be increased to 1400 volts with a solid polyethylene insulator. This example shows that the specific properties of coaxial cables must be known for a particular application even if the cables are of the same type.

The optimum ratio of b/a for the maximum operating voltage of a cable can be found from Eq. (22.216) by setting the derivative to zero, i.e.,

$$\frac{dV_{max}}{da} = \frac{d}{da}E_{max}a\left[\ln\left(\frac{b}{a}\right)\right] = E_{max}\left[\ln\left(\frac{b}{a}\right)\right] - E_{max} = 0. \tag{22.225}$$

Thus the derivative vanishes only if $\ln(b/a) = 1$. For an air-gap coaxial cable, Eq. (22.223) indicates that the characteristic impedance that can hold the highest peak voltage is 60 Ω. The maximized ratio $\ln(b/a) = 1$ holds for all coaxial dielectrics, so that the voltage-maximized characteristic impedance Z_0 decreases with $\kappa^{-1/2}$.

Table 22.8. A few examples of coaxial cable properties. All values from Belden catalogue.

The maximum *peak power* that a cable can handle is found from

$$P_{max} = \frac{V_{max}^2}{2Z_0}. \tag{22.226}$$

where V_{max} is located at the conductor surface a. Substitution of Eq. (22.216) and Eq. (22.223) into Eq. (22.226) yields

$$P_{max} = \frac{\left(E_{max} a \ln\left[\frac{b}{a}\right]\right)^2 \kappa^{1/2}}{2(60\ \Omega)\ln\left[\frac{b}{a}\right]} = \frac{(E_{max}a)^2 \ln\left[\frac{b}{a}\right] \kappa^{1/2}}{120}. \tag{22.227}$$

It is easily shown from Eq. (22.227) that the maximum power is obtained when the ratio $b/a = \sqrt{e}$. From Eq. (22.223), an air gap coaxial cable transmits maximum power when $Z_0 = 30\ \Omega$.

The values of κ and dielectric strength for several common dielectrics are listed in Table 22.9. The dielectric strength of dry air is approximately 3 kV/mm, but the value diminishes in a humid environment, and a value of 1 kV/mm is probably a safer number to use. Stronger dielectrics, such as HDPE and TFE have substantially higher dielectric strengths, thereby allowing high voltages and power ratings. Hence, many coaxial cables have much higher maximum voltage ratings than others (see Table 22.8). Although the maximum peak voltage rating ($V_{max} \approx V_{RMS}/0.71$) may be substantially high, the weakest location in the cable connections determines the actual maximum allowed voltage and power. Hence, if there is an air gap between connections of a coaxial cable and instrumentation, where air gap appears instead of the dielectric, it is actually the geometry of the connection at that air gap location that determines the breakdown voltage. Excessive voltage can cause arcing, and operators should be aware of this potential problem.

Wave Propagation

Signals propagated along a cable to an instrument are usually partially reflected at the cable/instrument interface. To minimize such reflections between components connected by a cable, all components should have, nominally, the same impedance. In general, a transmission line length should be greater than 1/8 of the propagation wavelength λ. For instance, a signal with a frequency of 400 MHz has a wavelength $\lambda = c/f = 750$ mm, so that a coaxial transmission line should be at least 94 mm (3.7 in) long. When a wave

propagating through a transmission line arrives at the load with impedance Z_L, the amount of reflection is determined by the standing wave ratio (SWR) and the reflection coefficient (Γ).

Consider a transmission line connected to a load Z_L, where the load is at the origin $z = 0$. The impedance at location $z = -l$ is $Z(-l)$ for a transmission line of characteristic impedance Z_0. The voltage along the line is written as

$$V(z) = V_+ e^{-jkz} + V_- e^{jkz} \tag{22.228}$$

or

$$V(z) = V_+ \left(e^{-jkz} + \Gamma e^{jkz}\right), \tag{22.229}$$

where V_+ is the incident voltage amplitude for a wave traveling in the positive z direction, V_- is the reflected voltage amplitude for a wave traveling in the negative z direction, Γ is the reflection coefficient, and

$$k = \omega\sqrt{LC} = 2\pi f\sqrt{LC}. \tag{22.230}$$

The *generalized* reflection coefficient, as a function of position, is

$$\Gamma(z) = \frac{V_- e^{jkz}}{V_+ e^{-jkz}} = \Gamma e^{2jkz}. \tag{22.231}$$

Equation (22.231) indicates that the reflection coefficient has real and imaginary components in the complex plane. Substitution of Eq. (22.231) into Eq. (22.229) gives voltage along the cable

$$V(z) = V_+ e^{-jkz} \left[1 + \Gamma(z)\right]. \tag{22.232}$$

If the amplitude V_+ is unity, then the magnitude of Eq. (22.232) becomes

$$|V(z)| = |1 + \Gamma(z)| \tag{22.233}$$

It should be noted that $\Gamma(z)$ can have a positive or negative imaginary component, so that voltage along the transmission line has maximum and minimum voltages where,

$$V_{max} = 1 + |\Gamma| \qquad \text{and} \qquad V_{min} = 1 - |\Gamma|. \tag{22.234}$$

The ratio of the maximum to minimum voltages is an important parameter known as the *voltage standing wave ratio*

$$\text{VSWR} = \frac{V_{max}}{V_{min}} = \frac{1 + |\Gamma|}{1 - |\Gamma|}. \tag{22.235}$$

Rearrangement of this result gives

$$|\Gamma| = \frac{\text{VSWR} - 1}{\text{VSWR} + 1}. \tag{22.236}$$

Also, the VSWR can be defined as

$$\text{VSWR} = \frac{Z_L}{Z_0}, \tag{22.237}$$

which, upon substitution into Eq. (22.236), yields

$$\Gamma = \frac{Z_L - Z_0}{Z_L + Z_0}. \tag{22.238}$$

Notice that if $Z_L < Z_0$, then the reflected voltage signal changes polarity.

Following the result of Eq. (22.226), the power transmitted in the line is

$$P_+ = \frac{|V_+|^2}{2Z_0} \tag{22.239}$$

while the reflected power is

$$P_- = \frac{|V_-|^2}{2Z_0}. \tag{22.240}$$

The ratio of Eq. (22.240) to Eq. (22.239) gives the reflected power

$$R_L \equiv \frac{P_-}{P_+} = \frac{|V_-|^2}{|V_+|^2} = |\Gamma|^2. \tag{22.241}$$

The reflected power, or return loss R_L, is often represented in units of decibels

$$R_L = 20 \log_{10} \left| \frac{V_-}{V_+} \right| = 20 \log_{10} |\Gamma| . \tag{22.242}$$

Thus, another factor to consider in cable selection is the line loss by attenuation. The line loss reported in decibels per unit length is usually given by cable manufacturers on data specification sheets (see Table 22.8). The following example shows three important cases.

Example 22.9: Consider three cases for a 50 Ω coaxial transmission line. In the first case, the line is shorted at the end, the second case the line is open at the end, and in the third case the line is terminated with a 50 Ω load. What is the condition and percent power reflection for these three cases?

Solution:
In the first case, the line is terminated with a short, so $Z_L = 0$,

$$\Gamma = \frac{Z_L - Z_0}{Z_L + Z_0} = -1 \qquad \text{so} \qquad |\Gamma|^2 = \frac{|Z_L - Z_0|^2}{|Z_L + Z_0)|^2} = 1,$$

which indicates that the signal changes sign and is completely reflected. In the second case, the line is open and $Z_L = \infty$ and

$$|\Gamma|^2 = \frac{|Z_L - Z_0|^2}{|Z_L + Z_0)|^2} = 1,$$

which indicates that the wave is also completely reflected but does not change sign. In the third case, $Z_L = Z_0$,

$$|\Gamma|^2 = \frac{|Z_L - Z_0|^2}{|Z_L + Z_0)|^2} = 0,$$

which shows that the wave is completely transmitted with no reflection losses. The return loss in the first two cases is 0 dB, while the return loss in the last case is $-\infty$ dB.

Cables and connectors are usually impedance matched to the load to reduce reflections so as to transfer the maximum amount of power. The calculations for this operation are usually conducted with the use of a *Smith chart*, an exercise beyond the scope of this text. However, there are numerous books that cover the method of a Smith chart in detail, including Adler et al. [1960], Shen and Kong [1983], and Kosow [1963], and modern electronic equipment (such as a network analyzer) has the capability of performing such calculations for the user.

Delay Lines

Under some circumstances it is necessary to delay the signal from a detector before it enters the analyzing electronics. For instance, a coincidence measurement may be desired for two different types of detectors, but the signal processing times are different for the two devices. A delay line can be used to retard the progression of the faster signal, thereby allowing coincident events to arrive at the same time. A simple delay line consists of a long coaxial cable where the propagation time per unit length of cable is

$$t_d = \frac{1}{v} = \frac{\sqrt{\mu_r \kappa}}{c} = \sqrt{\frac{LC}{d^2}}, \tag{22.243}$$

where v_s is the signal propagation speed, d is the cable length, L is the cable inductance, and C cable capacitance. For typical coaxial cables that have polyethylene as the insulating filling ($\epsilon_r \simeq 2.25$), the delay time is approximately 5 nanoseconds per meter. There are special cables designed as delay lines that have spiral conductors to increase the time delay per unit length, thereby shortening the required cable.

Delay lines not only cause a delay in the arrival time of a signal, but also can attenuate the signal as it travels down the cable. If the delay line is purposely shorted at the output terminal, then the signal can be reflected back, inverted in form, towards the input terminal. As a result, the combined attenuation and reflection of the original signal can be used to alter the final output electronic signal to a desirable outcome, referred to as single delay line pulse shaping, which is described in Sec. 22.1.2 of this chapter.

PROBLEMS

1. Find the Laplace transform of the following functions:

$$\text{(a) } f(t) = \cos at \quad \text{(b) } f(t) = t^n \quad \text{and} \quad \text{(c) } f(t) = \begin{cases} at, & \text{if } 0 \le t \le t_{end} \\ 0, & \text{otherwise} \end{cases} .$$

2. Derive the results of Eq. (22.43).

3. Solve Eq. (22.46) for $v_{in}(t) = v_o H(t)$, where $H(t)$ is the unit step function, by (a) finding a particular solution and the homogeneous solution of the corresponding ordinary differential equation, and (b) by taking the Laplace transform of Eq. (22.46) to find $V_{out}(s)$ and inverting this result to obtain $v_{out}(t)$.

4. Derive the solution to Eq. (22.89) to obtain the results of Eqs. (22.90).

5. Prove that the inverse Laplace transform of Eq. (22.108) yields the result of Eq. (22.106).

6. Given a Cu core diameter of .8 mm with HDPE insulator ($\kappa = 2.26$), what diameter of insulator is required to yield the maximum operating voltage? What is the maximized characteristic impedance?

7. Prove that the maximum power of a coaxial cable is found when $b/a = \sqrt{e}$.

8. For a coaxial cable with inner conductor diameter 0.9 mm and outer HDPE insulator diameter of 3 mm, what is the expected peak breakdown voltage and maximum power? The breakdown field for HDPE is approximately 20 kV/mm.

9. After looking around the lab, all you can find is an RG59/U cable to connect your detector preamplifier to the subsequent electronics. However, the input to your amplifier has an impedance of 50 Ω. What is the expected power loss from this arrangement?

Appendix A

Fundamental Physical Data and Conversion Factors

A.1 Fundamental Physical Constants

Although there are many physical constants, which determine the nature of our universe, the following values are of particular importance when dealing with atomic and nuclear phenomena.

Table A.1. Some important physical constants as internationally recommended in 2018 by CODATA. These and other constants can be obtained through the web from http://physics.nist.gov/cuu/Constants/index.html

Constant	Symbol	Value
Speed of light (in vacuum)	c	$2.997\,924\,58 \times 10^{8}$ m s^{-1} (exact)
Electron charge	e	$1.602\,176\,634 \times 10^{-19}$ C (exact)
Atomic mass unit	u	$1.660\,539\,066\,60(50) \times 10^{-27}$ kg $(931.494\,102\,42(28)$ MeV/$c^2)$
Electron rest mass	m_e	$9.109\,383\,7015(28) \times 10^{-31}$ kg $(0.510\,998\,950\,00(15)$ MeV/$c^2)$ $(5.485\,799\,090\,65(16) \times 10^{-4}$ u)
Proton rest mass	m_p	$1.672\,621\,923\,69(51) \times 10^{-27}$ kg $(938.272\,088\,16(29)$ MeV/$c^2)$ $(1.007\,276\,466\,621(53)$ u)
Neutron rest mass	m_n	$1.674\,927\,498\,04(95) \times 10^{-27}$ kg $(939.565\,420\,52(54)$ MeV/$c^2)$ $(1.008\,664\,915\,95(49)$ u)
Planck constant	h	$6.626\,070\,15 \times 10^{-34}$ J s (exact) $4.135\,667\,696 \times 10^{-15}$ eV s (exact)
Avogadro constant	N_a	$6.022\,140\,76 \times 10^{23}$ mol^{-1} (exact)
Boltzmann constant	k	$1.380\,649 \times 10^{-23}$ J K^{-1} (exact) $(8.617\,333\,262\ldots \times 10^{-5}$ eV K$^{-1})$
Molar gas constant (STP)	R	$8.314\,462\,618\ldots$ J mol^{-1} K^{-1}
Vacuum electric permittivity	ϵ_o	$8.854\,187\,8128(13) \times 10^{-12}$ F m^{-1}
Vacuum magnetic permeability	μ_o	$1.256\,637\,062\,12(19)$ N A^{-2}

In 2017 the International Bureau of Weights and Measures defined the Avogadro constant N_a to be exactly the very large integer $6.02214076 \times 10^{23}$ entities per mol. This change redefined the mol as the amount of a substance containing N_a entities (atoms, molecules, etc.). As a consequence, the molar mass

constant M_u is no longer 1 g/mol but now is $0.999\,999\,999\,65(30) \times 10^{-3}$ kg mol^{-1}. It also means that 1 mol of ^{12}C atoms no longer has a mass of 0.001 kg. However, the atomic mass unit remains unchanged as 1/12 the mass of a ^{12}C atom.

On the 144th anniversary of the Metre Convention, 20 May 2019, the redefinition of SI base unit was affirmed and came into force. In the redefinition, four of the seven SI base units—the kilogram, ampere, kelvin, and mole—were redefined by setting exact numerical values for the Planck constant h, the elementary electric charge e (q_e as used in this book), the Boltzmann constant k, and the Avogadro constant N_a, respectively.

A.2 The Periodic Table

The periodic table presented in Table A.2 uses the new group format numbers from 1 to 18 approved by the International Union of Pure and Applied Chemistry (IUPAC), while the numbering system used by the Chemical Abstract Service is given in parentheses at the top of each column. In the left of each elemental square, the number of electrons in each of the various electron shells are given. In the upper right of each square, the melting point (MP), boiling point (BP), and critical point (CP) temperatures are given in degrees Celsius. Sublimation and critical temperatures are indicated by s and t. In the center of each elemental square the oxidation states, atomic weight, and natural abundance is given for each element. For elements that do not exist naturally, (e.g., the transuranics), the mass number of the longest-lived isotope is given in square brackets. The abundances are based on meteorite and solar wind data.

The table is from Firestone et al. [1999] and may be found on the web at `http://isotopes.lbl.gov/isotopes/toi.html`. Data for the table are from Lide [1997], Leigh [1990], Anders and Grevesse [1989], and CE News [1985]. Since this table was published, research at several accelerator facilities around the world discovered and added ten new elements to the periodic table and, thereby completed the 7th period (or row) of the periodic table. These new elements officially recognized by IUPAC are listed in Table A.2. The newest elements (Nh, Mc, Ts and Og were recognized in 2016). Often only a few atoms of these short lived radionuclides were produced and little information about their physical properties has been obtained other than that suggested by theory and the elements' location (or group number) in the table.

Table A.2. The "new" elements discovered and officially named since 2000. All are radioactive and the atomic mass number A of the longest lived isotope is given in [ ].

Meit-erium	Darn-stadtium	Roent-genium	Coper-nicium	Nihon-ium	Flero-vium	Moscov-ium	Liver-morium	Tenn-essine	Oga-nesson
$_{109}$**Mt**	$_{110}$**Dd**	$_{111}$**Rg**	$_{112}$**Cn**	$_{113}$**Nh**	$_{114}$**Fl**	$_{115}$**Mc**	$_{116}$**Lv**	$_{117}$**Ts**	$_{118}$**Og**
[278]	[281]	[282]	[285]	[286]	[289]	[290]	[290]	[294]	[294]

A.3 Physical Properties and Abundances of Elements

Some of the important physical properties of the naturally occurring elements are given in Table A.3. In this table the atomic weights, densities, melting points, and boiling points.

The atomic weights are for the elements as they exist naturally on earth, or, in the cases of thorium and protactinium, to the isotopes which have the longest half-lives. For elements whose isotopes are all radioactive, the mass number of the longest lived isotope is given in square brackets.

Mass densities for solids and liquids are given at 25°C, unless otherwise indicated by a superscript temperature (in °C). Densities for normally gaseous elements are for the liquids at their boiling points. The melting and boiling points at normal pressures are in degrees Celsius. Superscripts "t" and "s" are the critical and sublimation temperature (in degrees Celsius).

Data are from the 78th edition of the *Handbook of Chemistry and Physics* [Lide 1997] and have been extracted from tables on the web at http://isotopes.lbl.gov/isotopes/toi.html.

A.4 SI Units

With only a few exceptions, units used in radiation detection and nuclear science are those defined by the SI system of metric units. This system is known as the "International System of Units" with the abbreviation SI taken from the French "Le Système International d'Unités." In this system, there are four categories of units: (1) base units of which there are seven (m, kg, s, A, K, cd, and mol), (2) derived units which are combinations of the base units (e.g., N $\equiv$ kg m s^{-2}), (3) supplementary units (rad and sr), and (4) "temporary" units (e.g., b, Ci, R, Gy, and Sv) which are in widespread use for special applications. To accommodate very small and large quantities, the SI units and their symbols are scaled by using the SI prefixes given in Table A.5.

There are several units outside the SI which are in wide use. These include the time units day (d), hour (h), and minute (min); the liter (L or ℓ); plane angle degree ($^\circ$), minute ($'$), and second ($''$); and, of great use in nuclear and atomic physics, the electron volt (eV) and the atomic mass unit (u). Conversion factors to convert some non-SI units to their SI equivalent are given in Table A.5.

A.5 Internet Data Sources

The data presented in this appendix are sufficient to allow you to do most assigned problems. All of these data have been taken from the web, and you are encouraged to become familiar with these important resources. Some sites, which have many links to various sets of nuclear and atomic data, are

Table A.3. The periodic table of the elements. The new IUPAC group format numbers are from 1 to 18, while the numbering system used by the Chemical Abstract Service is given in parentheses. For elements that are not naturally abundant (e.g., the transuranics), the mass number of the longest-lived isotope is given in square brackets. The abundances are based on meteorite and solar wind data. The melting point (MP), boiling point (BP), and critical point (CP) temperatures are given in degrees Celsius. *Source*: Firestone, Baglin, and Chu [1999].

Appendix B

Cross Sections and Related Data

The tables in this appendix present basic interaction data for thermal neutrons and for photons. These tables give but a very small fraction of the data contained in comprehensive data libraries and other voluminous compilations. The data selected for these tables are for important interactions encountered in many nuclear and atomic analyses. However, for many calculations, it is necessary to obtain interaction data directly from data libraries maintained at several national nuclear data centers around the world. In the United States, the National Nuclear Data Center at Brookhaven National Laboratory (www.nndc.bnl.gov) and the Radiation Safety Information and Computational Center (RSICC) at Oak Ridge National Laboratory (rsicc.ornl.gov) provide access to extensive nuclear data libraries. The Nuclear Data Service of the International Atomic Energy Agency (www-nds.iaea.org) and the Japan Atomic Energy Research Institute (wwwndc.jaea.go.jp) also provide nuclear data to the international radiation community.

B.1 Data Tables

The following data are provided in this appendix.

- Table B.1. 2200-m/s macroscopic cross sections for the elements.
- Table B.2. Thermal microscopic neutron cross sections for special isotopes.
- Table B.3. Activation radionuclides produced from thermal neutron capture.
- Table B.4. Photon yields for thermal neutron capture.
- Table B.5. Prompt gamma-ray energies used for elemental identification.
- Table B.6. Photon interaction coefficients for air, water, concrete, iron, and lead.
- Table B.7. μ_t/ρ and μ_{t-coh}/ρ for the light elements.

Data for Tables B.1–B.7 have been extracted from the sources provided in the tables. In all these tables, entries such as $1.234 - 5$ should be read as 1.234×10^{-5}.

B.1.1 Thermal Neutron Interactions

The thermal neutron integration rate density for the ith type of interaction is given by Eq. (4.97) for absorption and by Eq. (4.102) for elastic scattering. The total reaction rate density is the sum of all absorption and scattering reactions. Thus

$$F_j = g_j(T)\Sigma_j(E_o)\phi_o, \qquad j = t, s, c, f, \alpha, \ldots. \tag{B.1}$$

Here the subscripts t, s, c, f, α refer to total, (elastic) scatter, (n, γ), fission, (n, α) reactions, respectively. In many radiation detection applications, the thermal neutron reaction rates in a natural element are needed.

Cross section data bases are almost always of microscopic cross sections for individual isotopes and, thus, to obtain thermal macroscopic cross sections for an element, it is necessary to average cross section values and the Westcott g-factors over all stable isotopes of an element, namely

$$\Sigma_j(E_o) = \frac{\rho N_a}{\mathcal{A}} \sum_i f_i \sigma_j^i(E_o) \tag{B.2}$$

and

$$g_j(T) = \sum_i f_i g_j^i(T) \sigma_j^i(E_o) \Big/ \sum_i f_i \sigma_j^i(E_o). \tag{B.3}$$

Here i refers to the stable isotopes and f_i is the isotopic abundance. The 2200-m/s macroscopic cross sections for Σ_t, Σ_s, and Σ_c are tabulated for most elements in Table B.1. In this table densities are at 25^{o}C except for elements that are normally gaseous and their densities are at their liquid's boiling point.

B.1.2 Photon Interactions

In Tables B.6 and B.7, listing photon interaction coefficients, the following notation is used: coherent scattering coefficient with electron binding, μ_{coh}; incoherent scattering coefficient with electron binding, μ_c; photoelectric effect coefficient, μ_{ph}; pair-production coefficient, μ_{pp}; total interaction coefficient $\mu_t \equiv \mu_c + \mu_{ph} + \mu_{pp}$; and the total interaction coefficient less the coherent coefficient $\mu_{t-coh} \equiv \mu_{coh} + \mu_c + \mu_{ph} + \mu_{pp}$.

[a] Decays by neutron emission.

Source: Data extracted from the National Nuclear Data Center Online Service, Brookhaven National Laboratory, Upton, NY, January 1995.

Table B.4. Radiative capture cross sections σ_γ and the number of capture gamma rays produced in common elements with natural isotopic abundances. The thermal capture cross sections are for 2200 m s^{-1} (0.0253 eV) neutrons in units of the barn (10^{-24} cm^2). Listed are the numbers of gamma rays produced, per neutron capture, in each of 11 energy groups. Unless otherwise noted, yields are for both line (discrete) and continuum (or unresolved) capture photons.

		Energy group (MeV)

Source: M.A. Lone, R.A. Leavitt, and D.A. Harrison, "Prompt Gamma Rays from Thermal Neutron Capture," *At. Data Nucl. Data Tables*, **26**, No. 6, 511–559 (1981). [Data files released as Package DLC-140 THERMGAM by the Radiation Shielding Information Center, Oak Ridge National Laboratory, Oak Ridge, TN.]

Table B.5. Listed are prompt gamma rays from thermal neutron absorption recommended for use in element identification. The *partial gamma ray production cross section* is $f_i P_\gamma \sigma_\gamma^i$ where f_i is the fractional isotopic abundance of the ith isotope, P_γ is the probability the gamma ray is emitted, and σ_γ^i is the thermal neutron capture cross section for the i isotope. Data are from Révay et al. [2004].

Table B.5. *(cont.)* Listed are prompt gamma rays from thermal neutron absorption recommended for use in element identification. The *partial gamma ray production cross section* is $f_i P_\gamma \sigma_\gamma^i$ where f_i is the fractional isotopic abundance of the ith isotope, P_γ is the probability the gamma ray is emitted, and σ_γ^i is the thermal neutron capture cross section for the i isotope. Data are from Révay et al. [2004].

Stacked discriminator, 1201
Standard normal distribution, 207
Steel shielding, 1140
Stochastic uncertainty, 183
Stokes shift, 487
Stopping power, 127, 307
collisional, 127–130, 127–130, 164
electrons and positrons, 132–135
ionization, 127
radiative, 130, 130, 164
restricted electron, 133
Stored energy, 287
Structure factor, crystals, 863
Summation peaks, 1047–1050
Superconducting nanowire single-photon detector, 1019
Superconducting tunnel junction detectors, 1017
Superconductors, 1014, 1016
Cooper pairs, 1013
transition temperature, 1014
types, 1014
Superfluid roton detector, 1020
Superheated drop detectors (SDD), 1004–1007
Systematic uncertainty, 184

T

Thermal detectors, (*see* Cryogenic detectors)
Thermal energy cutoff, neutrons, 870
Thermal neutron detectors
(*see also* Scintillation detectors)
(*see also* Semiconductor detectors)
calibration, 865–869
ceramic scintillators, 852
compensated, 837
fission chambers, 840–848
spectra, 847
foil activation, 870–880
gadolinium oxysulfide, 854
gas-filled, 822–829
$^{10}BF_3$, 826–829
^{3}He, 822–825
end effect, 824
wall effect, 823
liquid scintillators, 852
loaded scintillators, 850–854
McGregor and Shultis calibration, 868
miniature fission chambers, 847
NIST calibration, 866
organic scintillators, 851
ORNL calibration, 867
reactive coatings, 829–848
^{10}B-lined, 836
^{6}Li metal, 839
efficiency, 832–835
self-attenuation, 836
straggling, 830
straw tubes, 838
reactive materials, 813–822
Reuter Stokes calibration, 866
Sampson and Vincent calibration, 867
scintillators, 848–854
elpasolite, 849
GSO, 850
LGBO, 850
LiF, 848
self powered, 880–886
kinetics, 880–886
types, 884
semiconductors, bulk, 858–860
coated, 855
microstructured, 856
planar diodes, 855
slow neutrons, 855–860
zinc sulfide, 854
Thermal neutron flux, total, 870
Thermal neutron interactions, 121–126
(*see also* Neutrons)
Thermionic emission, 578
Thermistor, 1009
Thermoluminescent detectors, (*see* OSLD)
(*see* TLD)
Thermoluminescent models, 950–956
Thermonuclear reactions, 170
Thomson, J.J., 4
Thomson, 42
Threshold inelastic scattering, 103
Time-of-flight,
slow neutrons, 886–888
heavy ions, 1109
Time-to-amplitude converters, 29
Timing events, 1205–1208
jitter and time walk, 1205

methods, 1206–1208
ARC, 1207
constant fraction, 1207
leading edge, 1207
zero crossover, 1207
TLD, 949–984
advantages and disadvantages, 963
calibration, 961–963
effect of multiple traps, 953–956
emission spectra, 957
forms, 963
general operation, 950
glow curve, 951
maximum, 952
heating rate, 951, 955
material
Al_2O_3, 972
BeO, 972
CaF_2, 966
CaF_2:Dy (TLD-200), 967
CaF_2:MBLE, 966
CaF_2:Mn(TLD-400), 968
CaF_2:Tm(TLD-300), 958
$CaSO_4$, 969
$Li_2B_4O_7$, 970
LiF, 964–966
materials, 958
modeling thermoluminescent intensity, 950–956
radiation damage, 960
sensitivity, 957
sensitization, 959
stability and fading, 959
superlinearity, 959
systems, 956
thermal quenching, 953
tissue equivalent, 972
vs OSLD, 973
Townsend avalanche, 357
first ionization coefficient, 357
Track detectors, 991–1007
bubble chambers, 1002–1004
nuclear emulsions, 991
spark chambers, 1001
superheated drops, 1004–1007
track etching, 993–1001
track shrinkage, 992
Track etch detectors, 993–1001
etching conditions, 997
etching sensitivity, 999
etching speeds, 996
materials, 1000
neutron dosimetry, 999
track etch foil, 1016
track etching, 995
track formation, 993
Transfer function, 1160
gain, 1160
phase shift, 1160
Transmission probability, 434
Transuranic isotopes, fission neutron yields, 169
Triple coincidence spectrometer, 1151
Triplet production, 115
Tritium, fusion reactions, 170
Tungsten
for shielding, 1140
x-ray target material, 166

U

Uncertainty principle, 56
Undulators, 168
Unfolding
activation foils, 940
Bonner spheres, 902–904
by iteration, 903
by regularization, 903
recoil energy spectrum, 918
Unified atomic mass unit, 68
Unit conversion factors, 1255
Units, special, barn, 97
Uranium
fission neutron energy spectrum, 169
fission neutron yield, 169
neutron cross section, 120

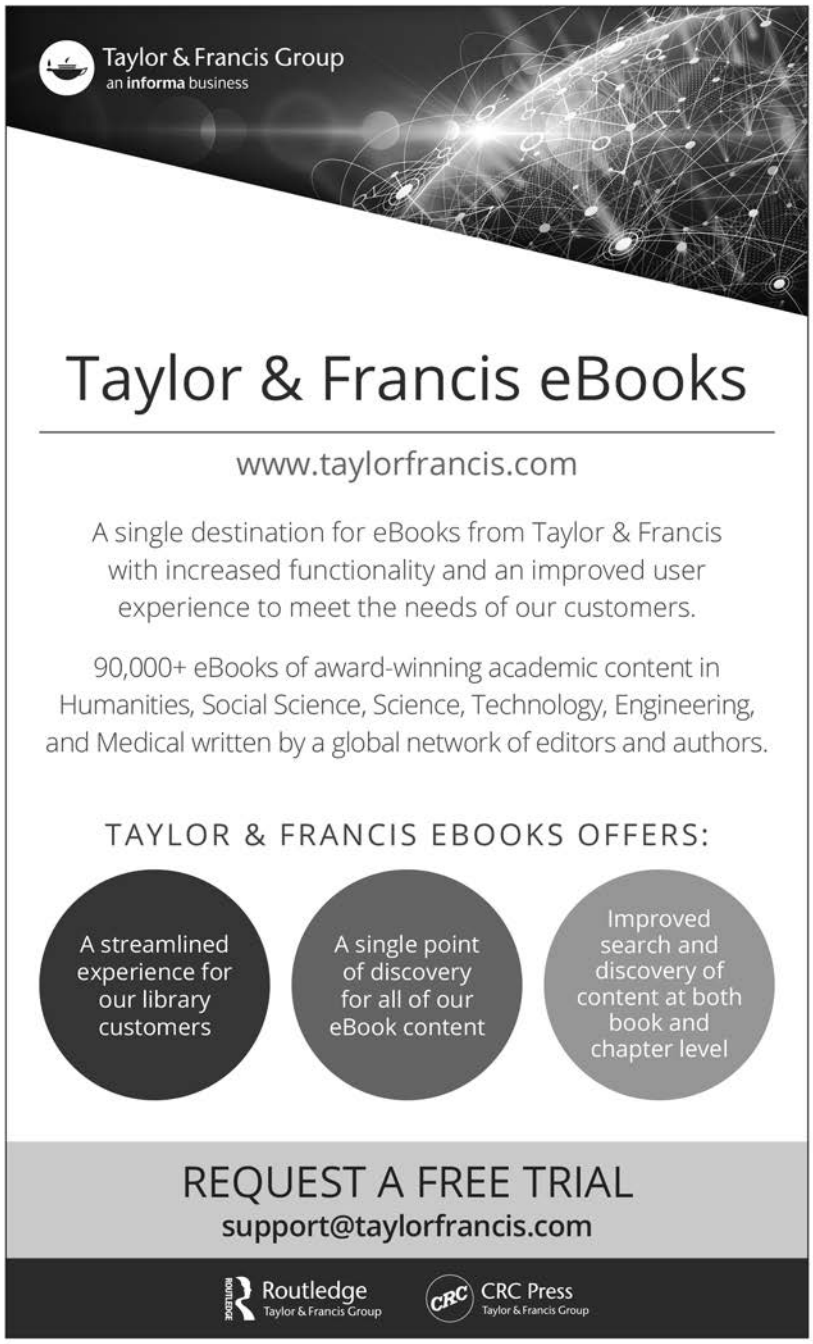
V

Valence band, 441
View factors, 268–274
area on sphere, 268
for cylindrical detector, 269
for rectangular aperature, 270
isotropic area source, 272
Monte Carlo method, 274
point isotropic source, 271–274
Villard, Paul, 6

W

Walkoff, Friedrich, 11
Water
photon interaction coefficients, 1268
shielding, 1140
stopping power, 134
Watt distribution, 169
Wave equation, 54, 433, 436, 458
Wave function, 55
Wave mechanics (*see* Quantum mechanics)
Wave-length shifters, 168
Wave-particle duality, 42–46, 54, 861
Wavelength-dispersive spectroscopy, 1020–1022
Weight fraction, 97
Weighting field, optimization, 693
Weighting potential, 289
cylindrical detector, 300
planar detector, 291
spherical detector, 302
Westcott g-factor, 123, 1259–1260
Wigglers, 168
Wilson, Charles, 7
Work function, 43, 576

X



X-ray sources, 159–168
(*see also* Fluorescence)
bremsstrahlung, 163–166
characteristic x rays, 161–163
machines, 166–168
filters, 168
photon spectrum, 166–168
radiation output, 167
target materials, 167
synchrotron, 168
X rays, (*see also* Photons)
characteristic, 1042
detectors, Si(Li), 739–745
discovery, 1
escape peak, 1042
production, 114
scattering, 44

Y

Yukwa, Hideki, 10

Z

Zastawny formula, 364
Zeeman effect, 53

Taylor & Francis Group
an informa business
Taylor & Francis eBooks
www.taylorfrancis.com
A single destination for eBooks from Taylor & Francis with increased functionality and an improved user experience to meet the needs of our customers.
90,000+ eBooks of award-winning academic content in Humanities, Social Science, Science, Technology, Engineering, and Medical written by a global network of editors and authors.
TAYLOR & FRANCIS EBOOKS OFFERS:
A streamlined experience for our library customers
A single point of discovery for all of our eBook content
Improved search and discovery of content at both book and chapter level
